**Cognate preparations. Dodecanolide (use of permaleic acid).\(^1^8^4\) (CAUTION: see Section 4.2.41, p. 439 for the precautions that must be adopted when using 30 per cent hydrogen peroxide. Safety screens and extra personal protection measures should also be employed.) Dichloromethane (1.6 litres) and acetic anhydride (1.25 litres) are stirred in a 5-litre flask fitted with a double surface condenser and an overhead stirrer, a dropping funnel, and cooled externally (ice-water) while 30 per cent hydrogen peroxide (1 litre) is added. After 1 hour maleic anhydride (1 kg) is added, the mixture is cooled and stirred for 1 hour, and then the cooling bath is removed, when the temperature rises during 1.5 hours and the mixture begins to reflux. External cooling is resumed when needed to moderate the reaction. When little more heat is evolved, cyclododecanone (250 g) is added; this does not greatly increase the rate of heating, and when spontaneous refluxing ceases, a heating mantle is used to maintain the mixture at its boiling point for 15 hours. The mixture is then cooled and the separated maleic acid is filtered off. The filtrate is washed in turn with water (3 × 600 ml), an aqueous solution containing 10 per cent each of potassium hydroxide and sodium sulphite (2 × 300 ml), and then water (600 ml); tests for peroxide are now negative. After being dried over anhydrous sodium sulphate the filtrate is evaporated to give the lactone (210.4 g, 77\%); when potassium carbonate, rather than potassium hydroxide, is used for washing, the crude lactone contains a pungent contaminant, possibly peracetic acid.

**Conversion into 12-hydroxydodecanoic acid.** The foregoing lactone is added to a solution of potassium hydroxide (150 g) in methanol (800 ml) and the
mixture is heated under reflux for 1 hour. Most of the solvent is then removed on a rotary evaporator. Water (2 litres) is added and the solution is extracted with ether (2 × 400 ml). The aqueous layer is acidified (concentrated hydrochloric acid) and the precipitated acid is collected, dried in vacuo, and recrystallised from acetone–light petroleum (b.p. 60–80 °C) to afford the acid (185.8 g, 63% from cyclododecanone), m.p. 84 °C.

8-Hydroxynonanoic acid lactone. (CAUTION: see Section 4.2.41 for the precautions to be adopted in the use of 90% hydrogen peroxide. Safety screens and extra personal protection must be employed.) To a mixture of 90 per cent hydrogen peroxide (1 ml, 40 mmol) and dichloromethane (5 ml) at 0 °C is added dropwise trifluoroacetic acid (7 ml, 50 mmol). The resulting homogeneous solution could be stored at −20 °C for several weeks. To a solution of 2-methylcyclooctanone (1.12 g, 8 mmol) (1) in dichloromethane (8 ml) and buffered with anhydrous disodium hydrogen phosphate (7.1 g, 50 mmol), is added at 0 °C dropwise pertrifluoroacetic acid solution (7 ml, 22 mmol). The resulting mixture is stirred at room temperature for 5 hours, poured into water, washed with aqueous sodium hydrogen carbonate and dried over magnesium sulphate. After removal of the solvents at reduced pressure, the oily residue is flash chromatographed using 4 per cent ethyl acetate in light petroleum to yield 890 mg (72%) of the lactone as a transparent sweet-smelling oil (3% of starting material is recovered); i.r. (thin film) 2940, 1730, 1450 cm⁻¹; p.m.r. (CDCl₃, TMS) δ 1.23 (d, 3H, J = 7 Hz), 1.1–2.0 (m, 10H), 2.15 (m, 2H), 5.00 (m, 1H); t.l.c. (silica gel, 5% ethyl acetate in pentane) Rᵢ 0.36.

Note. (1) 2-Methylcyclooctanone may be prepared by the procedures noted in earlier sections. Thus cyclooctanone may be converted into 1-methylcyclooctanone by reaction with methylmagnesium bromide (cf. Expt 5.40); dehydration then gives 1-methylcyclooct-1-ene (cf. Expt 5.12); hydroboration gives trans-2-methylcyclooctanol (cf. Expt 5.44); finally, oxidation with PCC yields 2-methylcyclooctanone (cf. Expt 5.76, or alternatively Expt 5.86).

**Experiment 5.172 CIS-1-IODO-7-OXABICYCLO[4.3.0]NONAN-8-ONE**

At room temperature, a solution of cyclohex-1-en-1-ylacetic acid (10 g) (1) and sodium hydrogen carbonate (19 g) in water (300 ml), is added to a solution of iodine (38 g) and potassium iodide (75 g) in water (600 ml). The oily precipitate is extracted after 4 hours with ether, and the ether solution washed with sodium hydrogen sulphite until the coloration of iodine has disappeared, and then with saturated sodium hydrogen carbonate solution. The dried ethereal extract is evaporated in vacuo; the oily residue gives on trituration with light petroleum 8.2 g (43%) of a white solid, m.p. 56 °C (2).

**Dehydrohalogenation of γ-iodolactone.** A solution of the foregoing lactone in pyridine (10 ml) (CAUTION) is kept at room temperature for 2 days. Etha-
nol (30 ml), zinc powder (5 g) and (during 1 hour) concentrated hydrochloric acid (10 ml) are added with stirring and cooling. The solution is filtered and extracted with benzene (CAUTION) and the organic layer washed successively with 10 per cent hydrochloric acid, 10 per cent sodium hydrogen carbonate, and finally water. Distillation of the benzene layer gives 1.4 g (54%) of the unsaturated lactone, b.p. 152–153 °C/30 mmHg, m.p. 28–30 °C; i.r. (thin film) 1750 (conjugated γ-lactone carbonyl), 1650 cm⁻¹ (C=C).

Notes. (1) Cyclohex-1-en-1-ylacetic acid may be prepared from ethyl 1'-hydroxy-cyclohexylacetate (Expt 5.170) by dehydration to the unsaturated ester followed by acidic hydrolysis to the unsaturated acid. An alternative method from cyclohexanone has been described.¹
(2) Iodolactones are unstable and should be used in further reactions without delay; recrystallisation may be carried out using an ethanol–light petroleum solvent mixture.

### 5.14.3 KETO ACIDS AND ESTERS
#### α-KETO ACIDS AND ESTERS

The simplest member of the series of aliphatic α-keto acids is pyruvic acid. It is conveniently prepared by the distillation of tartaric acid with a dehydrating agent such as potassium hydrogen sulphate (Expt 5.173). The reaction probably involves dehydration to the tautomeric oxaloacetic acid (13) intermediate, which then decarboxylates by virtue of its constitution as a β-keto acid.

![Reactions]

A retrosynthetic disconnection of the ester of a higher homologue [e.g. (14)] leads to the carbanion and the carbocation synthons (15) and (16) respectively.

![Synthons](15)(16)

The reagent for the carbanion synthon (15) could be an organometallic reagent (RMgX or RLi), or an α-carbanion arising from a carboxylic ester. The reagent for the carbocation synthon (16) could be a derivative of oxalic acid [e.g. diethyl oxalate (CO₂Et)₂ or ethyl oxalyl chloride (COCl·CO₂Et)]. Two methods which illustrate these strategies may thus be formulated. In the first, an initial mixed Claisen ester condensation (see p. 738) between a carboxylic ester and diethyl oxalate (cf. Expt 8.37, ethyl phenyl oxaloacetate) is followed by hydrolysis to the keto diacid (17) and subsequent decarboxylation of the β-keto acid function.
R\cdot CH_2\cdot CO_2Et + ^{\ominus}OEt \rightarrow [R\cdot CH\cdot CO_2Et] + EtOH

\begin{align*}
\text{EtO} & \quad \text{OEt} \\
\text{O} & \quad \text{OEt} \quad \text{(i) } \text{EtOH} \\
\text{EtO} & \quad \text{OEt} \quad \text{(ii) } \text{H_2O}^+ \\
\end{align*}

In the second method, ethyl oxalyl chloride is converted first into ethyl \(\alpha\)-oxo-\(1H\)-imidazole-1-acetate, which is then treated with a Grignard reagent. The precedent for this reaction is that acylimidazolides are highly reactive towards Grignard reagents to yield ketones without further significant reaction with the carbonyl function to give tertiary alcohols.

\begin{align*}
\text{N} & \quad \text{H} \\
\text{Cl}^- & \quad \text{EtO} \\
\text{OEt} & \quad \text{HCl} \\
\text{RMgX} & \quad \text{R} \\
\text{EtO} & \quad \text{OEt} \\
\end{align*}

The yield of \(\alpha\)-keto ester is best when an aromatic Grignard reagent is used, and the reaction is illustrated by the formation of ethyl benzoyleformate (Expt 5.174).

A general route to aryl-substituted pyruvic acids (e.g. phenylpyruvic acid, Expt 5.175) is the acid hydrolysis of 2-acetamido-3-arylacrylic acids (19), which are themselves formed by hydrolysis of the corresponding azlactones (18) (cf. Expt 8.21) with water.

\begin{align*}
\text{Ar-CH}, & \quad \text{CO-CO_2H} \\
\text{OH} & \quad \text{Ar-H} \\
\text{H_2O}^+ & \quad \text{Me-CO_2H} \\
\text{H_3O}^+ & \quad \text{NH_3} \\
\end{align*}

**\(\beta\)-KETO ACIDS AND ESTERS**

The \(\beta\)-keto acids are thermally unstable and readily decompose in the presence of hot acid or alkali into ketones (see Section 5.8.5, p. 617). On the other hand the \(\beta\)-keto esters are stable and are extremely important synthetic reagents.

The typical \(\beta\)-keto ester is ethyl acetoacetate (ethyl 3-oxo-butanoate). A retro-synthetic disconnection on this compound points to one of the most common methods for its synthesis, namely the Claisen ester condensation.
The condensation proceeds under the influence of strong base catalysts of which sodium ethoxide is the most common example. This is usually formed from the ethanol present in ordinary samples of ester by the action of the sodium used in the condensation. The first step in the mechanism is the removal of the \( \alpha \)-hydrogen in ethyl acetate by the base catalyst to produce the mesomerically stabilised \( \alpha \)-carbanion (20). The nucleophilic carbanion so formed then attacks the carbonyl carbon of a second ester molecule to produce the anion (21) which is converted into the \( \beta \)-keto ester (22) by loss of an ethoxide ion. Finally (22) reacts with the ethoxide ion to produce the mesomerically stabilised \( \beta \)-keto ester anion (23).

The equilibrium in the last step (iii) is far to the right because of the greater basic strength of the ethoxide ion compared to the anion (20), and this largely assists the forward reactions in (i) and (ii). The reaction product is therefore the sodio-derivative of the \( \beta \)-keto ester from which the free ester is obtained upon careful acidification.

With ethyl esters of higher straight-chain carboxylic acids (e.g. ethyl propanoate, ethyl butanoate, etc.) the products are \( \alpha \)-alkylated \( \beta \)-keto esters, and the condensation may also be affected by the action of sodium alkoxides.

\[
2R\cdot CH_2\cdot CO_2Et \xrightarrow{EtOH} R\cdot CH_2\cdot CO\cdot CHR\cdot CO_2Et
\]

For esters with only one \( \alpha \)-hydrogen, such as ethyl 2-methyl propanoate (ethyl isobutyrate), a more powerful base (e.g. sodium triphenylmethide, \( \text{Ph}_3\text{C}^-\text{Na}^+ \)) is required to affect the condensation reaction [the forced Claisen ester condensation, e.g. the synthesis of ethyl 2,2,4-trimethyl-3-oxopentanoate (ethyl isobutyrylisobutyrate), Expt 5.176]. In this case the reaction sequence is completed in the step corresponding to (ii) above since the \( \beta \)-keto ester (24) has no \( \alpha \)-hydrogen for step (iii), and the powerful base is required to force the equilibrium (i) to the right.
When a mixture of two dissimilar esters (R'\cdot CH_2\cdot CO_2Et and R^2\cdot CH_2\cdot CO_2Et) is treated with sodium as the ethoxide, a 'mixed' β-keto ester (R'\cdot CH_2\cdot CO\cdot CH(R^2)\cdot CO_2Et or R^2\cdot CH_2\cdot CH(R'\cdot)\cdot CO_2Et) may be formed. However the disadvantage which is common to all mixed reactions, i.e. the formation of both symmetrical and crossed products, reduces its preparative value. Exceptions are provided in those cases where one of the esters contains no \(\alpha\)-hydrogens. An important example is provided by the use of esters of oxalic acid in such mixed Claisen ester condensations (e.g. Section 5.14.3, p. 735, and Expt 8.37).

Retrosynthetic disconnection of a β-keto ester of the type R\cdot CO\cdot CH_2\cdot CO_2Et, gives the carbocation R\cdot CO and the carbanion CH_2\cdot CO_2Et. The reagent equivalent of the former synthon could be the acid chloride R\cdot COCl in place of the ester in the Claisen condensation above. The reagent equivalent of the carbanion synthon could be diethyl malonate (see Section 5.11.6, p. 680). The overall reaction then becomes an acylation of malonic ester followed by suitable removal of the carbethoxy group.

One preparative procedure for achieving this reaction involves the acylation of the magnesium enolate of diethyl malonate with an acid chloride in benzene solution (cf. Expt 5.96), and the resulting aclymalonic ester is then heated to 200 °C with an arylsulphonic acid to effect the decarbethoxylation step. An illustrative example is the preparation of ethyl 3-oxopentanoate (ethyl propionylacetate, Expt 5.177).

In an alternative method (cognate preparation in Expt 5.177), the dilithio complex of ethyl hydrogen malonate in tetrahydrofuran at low temperature is reacted with the acid chloride\(^{194}\); the decarboxylation process takes place spontaneously when the reaction mixture is quenched with dilute acid.

\(\gamma\)-KETO ACIDS AND ESTERS
The retrosynthetic disconnection for the \(\gamma\)-keto acid shown below generates an acyl anion synthon and a three-carbon carbocation.
Convenient reagent equivalents could be a nitroalkane (for the acyl anion synthon, p. 627), and acrolein or an acrylic ester (for the carbocation). The reaction would then be a Michael addition process (Section 5.11.6, p. 681), followed by functional group modification (e.g. C—NO₂ to C==O, p. 599, and CHO to CO₂H, p. 667).

This method is illustrated (Expt 5.178) by the reaction of nitroethane with acrolein in the presence of basic alumina¹⁹⁵; this catalyst apparently avoids the induction of undesirable side reactions. The Michael adduct is treated with hydrogen peroxide which effects the functional group modifications.

The alternative charge distribution of the synthons generated in the above disconnection leads to the acyl carbocation (R•CO) and the carbanion CH₂•CH₂•CO₂Et. From the latter the three-carbon unit of diethyl succinate may be recognised, and the Stobbe condensation is a suitable illustration of this process. Thus the reaction of aldehydes or ketones with succinic esters in the presence of potassium t-butoxide (or with sodium hydride) gives alkylidenesuccinic acid esters (25). The reaction is somewhat slower in the case of the less basic sodium ethoxide.

When the alkylidenesuccinic ester is derived from an aldehyde [e.g. (26)], functional group modification provides a route to γ-keto acids and the overall process relates to the disconnection strategy outlined above. The required modifications are hydrolysis of the diester to the diacid and photocatalysed
bromination to yield the dibromo acid (27), which on treatment with alkali is converted to the γ-keto acid. This sequence is illustrated by the preparation of 4-oxodecanoic acid (Expt 5.179).

\[
\begin{align*}
R\cdot\text{CHO} + \text{CH}_2\cdot\text{CO}_2\text{Et} & \rightarrow R\cdot\text{CH} = \text{C} \cdot \text{CO}_2\text{Et} \\
& \rightarrow R\cdot\text{CH} = \text{C} \cdot \text{CO}_2\text{H} \\
& + \text{Br}_2 \\
\end{align*}
\]

\[
\begin{align*}
\text{RCHBr} \cdot \text{CBr} \cdot \text{CO}_2\text{H} & \equiv \text{H}_2\text{O} \\
& \rightarrow R\cdot\text{CO} \cdot \text{CH} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H} \quad \text{at} \quad 75-80^\circ\text{C}/25\text{mmHg}.
\end{align*}
\]

**Experiment 5.173 PYRUVIC ACID**

\[
\begin{align*}
\text{HO}_2\text{C(CHOH)}_2\text{CO}_2\text{H} & \xrightarrow{\text{KHSO}_3} \Delta \quad \text{Me} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H} + \text{CO}_2 + \text{H}_2\text{O}
\end{align*}
\]

Grind together in a glass mortar 200 g (1.33 mol) of powdered tartaric acid and 300 g (2.2 mol) of freshly fused potassium hydrogen sulphate to form an intimate mixture. Place the mixture in a 1.5-litre round-bottomed flask, and fit the latter with a still-head and a long air condenser. Heat the flask in an oil bath maintained at 210–220 °C until liquid no longer distils over. If foaming is considerable and there is danger of the mixture frothing over, heat the upper part of the flask with a free flame. Fractionate the distillate under reduced pressure and collect the pyruvic acid at 75–80 °C/25 mmHg. The yield is 60 g (51%).

**Experiment 5.174 ETHYL BENZOYLFORMATE**

\[
\begin{align*}
\text{N} &= \text{NH} + \text{ClCO} \cdot \text{CO}_2\text{Et} \\
& \rightarrow \text{N} + \text{N} \cdot \text{CO} \cdot \text{CO}_2\text{Et} \\
& \xrightarrow{\text{PhMgBr}} \text{Ph} \cdot \text{CO} \cdot \text{CO}_2\text{Et}
\end{align*}
\]

**Ethyl α-oxo-1H-imidazole-1-acetate.** Ethyl oxalyl chloride (20.0 ml, 0.179 mol) (CAUTION) (Aldrich) (1) in tetrahydrofuran (80 ml) (2) is added to a stirred solution of imidazole (24.3 g, 0.35 mol) in tetrahydrofuran (500 ml) at 0 °C under nitrogen over a 1-hour period. After an additional 1 hour of being stirred at 0 °C, the mixture is filtered and the precipitate washed with anhydrous tetrahydrofuran (100 ml). The tetrahydrofuran is removed from the filtrate and washings under vacuum, and the residue is distilled to furnish 27.2 g (90%) of product, b.p. 100 °C/1 mmHg; i.r. (neat) 1730 (ester) and 1770 (amide) cm⁻¹; p.m.r. (CDCl₃, TMS) δ 1.45 (t, 3H), 4.45 (q, 2H), 7.05 (s, 1H), 7.60 (s, 1H), and 8.40 (s, 1H); m/z 168 (M). This material undergoes slow discoloration at room temperature and is stored at 5 °C.

**Ethyl benzoylformate.** The foregoing imidazolide (3.03 g, 24 mmol) is dis-
solved in tetrahydrofuran (75 ml) under nitrogen and cooled to \(-50^\circ\text{C}\) in a dry-ice-acetone bath. Phenylmagnesium bromide (1.0 equiv. in 50 ml of tetrahydrofuran) is added by a dropping funnel over 1 hour with stirring. The solution is allowed to come to room temperature over 3 hours and poured into ice-water (200 ml). The solution is extracted with ether (a few drops of acetic acid are added to break up emulsions), and the ether extract is washed with brine and dried over magnesium sulphate. Removal of solvents under reduced pressure and distillation affords ethyl benzoylformate (72%), b.p. 88 °C/0.5 mmHg.

Notes. (1) Ethyl oxalyl chloride should be handled with care in a fume cupboard since it is lachrymatory.
(2) The tetrahydrofuran should be distilled from sodium benzophenone ketyl immediately prior to use.

Experiment 5.175 PHENYLPYRUVIC ACID

\[
\text{Ph-CH=CH-NH-CO-Me} \xrightarrow{+2\text{H}_2\text{O}} \text{Ph-CH}_2\text{-CO-CO}_2\text{H} + \text{Me-CO}_2\text{NH}_4
\]

Place 10.3 g (0.05 mol) of \(\alpha\)-acetamidocinnamic acid (Expt 8.21) and 200 ml of 1 M hydrochloric acid in a 500-ml round-bottomed flask and boil the mixture steadily under reflux for 3 hours. Remove a small quantity of green oil by rapidly filtering the hot reaction mixture through a small plug of cotton wool loosely inserted into the stem of a preheated glass filter funnel, cool the filtrate to room temperature and leave it at \(0^\circ\text{C}\) for 48 hours. Collect the crystalline product by filtration, wash it with a small quantity of ice-cold water and dry it in a vacuum desiccator over anhydrous calcium chloride and potassium hydroxide pellets. The yield of phenylpyruvic acid, which is sufficiently pure for most purposes, is 4.4 g, m.p. 157 °C (decomp.). A further 1.7 g of product of comparable purity (total yield 74%) separates from the aqueous acidic filtrate when this is set aside at \(0^\circ\text{C}\) for about one week.

Experiment 5.176 ETHYL 2,2,4-TRIMETHYL-3-OXOPENTANOATE
(Ethyl isobutyrylbutyrate)

\[
2\text{Me}_2\text{CH-CO}_2\text{Et} \xrightarrow{\text{PhC}^+\text{Na}^-} \text{Me}_2\text{CH-CO-C(Me)}_2\text{-CO}_2\text{Et}
\]

Triphenylmethyl sodium. Prepare a 1.5 per cent sodium amalgam from 15 g (0.65 mol) of sodium and 985 g of mercury (Section 4.2.70, p. 464). Place a mixture of 1000 g of the amalgam and 74 g (0.265 mol) of triphenylchloromethane (Section 4.2.79, p. 466) in a 2-litre Pyrex glass-stoppered bottle and add 1500 ml of sodium-dried ether. Grease the glass stopper with a little Silicone grease, insert it firmly, clamp the bottle in a mechanical shaker and shake. CAUTION: the reaction is strongly exothermic; cool the bottle with wet rags and stop the shaking from time to time, if necessary. A characteristic red colour appears after about 10 minutes' shaking. After shaking for 4 to 6 hours, cool the bottle to room temperature, remove it from the shaker, wire the stopper down and allow the mixture to stand undisturbed; sodium chloride and particles of mercury settle to the bottom.

Separate the ether solution of triphenylmethyl sodium as follows. Remove
the glass stopper and replace it immediately by a tightly fitting two-holed bung carrying a short glass tube that protrudes about 1 cm into the bottle, and a long glass tube bent into an inverted U-shape. Connect the bottle through a drying train to a cylinder of nitrogen. Lead the other arm of the U-tube into a 2-litre, two-necked round-bottomed flask (which has been previously filled with nitrogen) via a suitable screw-capped adapter and fit a dropping funnel into the other neck. Open the stopcock of the dropping funnel slightly and force the ether solution of triphenylmethyl sodium slowly and steadily into the nitrogen-filled flask by means of a small pressure of nitrogen from the cylinder. By carefully adjusting the depth of the siphon tube in the bottle, all but 50–75 ml of the clear ether solution may be removed.

If pure triphenylchloromethane and freshly prepared sodium amalgam are used, the yield of triphenylmethyl sodium should be almost quantitative and the concentration is usually 0.15 mol per litre (1). The reagent should be used as soon as possible after its preparation.

**Ethyl 2,2,4-trimethyl-3-oxopentanoate.** Add 24 g (28 ml, 0.21 mol) of ethyl 2-methylpropanoate b.p. 110–111 °C, to the solution of c. 0.21 mol of triphenylmethyl sodium in approximately 1400 ml of ether contained in the 2-litre two-necked flask. Stopper the flask, shake well to effect complete mixing and keep at room temperature for 60 hours. Acidify the reaction mixture by adding, with shaking, 15 ml of glacial acetic acid, and then extract with 100 ml of water. Wash the ethereal solution with 50 ml portions of 10 per cent sodium carbonate solution until free from excess acid, dry over anhydrous sodium sulphate; remove the ether under reduced pressure with a rotary evaporator. Distil the residue under reduced pressure through a short fractionating column. Collect the ethyl 2,2,4-trimethyl-3-oxopentanoate at 95–96 °C/18 mmHg; the yield is 14.5 g (74%). The b.p. at atmospheric pressure is 201–202 °C.

**Note.** (1) The solution may be analysed approximately as follows. Remove 25 ml of ether solution, run it into 25 ml of water contained in a small separatory funnel and shake. Run off the aqueous layer into a 250-ml conical flask and extract the ether layer with two 25 ml portions of water. Titrate the combined aqueous extracts with 0.95 m-sulphuric acid, using methyl red as indicator.

**Ketonic hydrolysis to di-isopropyl ketone.** Mix 14 g (0.75 mol) of the ester with 30 ml of glacial acetic acid, 10 ml of water and 10 ml of concentrated sulphuric acid, and boil under reflux until evolution of carbon dioxide ceases. Dilute the cooled solution with 180 ml of water, add 100 ml of ether and render alkaline to phenolphthalein with 20 per cent sodium hydroxide solution. Separate the ether layer, extract the aqueous layer with two 50 ml portions of ether, dry the combined ether layer and extracts with anhydrous sodium sulphate, distil off the ether and fractionate the residue. The yield of di-isopropyl ketone (2,4-dimethylpentan-3-one), b.p. 123–124 °C, is 6.5 g (76%).

**Experiment 5.177 ETHYL 3-OXOPENTANOATE (Ethyl propionylacetate)**

\[
\text{Et} \cdot \text{COCl} + \text{CH} (\text{CO}_2 \text{Et})_2 \rightarrow \text{Et} \cdot \text{CO} \cdot \text{CH} (\text{CO}_2 \text{Et})_2 \xrightarrow[\Delta \text{Ar-SO}_2 \text{H}]{} \text{Et} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CO}_2 \text{Et} \\
\text{MgOEt}
\]
Prepare the ethoxymagnesium diethyl malonate derivative from 13 g (0.53 mol) of magnesium and 80 g (0.5 mol) of diethyl malonate following the procedure described in Expt 5.96. Then add with vigorous stirring a solution of 49 g (46 ml, 0.53 mol) of propanoyl chloride in 50 ml of anhydrous ether. Reflux the reaction mixture for 30 minutes and then cool and acidify with 60 ml of dilute sulphuric acid. Separate the ether layer, extract the residual aqueous solution with two 50 ml portions of ether. Wash the combined organic phases with water, dry over anhydrous sodium sulphate and remove the ether on a rotary evaporator. Add to the residue 8 g of naphthalene-2-sulphonic acid monohydrate and heat the mixture slowly to 200°C in an oil bath. A vigorous evolution of gas sets in at about 120°C; when gas evolution has subsided, cool the reaction mixture and dissolve it in about 150 ml of ether. Wash the ethereal extract with four 25 ml portions of 10 per cent sodium carbonate solution and then with water; back extract the combined aqueous solutions with three 25 ml portions of ether. Dry the combined ether extracts with anhydrous sodium sulphate, remove the ether on a rotary evaporator and distil the residue under reduced pressure. Collect the ethyl 3-oxopentanoate as a fraction of b.p. 100–105°C/22 mmHg; the yield is 34 g (47%).

**Cognate preparation. General procedure for the acylation of the diaion of ethyl hydrogen malonate** (1). To 250 ml of tetrahydrofuran (distilled from sodium/benzophenone under nitrogen prior to use) under nitrogen with stirring is added 13.47 g (0.1 mol) of monoethyl malonate (2) and several milligrams of 2,2'-bipyridyl as an indicator. After cooling to −70°C, butyllithium (hexane) is added slowly while allowing the temperature to rise to c. −5°C near the end of the addition (~130 ml of 1.6 M solution, 0.2 mol). After the pink indicator persists at −5°C the heterogeneous solution is recooled to −65°C and the acid chloride (0.057 mol) is added dropwise over 5 minutes. After the appropriate reaction time (3), the reaction solution is poured into 400 ml of ether and 200 ml of 1 M hydrochloric acid. After mixing and separating the aqueous phase, the organic phase is washed with 2 × 100 ml of saturated sodium hydrogen carbonate solution and 100 ml of water, dried over anhydrous sodium sulphate and concentrated to yield the β-keto ester.

**Notes.** (1) See Section 2.17.8, p. 120, for a suitable apparatus set-up for this moisture-sensitive reaction.
(2) Ethyl hydrogen malonate may be prepared from diethyl malonate by controlled hydrolysis with potassium hydroxide (see also Expt 5.147, Note (1)).
(3) The following acid chlorides have been used and the reaction times are given in parentheses: Pr⋅COCl (5 minutes); Me₂CH⋅CH₂COCl (5 minutes); Bu⋅COCl (5 minutes); Ph⋅CH₂COCl (5 minutes); and Ph⋅COCl (30 minutes).

**Experiment 5.178 4-OXOPENTANOIC ACID**

\[
\begin{align*}
\text{Me} & \quad + \quad \text{H}_2\text{C} & \rightarrow & \text{Me} & \quad \rightarrow & \text{Me} & \quad \rightarrow & \text{Me} & \quad \rightarrow & \text{Me} & \quad \rightarrow & \text{Me} \\

\]
**CAUTION:** All procedures should be conducted behind a safety screen; particular care should be taken in the handling of acrolein; see Section 4.2.41, p. 439, for the measures to be taken in the handling of 30 per cent hydrogen peroxide.

4-Nitropentanal. A 100-ml two-necked flask equipped with a mechanical stirrer is charged with nitroethane (3.75 g, 0.05 mol) and cooled with an ice-water bath. Acrolein (2.8 g, 0.05 mol) is added and the mixture stirred for 5 minutes. Chromatographic alumina (activity I on the Brockmann scale; 10 g) is added and stirring is continued for 6 hours. The reaction is monitored by t.l.c. (ethyl acetate–hexane, 2:8 as eluent). At the end of the reaction, the alumina is washed with ether (4 × 50 ml) and the filtered extract evaporated under reduced pressure. The product is purified by distillation to give 4-nitropentanal (50%), b.p. 71 °C/0.4 mmHg; i.r. 1720 (C=O) and 1545 cm⁻¹ (NO₂).

4-Oxopentanoic acid. Aqueous hydrogen peroxide (30 ml, 30%) is added to a cooled (0 °C) and stirred solution of the foregoing 4-nitroalkanal (1.96 g, 0.015 mol) in methanol (70 ml). To the resultant solution, potassium carbonate (12 g) is added, and stirring is continued for 15 hours at room temperature. The solution is then acidified with 2 M hydrochloric acid and extracted with dichloromethane (3 × 40 ml). The organic layer is washed with water (40 ml), and dried with magnesium sulphate. The solvent is removed under vacuum to leave the crude product which can be used without further purification. The pure 4-oxopentanoic acid (60%) is obtained by distillation and has b.p. 120 °C/10 mmHg.

**Experiment 5.179 4-OXODECANOIC ACID**

\[
\begin{align*}
C_6H_{13} \cdot CHO + CH_2 \cdot CO_2Et & \xrightarrow{\text{KOBu}^-} C_6H_{13} \cdot CH=CH \cdot CO_2H \\
& \xrightarrow{(i) \text{NaOH}} C_6H_{13} \cdot CH=C \cdot CH_2 \cdot CO_2H \\
& \xrightarrow{(ii) H_2O^-} C_6H_{13} \cdot CHBr \cdot CH_2 \cdot CO_2H \\
& \xrightarrow{\text{NaOH}} C_6H_{13} \cdot CO \cdot CH_2 \cdot CH_2 \cdot CO_2H
\end{align*}
\]

3-Carboxydec-3-enoic acid. (*Heptylidenessuccinic acid.*) Potassium t-butoxide. Prepare a solution of potassium t-butoxide in t-butyl alcohol using the following procedure. Equip a two-necked, round-bottomed 1-litre flask with a reflux condenser and a pressure-equalising dropping funnel. Attach to the top of the condenser a nitrogen inlet system with nitrogen escape valve (cf. Fig. 2.60) and place the flask in a magnetic stirrer-heating mantle unit. Flush the flask with a stream of dry nitrogen, charge the flask with 375 ml of dry t-butanol (Section 4.1.12, p. 402) and add 19.6 g (0.5 mol) of potassium [CAUTION: (1)]. Heat the mixture under reflux until the potassium completely dissolves (c. 4 hours). To the cooled solution add a mixture of 122 g
(0.7 mol) of diethyl succinate and 63 g (0.5 mol) of heptanal over half an hour; the reaction is exothermic. Finally heat the mixture under reflux for 1 hour. Rearrange the condenser for distillation and remove the t-butyl alcohol by vacuum distillation using a water pump. Acidify the residue with dilute hydrochloric acid and extract with three 200 ml portions of ether. Extract the acidic compounds from the ethereal solution by shaking with 50 ml portions of saturated sodium hydrogen carbonate solution until no more carbon dioxide is evolved. Acidify the combined aqueous solutions by the careful addition of concentrated hydrochloric acid. Extract the 3-ethoxycarboyndec-3-enoic acid which separates as an oil with ether, dry the ethereal extract over magnesium sulphate and evaporate the ether solution on a rotary evaporator. Saponify the crude half ester by heating it under reflux for 1 hour with 400 ml of 10 per cent sodium hydroxide solution. Cool the solution, acidify with concentrated hydrochloric acid and filter the precipitated acid with suction. Dissolve the crude acid in the minimum volume of ether (about 200 ml are required) and add the solution to an equal volume of light petroleum (b.p. 60–80 °C). Filter the precipitate with suction and recrystallise from benzene. The yield of 3-carboxydec-3-enoic acid, m.p. 128–130 °C, 37.3 g (31.6%). The infrared spectrum shows absorptions at 3500–2300 cm⁻¹ (O—H stretch of carboxylic acid), 1700 cm⁻¹ (C=O) and 1640 cm⁻¹ (C=C).

**3-Carboxy-3,4-dibromodecanoic acid.** This reaction should be carried out in a fume cupboard. Place 5.3 g (0.025 mol) of 3-carboxydec-3-enoic acid, 6.0 g (0.038 mol) of bromine and 60 ml of carbon tetrachloride in a 100-ml round-bottomed flask equipped with a magnetic stirrer and reflux condenser. Irradiate the stirred mixture with a 100-watt lamp for 6 hours; the dibromide forms and precipitates out during this period. Filter the product with suction and wash thoroughly with hexane. The yield of 3-carboxy-3,4-dibromodecanoic acid is 7.9 g (85%). The acid can be recrystallised from toluene, m.p. 142–143 °C. The infrared spectrum shows absorptions at 3400–2400 cm⁻¹ (O—H stretch of CO₂H) and 1730 cm⁻¹ (C=O).

**4-Oxodecanoic acid.** Dissolve 4.0 g of 3-carboxy-3,4-dibromodecanoic acid in 60 ml of 2 m sodium hydroxide solution and heat the solution at 80–90 °C for 2 hours. Cool to room temperature and acidify with dilute sulphuric acid; carbon dioxide is evolved and a white precipitate is formed. Filter the precipitated keto acid from the cold solution and recrystallise from light petroleum (b.p. 40–60 °C). 4-Oxodecanoic acid, m.p. 68–69 °C, is obtained; the yield is 1.6 g (80%). The infrared spectrum shows absorptions at 3400–2400 cm⁻¹ (OH stretch of CO₂H) and 1700 cm⁻¹ (C=O).

If the dibromo acid is treated with alkali under milder conditions, for example with 1 m sodium hydroxide solution at 20–25 °C for 0.5 hour, the intermediate y-hexylaconic acid (m.p. 123–125 °C) can be isolated after acidification. The infrared spectrum shows absorptions at 3110 cm⁻¹ (C—H stretch, alkene), 1715 and 1745 cm⁻¹ (C=O stretch of carboxylic acid and lactone) and 1630 cm (C=C stretch).

**Note.** (1) Great care must be taken in the handling of potassium. See Section 4.2.62, p. 460, for the precautions that must be adopted.
5.14.4 AMINO ACIDS AND PEPTIDES

The α-aminocarboxylic acids are of particular importance as the result of their involvement in the primary structure of protein molecules. Although customarily represented by the general formula \( \text{NH}_2\cdot \text{CHR}\cdot\text{CO}_2\text{H} \) amino acids are actually zwitterionic compounds, \( \text{NH}_3\cdot \text{CHR}\cdot\text{CO}_2^- \), and in the solid state have obvious polar properties. In solution, the following pH-dependent equilibria are established; the pH at which the molecule has no net charge is the isoelectric point, characteristic for a particular amino acid.

\[
\begin{align*}
\text{H}_3\text{N} \cdot \text{CHR} \cdot \text{CO}_2\text{H} & \xrightarrow{\text{H}^\oplus + \text{H}^\ominus} \text{NH}_3\cdot \text{CHR}\cdot\text{CO}_2^- \xrightarrow{\text{H}^\ominus + \text{H}^\oplus} \text{NH}_2\cdot \text{CHR}\cdot\text{CO}_2^- \\
\text{H}_3\text{N} \cdot \text{CHR} \cdot \text{CO}_2\text{H} & \xrightarrow{\text{H}^\ominus + \text{H}^\oplus} \text{NH}_2\cdot \text{CHR}\cdot\text{CO}_2^- \xrightarrow{\text{H}^\ominus + \text{H}^\oplus} \text{NH}_2\cdot \text{CHR}\cdot\text{CO}_2^- \\
\end{align*}
\]

Amino group reactions (e.g. acylation) proceed best under basic conditions, whereas carboxyl group reactions (e.g. esterification) are effected under acidic conditions with the amino function protected by protonation.

The main general routes for the synthesis of the α-amino acids are illustrated in the following sections (pp. 746–750). Some of the natural amino acids can be isolated from the hydrolates of suitable proteins; examples are provided on p. 750. They are optimally active having the \( \text{L} \) [(S)] configuration. The synthetic products, formed by routes not involving asymmetric syntheses, are of course racemic, from which the optically active forms may be obtained by the process of resolution. Some resolution procedures are discussed in Section 5.19.

THE AMINATION OF \( \alpha \)-HALOGENOCARBOXYLIC ACIDS

This method is generally suitable for those \( \alpha \)-amino acids \( [\text{H}_2\text{N} \cdot \text{CH}(\text{R})\cdot\text{CO}_2\text{H}] \) where \( \text{R} \) is an unsubstituted alkyl group. The examples included in Expt 5.180 are alanine \( (\text{R} = \text{CH}_3) \), glycine \( (\text{R} = \text{H}) \), valine \( (\text{R} = (\text{CH}_3)_2\text{CH}) \), norvaline \( (\text{R} = \text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2) \), norleucine \( (\text{R} = \text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2) \) and isoleucine \( (\text{R} = \text{CH}_3\cdot\text{CH}_2\cdot\text{CH}(\text{CH}_3)) \).

Chloroacetic acid is readily converted into glycine by treatment with concentrated aqueous ammonia solution, but in general an \( \alpha \)-bromocarboxylic acid is preferred. This can usually be prepared in good yield by a Hell–Volhard–Zelinsky bromination (Section 5.14.1, p. 720) of the corresponding carboxylic acid; if the carboxylic acid is not readily available it can usually be obtained by the synthesis and bromination of the appropriate alkylmalonic acid (see Expt 5.166).

\[
\begin{align*}
\text{R} \cdot \text{CH}_2\cdot\text{CO}_2\text{H} & \xrightarrow{\text{Br}_2, \text{P}} \text{R} \cdot \text{CHBr} \cdot \text{CO}_2\text{H} \\
\text{CH}_2(\text{CO}_2\text{Et})_2 & \xrightarrow{(\text{i}) \text{OEt} \ (\text{ii}) \text{RBr}} \text{R} \cdot \text{CH}(\text{CO}_2\text{Et})_2 \\
\text{R} \cdot \text{CHBr} \cdot \text{CO}_2\text{H} & \xrightarrow{\text{NH}_3} \text{R} \cdot \text{CH}(\text{NH}_2)\cdot\text{CO}_2\text{H} \\
\text{R} \cdot \text{CH}(\text{CO}_2\text{H})_2 & \xrightarrow{(\text{i}) \text{OH} \ (\text{ii}) \text{H}_2\text{O}^\ominus} \text{R} \cdot \text{CBr}(\text{CO}_2\text{H})_2
\end{align*}
\]

A large excess of concentrated ammonia has to be used to accomplish the amination step, otherwise the amino acid which is formed reacts further with the bromo acid to give substantial amounts of the secondary and tertiary amine.
derivatives. The use of an excess of ammonium carbonate in aqueous ammonia is also recommended. The reaction is usually carried out at room temperature, but temperatures of about 50 °C and advantageous when the substitution process is retarded as the result, for example, of steric effects. The higher homologous amino acids are not particularly water-soluble, and they may be isolated in the crude state by concentrating and filtering the reaction product. Care must be taken during the isolation of the readily water-soluble lower members of the series to free them from accompanying inorganic salts; in such cases advantage is taken of the solubility of ammonium bromide in methanol to achieve the required purification.

**THE FORMATION AND HYDROLYSIS OF α-AMINO NITRILES (the Strecker synthesis)**

The original Strecker procedure is the reaction of an aldehyde with ammonia and then with hydrogen cyanide to form the α-amino nitrile. This intermediate may also be obtained by reacting the aldehyde cyanohydrin with ammonia, but a more convenient method is to treat the aldehyde in one step with ammonium chloride and sodium cyanide. The α-amino acid is obtained when the amino nitrile is hydrolysed under either acidic or basic conditions; the former are usually preferred. The preparation of α-phenylglycine (R = Ph) from benzaldehyde is typical of the general procedure (cognate preparation in Ept 5.181).

\[
\begin{align*}
R \cdot CH(NH_2)OH & \xrightarrow{HCN} R \cdot CH(NH_2) \cdot CN & R \cdot CH(NH_2) \cdot CO_2H \\
& \xrightarrow{H_2O^{\oplus}} & \\
\uparrow NH_3 & \xrightarrow{NH_4Cl \text{ NaCN}} & \uparrow NH_3 \\
R \cdot CHO & \xrightarrow{HCN} & R \cdot CH(OH) \cdot CN
\end{align*}
\]

When applied to formaldehyde, however, the reaction is somewhat anomalous in that methyleneaminoacetonitrile (CH₂=N:CH₂:CN), the condensation product derived from the aldehyde and the amino nitrile, is formed (Expt 5.181). The free amino nitrile is obtained by careful basification of its sulphate salt, which is formed when methyleneaminoacetonitrile is treated with concentrated sulphuric acid in ethanol. Details of the hydrolysis of the amino nitrile (as the sulphate) under basic conditions are given. Barium hydroxide is used, the excess of which is finally removed by precipitation as the sulphate to facilitate the isolation of the glycine formed.

**THE REDUCTIVE HYDROLYSIS OF ARYLIDENOXAZOLONES (azlactones – the Erlenmeyer synthesis)**

This method is mainly restricted to the synthesis of amino acids with aromatic side-chains since the required unsaturated azlactones [e.g. (30)] are most readily prepared using aromatic aldehydes. Typically, benzaldehyde condenses under the influence of base with the reactive methylene group in the azlactone (29) which is formed by the dehydration of benzoylglycine (28) when the latter is heated with acetic anhydride in the presence of sodium acetate (cf. Expt 8.21). The azlactone ring is readily cleaved hydrolytically and compounds of the type (30) yield substituted acylaminoacrylic acids [e.g. (31)] on boiling with water. Reduction and further hydrolysis yields the amino acid [e.g. phenylalanine,
but this result can be achieved in one step (Expt 5.182) by heating the azlactone (30) in acetic anhydride solution with red phosphorus and hydriodic acid.

\[
\begin{align*}
\text{(28)} & \quad \xrightarrow{-\text{H}_2\text{O}} \quad \text{(29)} & \quad \xrightarrow{\text{Ph} \cdot \text{CHO}} \quad \text{(30)} & \quad \xrightarrow{-\text{H}_2\text{O}} \quad \text{(31)} \\
\text{(31)} & \quad \xrightarrow{\text{P/HI/H}_2\text{O}} \quad \text{(32)}
\end{align*}
\]

THE FORMATION AND HYDROLYSIS OF C-SUBSTITUTED ACYLAMINOMALONIC ESTERS

Acylaminomalonic esters and related reagents are widely used for the synthesis of \(\alpha\)-amino acids. The method differs from those syntheses already discussed in that the amino group is incorporated into the system from the outset. A popular reagent is diethyl acetamidomalonate (35). The acetamido group can readily be introduced into the reactive methylene position in diethyl malonate by first converting the latter into the hydroxy-imino derivative (33) by reaction with nitrous acid or an alkyl nitrite (cf. Section 4.2.7, p. 413). This derivative is then reduced catalytically to diethyl aminomalonate (34) which is acetylated using acetic anhydride.

\[
\text{CH}_2(\text{CO}_2\text{Et})_2 \xrightarrow{\text{HNO}_2 \text{ or RONO}} \text{O}=\text{N} \cdot \text{CH(}\text{CO}_2\text{Et})_2 \xrightarrow{\text{HONO=C(}\text{CO}_2\text{Et})_2} \text{H}_2\text{N} \cdot \text{CH(}\text{CO}_2\text{Et})_2 \xrightarrow{\text{MeCO}_2\text{O}} \text{Me} \cdot \text{CO} \cdot \text{NH} \cdot \text{CH(}\text{CO}_2\text{Et})_2
\]

In common with other malonate derivatives, the \(\alpha\)-hydrogen atom in the acetamidomalonic ester is reactive; on treatment with a base the reagent forms a mesomerically stabilised carbanion (36) from which a variety of substituted acetamidomalonic esters can be made. For example, \(C\)-alkylation ensues when the anion is allowed to react with an alkyl halide; the resulting product (37) is then subjected to the hydrolytic and decarboxylative sequence shown to yield a simple \(\alpha\)-amino acid.
The two examples illustrative of the section, however, involve alternative procedures for introducing the required substituent into the α-position of the acetylaminomalonate reagent. In the first (Expt 5.183) the hydroxymethyl group is introduced by a simple base-catalysed condensation with formaldehyde; subsequent hydrolysis and decarboxylation yields serine (R = CH₂OH). In this case, acidic conditions are preferred for the final hydrolytic stage, and the use of a weakly basic ion exchange resin to obtain the halide-free amino acid from a solution of its hydrochloride is described.

The second example is an interesting synthesis of the heterocyclic amino acid tryptophan (R = 3-indolymethyl) which involves the initial base catalysed 1,4-addition (the Michael reaction, Section 5.11.6, p. 681) of diethyl acetamidomalonate to the α,β-unsaturated aldehyde, acrylaldehyde, yielding the aldehydic derivative (38). The derived phenylhydrazone (39) is then cyclised under acidic conditions (see Expt 8.26) to form the indolylacetamidomalonate derivative (40) which is then converted into the corresponding α-amino acid (i.e. tryptophan) in the usual way (Expt 5.184).

Although it does not involve the use of an acylaminomalonic ester a related convenient synthesis of the heterocyclic amino acid, proline, is included here (Expt 5.185).

The synthesis starts with the preparation of diethyl (2-cyanoethyl)malonate (Expt 5.161) by the Michael addition of diethyl malonate to acrylonitrile. Hydrogenation over Raney nickel converts the cyanoethyl compound to the corresponding primary amine (41) which is converted into proline (isolated initially as the hydrochloride) by the reaction sequence shown. Liberation of the free amino acid from its salt is achieved in this case by treatment with triethylamine (cf. serine, Expt 5.183).
ISOLATION FROM PROTEIN HYDROLYSATES
The hydrolysis of proteins yields a complex mixture of amino acids having closely related physical properties. Although a quantitative separation of the individual amino acids can be achieved by chromatographic methods, only in a few cases is the preparative isolation of an individual member worth while. Provided that racemisation is avoided during hydrolysis, however, amino acids are obtained in this way in the optically active form. The normal synthetic products are of course racemic, but they may be resolved by appropriate procedures (e.g. the enzymic method described in Expt 5.221).

The amino acid composition of keratin, the protein of hair and wool, includes a greater-than-average proportion of the sulphur-containing amino acid, cystine. Since this is the least soluble of the protein amino acids it can readily be isolated after carefully neutralising an acid hydrolysate of hair (Expt 5.187). Protein hydrolysis is usually effected by boiling for about 10–20 hours with 20 per cent hydrochloric acid. The hydrolysis of hair for the isolation of cystine is, however, best achieved using a mixture of hydrochloric and formic acids.

Many relatively specific reagents, particularly a variety of metal complexes, have been developed as an aid to the isolation of individual amino acids. An example is provided by the isolation of L-proline from a gelatine hydrolysate using the chromium complex ammonium rhodanilate \(\left\{\text{ammonium di-aniline-tetrathiocyanatochromate (iii), } \left[\text{Cr(CNS)}_{4}(\text{C}_{6}\text{H}_{5}\text{NH}_{2})_{2}\right]\right\}^{\text{+}}\text{NH}_{4}\). Proline is isolated as the rhodanilate salt, which is purified and then treated with pyridine to form the less soluble pyridine rhodanilate, thus liberating the proline into solution.

PEPTIDE SYNTHESIS
In a polypeptide chain the \(\alpha\)-amino acid residues are linked 'head to tail' by means of amide (peptide) bonds.

\[
\text{NH}_2\cdot\text{CHR}^1\cdot\text{CO} \cdot \text{NH} \cdot \text{CHR}^2 \cdot \text{CO} \cdot \text{NH} \cdot \text{CH}_2 \cdot \text{R}^3 \cdot \text{CO} \cdot \text{NH} \ldots \text{CO} \cdot \text{NH} \cdot \text{CHR}^x \cdot \text{CO}_2\text{H}
\]

The formation of a dipeptide, for example, thus involves the condensation of the carboxyl group of one amino acid with the amino group of another. To achieve this apparently simple synthetic objective efficiently however, a number of reaction steps, requiring the use of appropriate functional group protection procedures (see p. 13), must be carried out. An illustrative synthesis is that of L-prolylglycine described in Expt 5.188, where the sequence is formulated in full. Note that proline is actually a secondary rather than a primary \(\alpha\)-amino acid,
the side chain R being linked to the nitrogen atom to form a pyrrolidine ring. The principal phases in the synthetic sequence are as follows.

**Functional group protection.** The NH— group in proline is protected by acylation in the usual Schotten–Baumann manner with benzyl chloroformate to yield the benzyloxy carbonyl derivative (42). Correspondingly the —CO₂H group in glycine is protected by esterification in ethanol to form the ethyl ester, obtained as the hydrochloride (43) under Fischer–Speier conditions.

\[
\begin{align*}
\text{Ph} & \cdot \text{CH}_2 \cdot \text{O} \cdot \text{CO} \cdot \text{N} & \cdot \text{CH} & \cdot \text{CO}_2 \text{H} & \quad (42) \\
\text{Cl} & \quad \text{NH}_3 & \cdot \text{CH}_2 & \cdot \text{CO}_2 \text{Et} & \quad (43)
\end{align*}
\]

**Peptide bond formation.** The process requires that the derivative (42), a carboxylic acid, should be caused to acylate the free base liberated from the hydrochloride (43). Activation of the carboxyl group is effected by conversion into a type of acid anhydride; the mixed carbonic anhydride (44) is used here, and is prepared by reaction of the acid (42) with ethyl chloroformate.

\[
\begin{align*}
\text{Ph} & \cdot \text{CH}_2 \cdot \text{O} \cdot \text{CO} \cdot \text{N} & \cdot \text{CH} & \cdot \text{C} & \cdot \text{O} & \cdot \text{O} & \cdot \text{Et} \\
\text{H}_2 & \text{N} & \cdot \text{CH}_2 & \cdot \text{CO}_2 \text{Et} & \quad (44)
\end{align*}
\]

The free glycine ethyl ester nucleophilically attacks the mixed anhydride specifically at the amino acid carbonyl, rather than the carbethoxycarbonyl group, liberating carbon dioxide and ethanol and forming the acylated dipeptide ester in good yield.

**Deprotection.** Subsequent treatment of the fully protected dipeptide illustrates, in an elementary way, an important aspect of functional group protection, namely the selective removal of specific protecting groups. Here the ester group is smoothly removed by hydrolysis with aqueous alkali at room temperature, conditions which do not affect the benzyloxy carbonyl group. The latter can readily be cleaved by catalytic hydrogenolysis without affecting the ethyl ester group. Performance of these two procedures sequentially affords the required dipeptide. The intermediate mono-protected derivatives can of course be used in similar synthetic sequences for the construction of longer peptide chains.

**Experiment 5.180 DL-ALANINE (2-Aminopropanoic acid)**

\[
\text{Me} \cdot \text{CHBr} \cdot \text{CO}_2 \text{H} \xrightarrow{\text{NH}_3} \text{Me} \cdot \text{CH} (\text{NH}_2) \cdot \text{CO}_2 \text{H}
\]

Place 2 litres (1760 g, 36 mol) of concentrated ammonia solution (d 0.88, 35% w/w) (1) in a large (e.g. Winchester) bottle, cool thoroughly in an ice bath and pour in slowly 77 g (0.5 mol) of 2-bromopropanoic acid (Expt 5.164). Close the bottle with a rubber bung held in place with wire, and leave at room temperature for 4 days. Concentrate the solution to about 250 ml by distillation under reduced pressure using a rotary evaporator; apply the vacuum with caution in the initial stages when most of the excess of ammonia is being removed. Filter, concentrate further to 150 ml, cool in ice and add 750 ml of...
methanol with swirling. Leave the resulting suspension overnight in a refrigerator, and then filter off the crude alanine with suction and wash it with 200 ml of methanol. Dissolve the product in 150 ml of water, precipitate the alanine by adding 750 ml of methanol and filter and wash as before. The yield of almost pure DL-alanine, m.p. 295–296 °C (decomp.), is 30 g (67%).

Note. (1) Alternatively use 225 g of ‘ammonium carbonate’, 175 ml of water and 250 ml (4.5 mol) of concentrated ammonia solution. ‘Ammonium carbonate’ is a mixture of roughly equimolar amounts of ammonium hydrogen carbonate and ammonium carbamate (NH₄HCO₃·NH₂CO₂NH₄).

Cognate preparations. Glycine (aminoacetic acid). Use 47 g (0.5 mol) of chloroacetic acid (CAUTION: the compound causes blistering if it is allowed to come into contact with the skin) and 2 litres of concentrated ammonia solution. Allow the reaction to proceed for 2 days, concentrate to 60 ml and precipitate the crude glycine by adding 360 ml of methanol. This material contains ammonium chloride as the chief impurity; remove most of this by stirring the crystals with 150 ml of methanol and refiltering. Finally purify the glycine by dissolving it in 50 ml of hot water and adding 250 ml of methanol; the yield is 25 g (67%), m.p. c. 252–254 °C (decomp.).

DL-Valine (2-amino-3-methylbutanoic acid). Use 60 g (0.33 mol) of 2-bromo-3-methylbutanoic acid (Expt 5.164) and 400 ml (7.25 mol) of concentrated ammonia solution. Allow reaction to proceed at room temperature for 7 days. Concentrate the solution to 50 ml and filter the resulting thin paste. Dissolve the solid in 150 ml of hot water, decolourise with 1 g of charcoal, filter hot and dilute the filtrate with 150 ml of ethanol. Cool at 0 °C overnight, filter off the purified DL-valine and wash with 10 ml of cold ethanol. The yield is 12.5 g (32%); m.p. 280–282 °C (decomp.). A further 2 g may be isolated by concentrating the mother-liquor to about 25 ml and adding an equal volume of ethanol.

DL-Norvaline (2-aminopentanoic acid). Prepare as for valine, using 2-bromopentanoic acid (Expt 5.164); m.p. c. 300 °C (decomp.).

DL-Norleucine (2-aminoheptanoic acid). Use 65 g (0.33 mol) of 2-bromohexanoic acid (Expt 5.164) and 400 ml of concentrated ammonia. Ensure that the bung is securely wired to the reaction bottle and allow the latter to stand in a warm place (50–55 °C) for 30 hours. Filter the amino acid at the pump and keep the filtrate (A) separately. Wash the amino acid well with methanol to remove the ammonium bromide present. Concentrate the filtrate (A) almost to dryness and add 150 ml of methanol. A second crop of amino acid contaminated with ammonium bromide is thus obtained; wash it with methanol and recrystallise from hot water, thus affording a further 6 g of pure DL-norleucine. The total yield is 28 g (65%); the decomposition point is about 325 °C.

DL-Isoleucine (2-amino-3-methylpentanoic acid). Allow 65 g (0.33 mol) of 2-bromo-3-methylpentanoic acid (Expt 5.166) to react with 400 ml of concentrated ammonia solution as for valine. Concentrate the resulting solution to about 130 ml, filter off a first crop of crude product and wash with 20 ml of ethanol. Further concentrate the aqueous filtrate to about 60 ml to obtain a second crop of crude product, and wash it with 10 ml of water followed by
10 ml of ethanol. Dissolve the combined product (28 g) in 400 ml of hot water, decolourise with charcoal and add 200 ml of rectified spirit. Cool well in ice, and filter off the pure DL-isoleucine; yield 16.5 g (38%), m.p. 278–280 °C (decomp.). A further 5 g may be recovered by concentrating the recrystallisation mother-liquor to 40 ml and diluting with an equal volume of ethanol.

**Experiment 5.181 AMINOACETONITRILE AND GLYCINE** (*Amino-acetic acid*)

\[2H\cdot\text{CHO} + \text{CN} + \text{NH}_4^+ - \text{H}_2\text{O} \rightarrow \text{CH}_2=\text{N} \cdot \text{CH}_2 \cdot \text{CN} \quad \text{EtOH; } \text{H}^+ \rightarrow \text{CH}_2(\text{OEt})_2^+\]
\[\text{NH}_3 \cdot \text{CH}_2 \cdot \text{CN} \xrightarrow{\text{OMe}} \text{NH}_2 \cdot \text{CH}_2 \cdot \text{CN} \]
\[(\text{NH}_3 \cdot \text{CH}_2 \cdot \text{CN})_2\text{SO}_4 \xrightarrow{\text{H}_2\text{O}} (\text{NH}_2 \cdot \text{CH}_2 \cdot \text{CO}_2)\text{Ba} \xrightarrow{\text{H}_2\text{SO}_4} 2\text{NH}_2 \cdot \text{CH}_2 \cdot \text{CO}_2\text{H}\]

**N-Methyleneaminoacetonitrile.** Place 160 g (3 mol) of ammonium chloride in a 2-litre flange or three-necked flask surrounded by a large bath containing a cooling mixture of ice and salt (*fume cupboard*). Add 450 ml (6 mol) of filtered 40 per cent w/v formaldehyde solution and stir the mixture with an efficient mechanical stirrer. When the temperature has reached 0 °C, begin the dropwise addition of a solution of 150 g (3 mol) of sodium cyanide (98% pure) (**CAUTION**) in 250 ml of water; the addition should take about 5 hours and the temperature throughout should be kept between 0 and 5 °C. When half of the cyanide solution has been added and all of the ammonium chloride has dissolved begin the simultaneous gradual addition of 100 ml of glacial acetic acid, and adjust the rate so that addition is complete by the end of the remaining 2.5 hours. Stir the mixture for a further period of 1 hour, and then filter off the product and wash it with a little cold water. Transfer the filter-cake to a beaker, stir thoroughly with 500 ml of water to remove soluble salts, filter, wash with a little more water and dry in a vacuum desiccator. The yield of *N*-methyleneaminoacetonitrile (1) is 120 g (59%), m.p. 127–128 °C.

**Aminoacetonitrile sulphate.** Cautiously add 85 ml of concentrated sulphuric acid to 400 ml of rectified spirit in a 1-litre conical flask and adjust the temperature to 50 °C. Add rapidly 102 g (1.5 mol) of dried powdered *N*-methyleneaminoacetonitrile, shake vigorously until the solid has dissolved and continue shaking while the product crystallises. Cool in an ice bath for 4 hours, filter and wash the product with a little cold rectified spirit. Dissolve the crude product in a minimum of water, filter off traces of insoluble matter and run the solution with stirring into 400 ml of cold rectified spirit. Cool well, filter off the purified aminonitrile salt and wash it with a little cold rectified spirit. The yield is 105 g (67%), m.p. 164 °C (decomp.).

**Hydrolysis to glycine.** Boil a suspension of 79 g (0.25 mol) of barium hydroxide octahydrate in 175 ml of water in a 500-ml round-bottomed flask and add in portions 21 g (0.1 mol) of aminoacetonitrile sulphate. Fit a reflux condenser and continue boiling until no more ammonia is evolved (about 3 hours). Transfer the suspension to a beaker, add 50 per cent v/v aqueous sulphuric acid (about 20 ml) until precipitation of the barium is complete and the solution is slightly acidic, and digest on a steam bath. Filter the suspension through a medium-speed filter paper (e.g. Whatman No. 30) using gentle
suction, and adjust the filtrate to neutrality by carefully adding saturated barium hydroxide solution. Digest further and decant the supernatant solution through a similar filter paper (this is best done under gravity), suspend the precipitate in a little hot water and add this to the filter. Concentrate the filtrate under reduced pressure using a rotary evaporator until a thick suspension is obtained, and complete the precipitation of the glycine by adding 100 ml of methanol. Cool well and filter off the crude glycine (about 12 g). Dissolve the product in 25 ml of hot water, add gradually 125 ml of methanol, cool, filter and dry the crystals in an oven at 50 °C. The yield of glycine, m.p. c. 250 °C (decomp.), is 11.2 g (75%).

**Aminoacetonitrile.** Stir a suspension of 88 g (0.4 mol) of the nitrile sulphate in 100 ml of dry methanol in a 500-ml three-necked flask cooled in crushed ice. Add a few crystals of phenolphthalein as an indicator, pass a slow stream of nitrogen through the flask and run in during 1 hour a solution of sodium methoxide in methanol prepared from 17 g (0.75 mol) of sodium and 350 ml of dry methanol; the suspension should at no time be allowed to become permanently alkaline to phenolphthalein. Filter, and remove the methanol and distil the residue under reduced pressure under nitrogen. The yield of aminoacetonitrile, b.p. 73.5 °C/15 mmHg, is 35 g (83% based on sodium). Store the product at 0 °C under nitrogen.

**Note.** (1) The product in fact has a trimeric structure.

**Cognate preparation.** **DL-2-Aminophenylacetic acid** (α-phenylglycine). Dissolve 10 g (0.2 mol) of sodium cyanide in 40 ml of water, add 11 g (0.2 mol) of ammonium chloride and shake until dissolved. Add a solution of 21 g (0.2 mol) of redistilled benzaldehyde in 40 ml of methanol and shake vigorously. The mixture soon becomes warm; allow it to stand at ambient temperature for 2 hours, shaking occasionally. Then add 100 ml of water and shake well, and extract out the oily aminonitrile which separates using two portions (60 ml and 40 ml) of toluene. Combine the toluene layers, wash twice with water and extract with two 60 ml portions of 5 M hydrochloric acid. Boil the acid extract under reflux for 22 hours (CARE: hydrogen cyanide is evolved). Cool and filter through a small plug of cotton wool to remove a little tarry matter. Basify the solution by adding about 40 ml of concentrated ammonia solution (d 0.88) with stirring and cooling, collect the resulting precipitate by filtration and wash it with 100 ml of cold water and then with 15 ml of warm ethanol. The crude material is almost colourless; the yield is 11.5 g after drying in an oven at 50 °C. To purify the phenylglycine, dissolve it in 80 ml of 1 M sodium hydroxide, add 50 ml of ethanol and clarify the solution by adding a little decolourising charcoal, warming and filtering. Heat the filtrate almost to boiling and neutralise by slowly adding with stirring 16 ml of 5 M hydrochloric acid. Filter off the purified DL-phenylglycine, wash it with 10 ml of ethanol followed by 20 ml of water and dry at 50 °C; the yield of colourless glistening plates is 9 g (30%). The compound has no m.p.; when placed in a rapidly heated melting point apparatus when the temperature reaches 275 °C, it sublimes between 300 and 310 °C, depending upon the rate of heating.
Experiment 5.182 DL-PHENYLALANINE (2-Amino-3-phenylpropanoic acid)

\[
\begin{align*}
\text{Ph} & \text{H} \\
\text{N} & \text{O} \\
\text{O} & \text{Ph}
\end{align*}
\]

\[
\text{Ph} + 2\text{H}_2\text{O} + 2[\text{H}] \xrightarrow{\text{P/HI}} \text{Ph} \text{H}_{\text{NH}_2} \text{CO}_2\text{H}
\]

In a 1-litre three-necked flask, fitted with a reflux condenser, a sealed stirrer unit and dropping funnel, place 25 g (0.1 mol) of 4-benzylidene-2-phenyloxazol-5-one (Expt 8.21) 20 g (0.65 mol) of purified red phosphorus (Section 4.2.59, p. 458) and 135 g (125 ml, 1.32 mol) of acetic anhydride. Add with stirring over a period of 1 hour 125 ml of hydriodic acid (d 1.56; 50%). Reflux the mixture for 3 hours, cool and filter with suction; wash the unreacted phosphorus on the filter with two 5 ml portions of glacial acetic acid. Evaporate the filtrate and washings on a water bath (rotary evaporator) and collect the distillate (which may be used for another reduction) in a flask cooled in ice. Add 100 ml of water to the dry residue and repeat the evaporation to dryness. Shake the residue in the flask with 150 ml of water and 150 ml of ether until solution is complete; separate the aqueous layer and extract it with three 75 ml portions of ether. Discard the ether extracts. Introduce 2–3 g of decolourising carbon and a trace of sodium sulphite into the aqueous phase, heat on a water bath until the dissolved ether has been removed, filter, heat the filtrate to boiling and neutralise to Congo red with ammonia solution (d 0.88; about 25 ml are required). When cold, filter the colourless DL-phenylalanine at the pump and wash with two 30-ml portions of cold water and finally with a little cold ethanol. The yield is 11 g (67%), m.p. 284–288 °C (decomp., rapid heating).

Experiment 5.183 DL-SERINE (2-Amino-3-hydroxypropanoic acid)

\[
\begin{align*}
\text{Me} & \text{NH}_2 \text{CO}_2\text{Et} \xrightarrow{\text{HCHO}} \text{Me} \text{NH} \text{CO}_2\text{Et} \\
\text{Me} & \text{NH}_2 \text{CO}_2\text{Et} \xrightarrow{(i) \text{OH}^{-}} \text{Me} \text{CH}_2\text{OH} \text{CO}_2\text{Et} \\
\text{Me} & \text{NH}_2 \text{CO}_2\text{H} \xrightarrow{\text{H}_2\text{O}^\circ; \Delta} \text{Me} \text{NH}_2 \text{CO}_2\text{H}
\end{align*}
\]

Prepare a suspension of 43.5 g (0.2 mol) of diethyl acetamidomalonate in 25 ml of water and add in one portion 17 g of neutral (1) 37–41 per cent w/v aqueous formaldehyde (0.21–0.23 mol). Add 0.5 ml of 1 M sodium hydroxide solution as the catalyst, shake vigorously and leave at room temperature for 2 hours. (Most of the solid goes into solution within 30 minutes; the mixture may require gentle warming on a steam bath to complete the dissolution of the solid.) Then add a solution of 18 g (0.45 mol) of sodium hydroxide in 350 ml of water and leave at room temperature overnight. Acidify the solution by adding 40 g (38 ml, 0.67 mol) of glacial acetic acid and heat almost to boiling, when brisk decarboxylation sets in. Continue to heat on a boiling water bath under reflux for 1 hour to complete the decarboxylation and then
evaporate the solution to a syrup under reduced pressure on a rotary evaporator. Dissolve the syrup in 120 ml of concentrated hydrochloric acid, boil under reflux (fume cupboard) for 1 hour and evaporate to dryness under reduced pressure. Extract the dry residue with 200 ml of boiling absolute ethanol, filter off the sodium chloride and extract the latter with a further 100-ml portion of hot ethanol. Evaporate the ethanol extracts on the rotary evaporator and boil the residue under reflux with 100 ml of concentrated hydrochloric acid for 1 hour (fume cupboard). Evaporate again to a syrup, and dissolve the latter in water and re-evaporate twice more to remove most of the excess hydrochloric acid. Finally dissolve the residual gum in about 200 ml of distilled water and pass the solution through a 50 x 2.75 cm column of a weakly basic anion exchange resin (e.g. Amberite IR 45, OH\(^{-}\) form, about 300 ml of moist granules). Continue to elute the column with distilled water (about 1.5 litres) until the eluate gives no purple coloration when a portion is tested by boiling with a few mg of ninhydrin (2). Combine all the ninhydrin-positive eluates, which should be free from chloride ion, and evaporate to dryness under reduced pressure (rotary evaporator). Dissolve the straw-coloured residue in 150 ml of hot water, boil with a little decolourising charcoal, filter and add to the filtrate 750 ml of hot ethanol. Cool in ice, filter off the purified DL-serine which crystallises, wash it with a little cold ethanol and dry in an oven at 50°C. The yield is 12 g (57%), m.p. c. 235°C (decomp.).

The product thus obtained is homogeneous (\(R_f\) 0.57) on t.l.c. (silica gel, 15 cm run; butan-1-ol–formic acid–water, 6:3:1) (3).

Notes. (1) If necessary, the formaldehyde solution should be neutralised (narrow range pH paper) by the careful dropwise addition of 1 M sodium hydroxide solution.
(2) After use, regenerate the resin in the following way. Firstly exhaust the column by passing 0.25 M hydrochloric acid through it until the pH of the eluate is about 2. Wash the column with 2 or 3 bed-volumes of distilled water, and then regenerate the resin by passing through it 0.25 M sodium hydroxide solution until the eluate is strongly alkaline. Finally wash the column thoroughly with much distilled water until the pH of the eluate is within the range 5.5–6.5 (narrow range indicator paper).
(3) Using this solvent system, serine is not completely separable from glycine (\(R_f\) 0.58) which is a possible contaminant. The latter may be distinguished, however, by the characteristic brownish-pink spot which it gives on spraying with ninhydrin; that of serine is purple.

**Experiment 5.184** DL-TRYPTOPHAN [2-Amino-3-(3-indolyl)propanoic acid]
Phenylhydrazone of 4-acetamido-4,4-diethoxycarbonylbutanal. **CAUTION:** *Carry out all operations in an efficient fume cupboard.* Place 43.5 g (0.2 mol) of diethyl acetamidomalonate and 70 ml of benzene (CAUTION) in a 250-ml three-necked flask fitted with a stirrer and dropping funnel and surrounded by a bath of water at room temperature. Stir mechanically, add about 0.5 ml of a concentrated solution of sodium ethoxide in ethanol and then add slowly from the dropping funnel a solution of 12 g (14 ml, 0.215 mol) of acrylaldehyde [acrolein – **CAUTION:** *highly toxic and irritant vapour* (1)] in 14 ml of benzene; adjust the rate of addition so that the temperature of the reaction mixture does not exceed 35 °C. When the addition is complete, stir for 2 hours more and filter off any traces of insoluble material. Add 5 ml of glacial acetic acid and 24 g (22 ml, 0.22 mol) of redistilled phenylhydrazone [CAUTION: (2)], warm to 50 °C and leave the resulting orange solution at room temperature for 2 days. Collect the crystalline phenylhydrazone by filtration and wash it thoroughly by triturating with two 40 ml portions of benzene. The yield of off-white crystals, m.p. 141 °C, is 50 g (69%). If the yield is low, warm the filtrate to 50 °C and set it aside for a further 2 days, when a further crop of the product may be obtained.

**Diethyl (3-indolylmethyl)acetamidomalonate.** Add 47 g (0.13 mol) of the phenylhydrazone to 300 ml of water containing 14 ml of concentrated sulphuric acid in a 500-ml two-necked flask fitted with a sealed stirrer unit and a reflux condenser. Boil the mixture under reflux with vigorous stirring for 4.5 hours; the suspended solid liquefies and then solidifies during this time. Cool, filter off the resulting product (in the form of hard nodules) and wash it thoroughly by grinding it with water and re-filtering. Recrystallise the product from 1:1 aqueous ethanol to obtain the purified malonate derivative; yield 32 g (71%). The product melts at 143 °C, re-solidifies and then melts at 159 °C.

dl-Tryptophan. Boil 31 g (0.09 mol) of the above product under reflux for 4 hours with a solution of 18 g (0.45 mol) of sodium hydroxide in 180 ml of water. Add a little decolourising charcoal, filter and cool the filtrate in an icesalt bath. Acidify the filtrate by adding about 55 ml of concentrated hydrochloric acid slowly and with shaking, keeping the temperature below 20 °C. Cool the resulting suspension at 0 °C for 4 hours and then collect the crude (indolylmethyl)malonic acid, a pale buff solid, by filtration. Boil the crude product under reflux with 130 ml of water for 3 hours; decarboxylation ensues and some N-acetyltryptophan separates. Add a solution of 16 g (0.4 mol) of sodium hydroxide in 30 ml of water, continue to boil under reflux for 20 hours and then add about 1 g of decolourising charcoal and filter. Cool, acidify the filtrate by adding 24 g (23 ml, 0.4 mol) of glacial acetic acid and cool the mixture at 0 °C for 5 hours. Collect the crude tryptophan by filtration, dissolve it in a solution of 5 g of sodium hydroxide in 200 ml of water and warm to 70 °C. Dilute the solution with 100 ml of ethanol at 70 °C and decant it from a little gummy precipitate which separates. Acidify the hot solution with 7.5 ml of glacial acetic acid and allow to cool slowly. When crystallisation is complete, filter off the purified dl-tryptophan and wash it successively with ice-cold water (2 × 40 ml), ethanol (2 × 40 ml) and ether (2 × 40 ml). The yield of colourless plates is 15 g (82%), m.p. 283–284 °C (decomp.). The i.r. spectrum of the l-enantiomer is shown in Fig. 3.37.
Notes. (1) Acrolein is usually supplied in sealed amber-coloured ampoules stabilised by the addition of a little hydroquinone. The ampoule should be cooled thoroughly before being opened with great care. It has been recorded that opened samples of acrolein stored in screw-capped bottles may explode violently, presumably as the result of rapid exothermic polymerisation.
(2) Phenylhydrazine is highly poisonous and produces unpleasant burns in contact with the skin. Always wear disposable gloves. If any liquid does come in contact with the skin wash off immediately with 2 per cent acetic acid, then with soap and water.

Experiment 5.185 dl-PROLINE (dl-Pyrrolidine-2-carboxylic acid)

\[
\begin{align*}
(EO_2C)_2CH + CH_2=CH-CN & \xrightarrow{EtO^+} (EO_2C)_2CH\cdotCH_2\cdotCH-CN & \xrightarrow{Ni/H_2} \\
\begin{array}{c}
\text{HN} \\
\text{EtO}_2\text{C} \text{CO}_2\text{Et}
\end{array} & \text{HN} & \text{Cl} & \text{Cl} & \text{HN} & \text{CO}_2\text{H}
\end{align*}
\]

3-Ethoxycarbonyl-2-piperidone. Dissolve 160 g (0.75 mol) of diethyl (2-cyanoethyl)malonate (Expt 5.161) in 600 ml of ethanol and hydrogenate in the presence of about 4–5 g of Raney nickel catalyst (Section 4.2.50, p. 450) at 80 °C and 75 atmospheres pressure of hydrogen in an autoclave (Section 2.17.1); uptake of hydrogen is complete in about 2 hours. Remove the catalyst by filtration and the solvent by distillation under reduced pressure (rotary evaporator) and pour the residue with stirring into 500 ml of light petroleum (b.p. 60–80 °C). Filter off the precipitated piperidone and allow it to dry in the air; yield 115 g (90%), m.p. 74 °C. A specimen crystallised from ethanol/light petroleum has m.p. 80 °C.

3-Chloro-3-ethoxycarbonyl-2-piperidone. Assemble in a fume cupboard a 500-ml three-necked flask fitted with a sealed stirrer unit, a dropping funnel and a reflux condenser protected by a calcium chloride guard-tube. Charge the flask with a solution of 111 g (0.65 mol) of 3-ethoxycarbonyl-2-piperidone in 175 ml of dry chloroform (CAUTION), and the dropping funnel with 90 g (54 ml, 0.67 mol) of redistilled sulphuryl chloride dissolved in 125 ml of dry chloroform; close the neck of the funnel with a calcium chloride guard-tube. Start the stirrer, and slowly run in the solution of sulphuryl chloride so that the reaction mixture refluxes gently. When the addition is complete, warm on a steam bath until hydrogen chloride evolution ceases. Remove the solvent under reduced pressure using a rotary evaporator, and cool the residue, scratching the sides of the flask to induce crystallisation. Dissolve the solid in 70 ml of hot ethyl acetate, add hot light petroleum (b.p. 80–100 °C) until the solution is slightly turbid, and cool while scratching the side of the vessel vigorously until the product crystallises (it helps to add a few crystals of the crude solid as a seed). Add 30 ml more of light petroleum, cool further and filter. The chloropiperidone is obtained as a somewhat sticky white solid, m.p. 64–68 °C; yield is 100 g (82%).
**DL-Proline hydrochloride.** Boil 103 g (0.5 mol) of the above chloropiperidone under reflux with 200 ml of concentrated hydrochloric acid (fume cupboard) for 5 hours during which time decarboxylation ensues. Boil the solution with about 2 g of decolourising charcoal (acid-washed grade), filter and evaporate under reduced pressure using a rotary evaporator; dissolve the residue in water and re-evaporate to assist the removal of most of the excess hydrochloric acid. Dissolve the resulting pale golden syrup in 80 ml of water, add a solution of 60 g of sodium hydroxide in 120 ml of water and leave at room temperature for 2 days. Acidify the solution to Congo red paper with concentrated hydrochloric acid (about 130 ml are needed) and evaporate to dryness under reduced pressure (rotary evaporator). Dry the resulting solid completely by leaving it overnight in a vacuum desiccator over phosphorus pentoxide and potassium hydroxide pellets, and then extract it with 200 ml of boiling absolute ethanol. Filter off the sodium chloride and re-extract it with 150 ml more of boiling ethanol. Evaporate the ethanol from the combined filtrates and boil the residue under reflux for 1 hour with 1.25 litres of 2 M hydrochloric acid to hydrolyse any proline ester formed in the extraction process. Evaporate to dryness, redisolve the residue in water and re-evaporate, and dry the resulting crude DL-proline hydrochloride in a vacuum desiccator over phosphorus pentoxide and potassium hydroxide; the yield is 70 g. Recrystallise the product from 175 ml of hot propan-2-ol, cool in ice, filter and wash the crystals with 20 ml of ice-cold propan-2-ol. The yield of the purified product, m.p. 148–150°C, is 50 g (66%).

**Conversion to DL-proline.** Suspend 15 g (0.1 mol) of dry proline hydrochloride in 70 ml of dry chloroform, stir vigorously and run in dropwise 15 g (0.15 mol) of dried, redistilled triethylamine. Continue stirring for 1 hour, filter off the product and wash it with a little cold chloroform. The yield of DL-proline is 10 g (87%); a sample crystallised from absolute ethanol has m.p. 206–207°C (with preliminary sintering).

**Experiment 5.186 L-PROLINE (L-Pyrrolidine-2-carboxylic acid)**

\[
\begin{align*}
\text{PhNH}_2 \overset{\text{Cr}^{3+}, \text{CNS}^-}{\text{Me-CO}_2\text{H}} & \rightarrow \text{PhNH}_3\text{[Cr(CNS)_4(PhNH}_2)_2]}^+ \overset{\text{NH}_3}{\rightarrow} \\
& \overset{\text{NH}_4\text{[Cr(CNS)_4(PhNH}_2)_2]}^+ \overset{\text{gelatine}}{\rightarrow} \text{Ammonium rhodanilate} \\
& \overset{\text{hydrolysate}}{\rightarrow} \\
\text{L-Proline rhodanilate} & \overset{\text{pyridine}}{\rightarrow} \text{L-Proline + Pyridine rhodanilate}
\end{align*}
\]

**Ammonium rhodanilate.** Heat a mixture of 250 g (0.5 mol Cr\(^{3+}\)) of hydrated chromium(III) potassium sulphate (chrome alum), 290 g (3.0 mol) of potassium thiocyanate and 250 ml of water in a 5-litre flask on a steam bath for 4 hours. Cool, add 235 g (230 ml, 2.53 mol) of redistilled aniline and heat in a water bath at 60°C with stirring for 3 hours. Cool again, add while still stirring 3 litres of water containing 300 ml of glacial acetic acid and leave at 0°C overnight. Filter off the purple precipitate with suction, wash it with water and suck as dry as possible. Extract the filter cake with 750 ml of methanol, filter and run into the filtrate, with stirring, 3 litres of water. Cool at 0°C for 1 hour and filter off the crystalline purple mass of aniline rhodanilate. Dissolve
the damp product in 400 ml of methanol, add 200 ml of concentrated ammonia solution (d 0.88), cool to 0 °C and then run in slowly, with stirring, 2 litres of water. Collect the precipitate by filtration, and again treat it with 250 ml of methanol, 125 ml of ammonia solution and 1250 ml of water in the above manner. Dry the resulting ammonium rhodanilate sesquihydrate in an oven at 50 °C; the yield is 130 g (50.5%).

L-Proline. Place 150 g of good quality sheet gelatin (cut into conveniently sized pieces) in a 1-litre flask and add 450 ml of concentrated hydrochloric acid. Boil gently under reflux for 8 hours (fume cupboard), or boil under reflux for about 3 hours and leave on a steam bath overnight; complete hydrolysis is indicated by a negative biuret reaction (1). Concentrate the hydrolysate to a syrup by distillation under reduced pressure (rotary evaporator), and remove excess hydrochloric acid by dissolving the syrup in water and evaporating twice more. Dissolve the residual syrup finally in 500 ml of water, boil briefly with 3 g of decolourising charcoal, filter, cool and dilute with water to 1200 ml. Add this solution slowly with stirring to a filtered solution of 125 g of ammonium rhodanilate in 750 ml of methanol and keep at 0 °C for 2 hours to allow the complete separation of proline rhodanilate. Filter off the latter, wash it with water and suck as dry as possible. Dissolve the damp crude product in 400 ml of methanol, filter and add 800 ml of 0.5 M hydrochloric acid slowly with stirring. Cool at 0 °C for 2 hours, filter off the purified proline rhodanilate and wash it with 250 ml of cold water. Dry the product in an oven at 50 °C; the yield is about 100 g, m.p. c. 130 °C, with preliminary softening and blackening.

Suspend the purified salt in 850 ml of water in a stoppered bottle, add 25 ml of pure pyridine and shake the mixture for 4–5 hours. Remove the insoluble pyridine rhodanilate by filtration and wash it with 100 ml of cold water (2). Combine the pale pink filtrate and washings, and add glacial acetic acid dropwise until the formation of a small pink precipitate is complete. Filter, evaporate the almost colourless filtrate to dryness (rotary evaporator) and suspend the residue in absolute ethanol and re-evaporate twice. Dry the resulting faintly pink crude proline in a vacuum desiccator over silica gel; the yield is about 18 g. Recrystallise from the minimum volume of absolute ethanol to obtain 11 g (7.3% based on gelatin) of L-proline, m.p. 218–219 °C (decomp.), $[\alpha]_D^{18} = -85.6^\circ$ (c 3.0 in H$_2$O). Check the purity of the product by t.l.c. on silica gel using the solvent system butan-1-ol-acetic acid–water, 4:1:1; $R_f$ 0.26 (yellow spot with ninhydrin).

Notes. (1) Remove about 0.25 ml of the hydrolysate, cool it and basify it with 5 M sodium hydroxide solution. To a portion add a few drops of very dilute copper(II) sulphate solution, and note the absence of any colour change. As a control, prepare a specimen of biuret (NH$_2$CO·NH·CO·NH$_2$) by heating about 10 mg of urea just above its melting point for about 2 minutes. Add a little basified hydrolysate warm to dissolve, cool and add a trace of copper(II) sulphate. A deep pink colour superimposed upon the pale brown colour of the hydrolysate should be observed. If the hydrolysate gives a similar colour originally, it contains peptide material and hydrolysis should be continued until the biuret test is negative.

(2) About 100 g of pyridine rhodanilate is obtained. To convert this into the ammonium salt for re-use, suspend it in 175 ml of methanol and add 90 ml of concentrated ammonia solution. Stir at 0 °C for 30 minutes and then dilute gradually with 900 ml of water. Filter off the precipitated ammonium salt, wash it with water and repeat the
methanol–ammonia treatment once more. The final yield of dried ammonium rhodanilate is about 80 g.

**Experiment 5.187 l-CYSTINE (3,3'-Dithiodialanine)**

\[
\text{Keratin (hair)} \xrightarrow{\text{hydrolysis}} [\text{S} \cdot \text{CH}_2 \cdot \text{CH(NH}_2)_2 \cdot \text{CO}_2 \text{H}]_2
\]

Place 500 g of washed, dried human hair (1) in a 3-litre round-bottomed flask and add 1 litre of a 1:1 mixture of concentrated hydrochloric acid and formic acid. Fit a reflux condenser and boil the mixture gently under reflux (fume cupboard) until the biuret test [Expt 5.186, Note (1)] is negative (about 20 hours). Treat the hydrolysate with about 12 g of acid-washed decolourising charcoal, filter hot and concentrate the filtrate to a thick syrup under reduced pressure using a rotary evaporator. Dissolve the residue in 250 ml of water and add with shaking warm 50 per cent aqueous sodium acetate until the solution is no longer acid to Congo red. Leave the mixture at room temperature for 3 days, and then filter off the precipitate of crude cystine and wash it with 50 ml of warm water. Dissolve the product in 750 ml of 1M hydrochloric acid, treat the hot solution with 5 g of acid-washed decolourising charcoal and filter. If the filtrate is more than faintly yellow, repeat the treatment with a further 5 g of charcoal. Neutralise the filtrate to Congo red and with sodium acetate solution as previously and leave at room temperature for 5–6 hours (2). Filter off the colourless plates of purified l-cystine, wash with two 50 ml portions of hot water, then with ethanol and finally with ether. The yield is about 25 g (5%); m.p. 260–262 °C (decomp.); \([\alpha]_D^0 -216° (c 0.69 \text{ in } 1 \text{ M HCl})\).

**Notes.** (1) Raw material can usually be obtained from barbers' shops. The washing procedure must remove effectively grease and natural oils. A warm aqueous solution of a good quality detergent is satisfactory; it is important that the washing medium should not be alkaline as this may markedly reduce the yield of cystine. Raw sheep's wool, adequately cleaned, may also be used as the starting material if available, but processed material (e.g. old woollen garments, etc.) may give poor yields. (2) The crude product contains some of the aromatic amino acid tyrosine which is present in the original hydrolysate. A portion of this is removed by the charcoal treatment and by the hot-water washing, but the final recrystallised cystine may be contaminated with tyrosine if the suggested 5–6 hour period for crystallisation is greatly exceeded.

\text{O} & \quad \text{NH} \\
\text{CO}_2 \text{H} & + \text{Ph} \cdot \text{Me} + \text{CO}_2
\end{align*}
\]

**CAUTION:** Benzyl chloroformate and ethyl chloroformate are highly lachrymatory and should be handled with great care in a fume cupboard; disposable plastic gloves should be worn.

**Glycine ethyl ester hydrochloride.** Esterify 15 g (0.2 mol) of glycine in 100 ml of absolute ethanol with the aid of about 10 g of dry hydrogen chloride in the manner described for the preparation of glycyglycine ethyl hydrochloride (Expt 8.38). Recrystallise the product from the minimum of absolute ethanol. The yield of glycine ethyl ester hydrochloride, m.p. 144 °C, is 18.5 g (66%).

**Benzyloxy carbonyl-L-proline.** Dissolve 4.6 g (0.04 mol) of L-proline (Expt 5.186) in 10 ml (0.04 mol) of 4 M hydroxide solution, cool to 0 °C in an ice bath, and add 7.0 g (0.041 mol) of benzyl chloroformate and 10 ml (0.04 mol) of 4 M sodium hydroxide solution alternately and portionwise, with shaking and cooling, during 30 minutes. Allow the mixture to warm to room temperature with intermittent shaking during 1 hour, extract with 2 × 15-ml portions of ether, and acidify the aqueous phase (Congo red) with dilute (1:1) hydrochloric acid. Extract the liberated oil with 4 × 10-ml portions of ether, dry over anhydrous sodium sulphate, and remove the ether to obtain 8.8 g (88%) of benzyloxy carbonyl-L-proline which crystallises slowly. A sample recrystallised from ether–light petroleum (b.p. 40–60 °C) has m.p. 75 °C.

**Benzyloxy carbonyl-L-prolylglycine.** Dissolve 6.2 g (25 mmol) of benzyloxy carbonyl-L-proline in 15 ml of dry chloroform containing 2.5 g (3.4 ml, 25 mmol) of dried redistilled triethylamine and cool the mixture in ice while adding 2.7 g (2.4 ml, 25 mmol) of ethyl chloroformate steadily and with shaking. Set the mixture aside at 0 °C for 15 minutes and then stir into the semi-solid mass a suspension of 3.5 g (25 mmol) of glycine ester hydrochloride in 20 ml of dry chloroform containing a further 2.5 g of dry triethylamine. Carbon dioxide is evolved and the solids go into solution. Set the mixture aside at room temperature for 30 minutes, warm at 50 °C for 10 minutes, and then wash it successively with 15 ml of water, 10 ml of 1 M hydrochloric acid, 2 × 10-ml portions of 0.5 M sodium hydrogen carbonate solution and 10 ml of water. Dry the solution over anhydrous sodium sulphate and remove the chloroform under reduced pressure to obtain 8.3 g (99%) of benzyloxy carbonyl-L-prolylglycine ethyl ester as an oil. Dissolve the entire product in a mixture of 26 ml of 1 M sodium hydroxide solution and 10 ml of acetone and set it aside at room temperature for 1 hour. Concentrate the solution somewhat under reduced pressure to remove most of the acetone and then acidify (Congo red) with dilute (1:1) hydrochloric acid. Extract the precipitated oil
with ethyl acetate, dry over anhydrous sodium sulphate and remove the solvent under reduced pressure. The resulting oil crystallises slowly on cooling and scratching under a small quantity of ethyl acetate. To recrystallise dissolve the product in the minimum of hot ethyl acetate, cool somewhat and add an equal volume of ether, and then seed and set aside overnight. The yield of benzyloxy carbonyl-L-prolyglycine, m.p. 122–123 °C, is 5.3 g (69%). A sample crystallised from water has m.p. 125 °C.

L-Prolyglycine. Dissolve 4.6 g (15 mmol) of the foregoing product in 75 ml of methanol and add 75 ml of water and 2 ml of glacial acetic acid. Place 0.4 g of palladium black (Section 4.2.54, p. 453) into a Drechsel bottle and add the above solution, taking care to rinse all traces of catalyst down below the surface of the liquid. Connect the Drechsel bottle inlet tube to a hydrogen cylinder and vent the exit tube to the external atmosphere or to a fume cupboard via a second Drechsel bottle charged with lime-water. Suspend the bottom of the inlet tube just above the surface of the liquid in the reaction bottle and pass in hydrogen to displace the air. Lower the Drechsel head to close the system and allow hydrogen to bubble through the reaction mixture at a rate sufficient to agitate the catalyst. Continue the passage of hydrogen for about 2 hours, shaking periodically. The onset of the reaction, accompanied by the liberation of carbon dioxide, is indicated by typical carbonate precipitation in the lime-water bubbler; continue to pass hydrogen until carbon dioxide evolution ceases (confirm using a fresh charge of lime-water). Then filter off the catalyst (CARE—pyrophoric when dry) and evaporate the solution to dryness under reduced pressure. Recrystallise the residue by dissolving it in the minimum of hot water, adding hot methanol and cooling. L-Prolyglycine is obtained as the monohydrate; yield 2.4 g (86%), m.p. 226–227 °C (decomp.), [α]D7 = 21.9 ° (c 3.9 in H2O). Check the homogeneity of the product by t.l.c. on silica gel using the system butan-1-ol–ethanol–acetic acid–water, 9:3:2:4; Rf 0.14.

5.15 NITROALKANES

Primary (R·CH₂·NO₂), and also secondary (R₂CH·NO₂), nitroalkanes exist in tautomeric equilibrium with the corresponding nitronic acids, the two species being interconvertible via the mesomerically stabilised α-carbanion. These nitroalkanes are therefore soluble in alkali.

\[
R \cdot CH₂ \cdot N = O \xrightarrow{H^+} \left[ \begin{array}{c} \text{R·CH = N} \\
\xrightarrow{H^+} \text{R·CH = N} \end{array} \right] \xrightarrow{\text{add H}^+} \text{R·CH = N·OH}
\]

Tertiary nitroalkanes (R₃C·NO₂) are neutral. The most important unsaturated analogues are the vinyl nitro compounds (e.g. R·CH = CH·NO₂). All these nitro compounds have in recent years become of great interest as versatile intermediates in organic synthesis.⁹ Some of these aspects are noted in Chapter 1, p. 21, in Section 5.7.7, p. 599, and in Section 5.9.3, p. 635, and are further exemplified in the following discussion.
Laboratory routes to the nitroalkanes (and nitroalkenes) include the following procedures.

1. The displacement of a halogen by a nitrite ion in an alkyl halide (Expt 5.189).
2. The oxidation of oximes and of primary amines (Expts 5.190 and 5.191).
3. C-Alkylation of nitroalkanes and other homologation procedures (Expt 5.192).

**SUMMARY OF RETROSYNTHETIC STRATEGIES**

Functional group interconversion (FGI) (method 2)

\[
\begin{align*}
R^1&\text{NOH} &\rightleftharpoons_{(2)} & R^1&\text{NO}_2 \\
(TM) & & & (TM) & \\
R^1&\text{NH}_2
\end{align*}
\]

Disconnection (methods 1 and 3)

\[
\begin{align*}
R^1&\text{NO}_2 \rightleftharpoons_{(i)} & R^1&\text{NO}_2 \\
(TM) & & & (TM) \\
R^1\cdot\text{CH}_2\cdot\text{NO}_2 + R^2X & \rightleftharpoons_{(ii)} & R^1&\text{R}^2\text{CHX} + \text{NaNO}_2 \\
R^1\text{R}^2\text{CHX} + \text{NaNO}_2 \rightleftharpoons_{(i)} & R^1&\text{NO}_2 \\
(TM) & & & (TM) \\
R^1&\text{NO}_2 \rightleftharpoons_{(iii)} & R^1&\text{CHO} + \text{MeNO}_2 \\

R^1&\text{CHO} + \text{MeNO}_2 \rightleftharpoons_{(ii)} & R^1&\text{R}^2\text{CHX} + \text{NaNO}_2
\end{align*}
\]

**SPECTROSCOPIC FEATURES**

The characteristic i.r. frequency for the nitro group is observed as twin absorptions which occur in the region of 1560 and 1388 cm\(^{-1}\) and are attributed to the asymmetric and symmetric stretching of the nitrogen–oxygen bonds respectively. The nitro group, being strongly electron withdrawing, causes the \(\alpha\)-protons in the alkyl group to be deshielded, and hence the signals occur in the \(\delta\) 4.4 region of the p.m.r spectrum (see Appendix 3). The structure of the alkyl group may be inferred from the spin–spin coupling patterns (cf. p. 341). Further illustrative and descriptive spectroscopic interpretations are given in some of the preparations below.

**5.15.1 THE DISPLACEMENT OF A HALOGEN BY A NITRITE ION IN AN ALKYL HALIDE**

Classically, primary nitroalkanes may be prepared by heating the alkyl bromide (or iodide) but not the chloride, with silver nitrite, frequently in anhydrous ether. The method is not satisfactory with secondary or tertiary halides, when the major products are the alkyl nitrites.
\[ \text{O} = \text{N} \rightarrow \text{O} \quad \text{R} \quad \text{Br} \quad \rightarrow \quad \text{R} \cdot \text{NO}_2 \quad + \quad \text{Br}^\ominus \]

This method is clearly expensive, and nowadays the cheaper sodium nitrite is employed with the alkyl halide in dimethyl sulfoxide or dimethylformamide as solvent.\(^1\)\(^9\)\(^7\) Although the yields are a little lower than in the silver nitrite method, a further feature is that secondary halides may be converted into secondary nitroalkanes, although even this modification fails with tertiary halides. The reaction is illustrated by the preparation of 2-nitrooctane (Expt 5.189).

This method offers therefore a means of preparation of primary and secondary nitroalkanes which then provides a facile route to primary amines (by reduction, Section 5.16.2, p. 774), aldehydes and ketones (the Nef reaction, Sections 5.7.7, p. 599, and 5.8.7, p. 623), and to the rapidly developing strategy of carbon–carbon bond construction by way of the mesomerically stabilised anions (Section 5.15.3, p. 768).

**Experiment 5.189 2-NITROOCTANE\(^1\)\(^9\)\(^7\)**

\[
\text{C}_6\text{H}_{13} \cdot \text{CHI} \cdot \text{Me} + \text{NaNO}_2 \xrightarrow{\text{DMSO}} \text{C}_6\text{H}_{13} \cdot \text{CH(NO}_2 \cdot \text{Me} + \text{NaI}
\]

**CAUTION:** Nitroalkanes should always be distilled in apparatus sited behind a safety screen.

2-Iodoctane (71.2 g, 0.30 ml) is poured into a stirred solution of 225 ml of dimethyl sulfoxide and 36 g of sodium nitrite (0.52 mol) contained in a 500-ml flask immersed in a water bath held at room temperature. Stirring is continued for 4 hours. The reaction mixture is poured into 600 ml of ice-water layered over with light petroleum (b.p. 35–37°C). After separation the aqueous phase is further extracted with four 100-ml portions of light petroleum. The combined organic extracts are washed with four 100-ml portions of water and dried over magnesium sulphate. The drying agent is removed by filtration and the light petroleum solution is distilled through a small fractionating column at atmospheric pressure, after which the residue is distilled under reduced pressure. The following fractions are obtained: (i) 14.0 g (30%) of 2-octyl nitrite, b.p. 32°C/2 mmHg, \(n^2_D\) 1.4089; (ii) 3.9 g, b.p. 53–56°C/1 mmHg, \(n^2_D\) 1.4111–1.4382; and (iii) 27 g (58%), b.p. 61°C/1 mmHg of 2-nitrooctane, \(n^2_D\) 1.4281.

**Cognate preparation. Nitrocyclopentane.** Use cyclopentyl bromide (22.0 g, 0.15 mol), sodium nitrite (18 g, 0.26 mol) and 100 ml of dimethyl sulfoxide; allow the reaction mixture to stir at 15°C for 3 hours. The product (9.9 g, 58%), b.p. 62°C/8 mmHg, \(n^2_D\) 1.4538, was isolated as above.

**5.15.2 THE OXIDATION OF OXIMES AND AMINES**

The oxidation of oximes offers an attractively simple route to nitroalkanes from carbonyl compounds. The most effective reagent is pertrifluoroacetic acid in acetonitrile in the presence of sodium hydrogen carbonate as a buffer. Yields are improved by the addition of small quantities of urea to remove oxides of nitrogen. The reaction is illustrated by the conversion of dipropyl ketoxime into 4-nitroheptane (Expt 5.190).
\[ R_2C=N^\text{OH} \xrightarrow{\text{IOl}} R_2C=N^\text{O} \xrightarrow{-H^+,+H^+} R_2CH\cdotN\equiv N^\text{O} \]

Since many aliphatic primary amines are usually prepared by methods not involving the reduction of a nitroalkane (cf. aromatic amines), their oxidation may provide a useful route to this class of compound. For amines which lead to tertiary nitroalkanes, potassium permanganate appears to be the most satisfactory reagent\(^{198}\) (the preparation of 2-nitro-2-methylpropane, Expt 5.191). In the case of amines which lead to primary or secondary nitroalkanes the oxidant of choice is m-chloroperbenzoic acid, and Expt 5.191 includes a general procedure for this reaction.\(^{199}\)

**Experiment 5.190 4-NITROHEPTANE**

\[(CF_3\cdotCO)_2O + H_2O_2 \rightarrow CF_3\cdotCO_2H + CF_3\cdotCO_2H\]

\[Pr_2C=O \xrightarrow{NH_2OH} Pr_2C=NOH \xrightarrow{\text{IOl}} Pr_2CH\cdotNO_2\]

CAUTION: The reactions involving hydrogen peroxide and pertrifluoroacetic acid should be carried out in a fume cupboard behind a safety screen. Adequate precautions should be observed in handling the hydrogen peroxide solution (1).

**Dipropyl ketoxime (heptan-4-one oxime).** Heat a mixture of 20 g (0.18 mol) of heptan-4-one, 17 g (0.25 mol) of hydroxylamine hydrochloride, 19.6 g (20 ml, 0.25 mol) of pyridine and 150 ml of ethanol under reflux for 1 hour in a 500-ml round-bottomed flask. Rearrange the condenser for downward distillation and remove the ethanol on the water bath. Allow the residue in the flask to cool and add 150 ml of water. Extract the oxime with three 50 ml portions of ether. Wash the combined extracts with water and dry over magnesium sulphate. Remove the ether on the rotary evaporator and distil the residue at atmospheric pressure. Collect the fraction having b.p. 192–195 °C; the yield is 18.2 g (80%). The oxime shows infrared absorptions at 3300 cm\(^{-1}\) (O−H stretch) and 1655 cm\(^{-1}\) (C=\text{N} stretch).

**4-Nitroheptane.** Prepare a solution of pertrifluoroacetic acid in acetonitrile as follows. Place 50 ml of acetonitrile in a two-necked, 250-ml round-bottomed flask fitted with a dropping funnel and a reflux condenser. Insert a plastic-covered magnetic stirrer follower bar and cool the flask in an ice bath sited on the stirrer unit. To the cooled and stirred solution add 5.8 ml (0.2 mol) of 85 per cent hydrogen peroxide (1) and then 39.0 ml (58.1 g, 0.24 mol) of trifluoroacetic anhydride. Stir the solution for 5 minutes and then allow to warm to room temperature. In a three-necked, 500-ml round-bottomed flask fitted with a sealed stirrer unit, dropping funnel and reflux condenser place 200 ml of acetonitrile, 47 g (0.56 mol) of sodium hydrogen carbonate, 2 g of urea and 12.9 g (0.1 mol) of dipropyl ketoxime. Heat the stirred suspension under reflux on the water bath and add dropwise over 90 minutes the prepared solution of pertrifluoroacetic acid. When the addition is complete heat the mixture under reflux for 1 hour. Pour the cooled reaction mixture into 600 ml of cold water and extract with four 100 ml portions of dichloromethane (note: the organic layer is the upper layer in the first extraction, but subsequently it is the lower layer). Wash the combined extracts with
three 100 ml portions of saturated sodium hydrogen carbonate solution and dry over magnesium sulphate. Remove the solvent on the rotary evaporator and distil the residue under reduced pressure through a short fractionating column packed with glass helices. Site the apparatus behind a safety screen. 4-Nitroheptane distils at 66–69 °C/2 mmHg; the yield is 8.4 g (58%). A small amount of dipropyl ketone is obtained as a forerun. The infrared spectrum of the nitroalkane shows absorption at 1555 and 1385 cm⁻¹ attributable to the antisymmetric and symmetric stretching of the nitro group. The purity of the product may be investigated by g.l.c. using a 10 per cent Silicone oil on Chromosorb W column held at 100 °C; the nitroalkane has a slightly shorter retention time than the oxime; the ketone is rapidly eluted from the column.

Note. (1) Considerable care should be exercised when carrying out reactions with 85 per cent w/v hydrogen peroxide (see also Section 4.2.41, p. 439). Rubber gloves and a face mask should be worn and reactions carried out behind a safety screen. Plenty of water should be at hand to wash away any spillages; fire may result if the peroxide is spilled on to combustible material. Any spillage on the skin similarly should be washed with plenty of water. Care should be taken to avoid the formation of potentially explosive emulsions with organic materials. Spirit thermometers and not mercury thermometers should be used; grease on taps and joints should be kept to the absolute minimum; safety pipettes must be used for pipetting. Disposal of high test peroxide solution may be effected by diluting with a large excess of water. The peroxide used in these experiments was supplied gratis by Interox Chemicals Ltd.

**Experiment 5.191 2-NITRO-2-METHYLPROPANE**$^{198}$

\[
\text{Me}_3\text{C}\cdot\text{NH}_2 \xrightarrow{\text{KMnO}_4} \text{Me}_3\text{C}\cdot\text{NO}_2
\]

**CAUTION:** All operations should be conducted behind a safety screen.

In the course of 15 minutes t-butyramine (1,1-dimethylolamime, 100 g) is added to a stirred solution of potassium permanganate (650 g) in 3 litres of water; the temperature rises to 45 °C. The stirring is continued for 8 hours without external heating, and the solution is then held at 55 ± 5 °C for a further 8 hours. The product is isolated by steam distillation and washed with dilute hydrochloric acid, then with water and dried. Distillation gives 117 g (83%) of the tertiary nitro compound, b.p. 127–128 °C, $n_D^\circ 1.3980$, m.p. 25–26 °C.

**Cognate preparation. General procedure for the oxidation of primary and secondary amines using m-chloroperbenzoic acid.**$^{199}$ m-Chloroperbenzoic acid (4.1 g, 0.020 mol, 85% pure) is dissolved in 30 ml of 1,2-dichoroethane in a three-necked flask equipped with a condenser and a pressure-equalising dropping funnel. The amine (0.0050 mol) in 3–5 ml of solvent is added drop-wise to the refluxing peracid solution. Refluxing temperature 83 °C, time 3 hours. After the addition the reaction mixture is cooled, filtered and washed with three 50-ml portions of 1 m sodium hydroxide solution and dried over magnesium sulphate. Removal of solvent gives a product which is distilled or recrystallised as appropriate. The following amines have been oxidised by this procedure: cyclohexylamine, 2-aminobutane, hexylamine, propylamine and 2-phenyl-1-aminoethane.
5.15.3 C-ALKYLATION OF NITROALKANES AND OTHER HOMOLOGATION PROCEDURES

Primary nitroalkanes when treated with two equivalents of butyllithium, in a mixed tetrahydrofuran–hexamethylphosphoramide solvent system held at −78 °C, may be doubly deprotonated to give the dilithio derivative (2) via the monolithio derivative (1).

\[
\text{R} \cdot \text{CH}_2\text{NO}_2 + \text{BuLi} \rightarrow \left[ \begin{array}{c} \text{R} \\ \text{N} \end{array} \right] \rightarrow \left[ \begin{array}{c} \text{R} \\ \text{N} \end{array} \right] \]

The dilithio derivative (2), in contrast to (1), may be C-alkylated or C-acylated to give homologous products.

An alternative and convenient α-alkylation reaction uses a 1-alkyl-2,4,6-triphenylpyridinium tetrafluoroborate with the monosodio derivative of a primary or secondary nitroalkane.

\[
\text{Ph} \cdot \text{N}^{+} \cdot \text{R}^{'} + \text{R}^{2} \cdot \text{R}^{3} \cdot \text{C} \cdot \text{NO}_2 \rightarrow \text{Ph} \cdot \text{N}^{+} \cdot \text{Ph} + \text{R}^{1} \cdot \text{R}^{2} \cdot \text{R}^{3} \cdot \text{C} \cdot \text{NO}_2
\]

The reaction is thought to proceed by a radical chain mechanism (\(S_{R\text{M}1}\)), probably first involving a charge transfer complex between cationic species (3) and the anionic species (4). The illustrative example is the synthesis of 2-phenylnitroethane from nitromethane and 1-benzyl-2,4,6-triphenylpyridinium tetrafluoroborate (Expt 5.192); this latter compound is prepared from benzylamine and 2,4,6-triphenylpyrylium tetrafluoroborate (Expt 8.31).

Other major homologation processes are the nitroaldol reaction, arising from the reaction between a nitronate anion and a carbonyl compound, and a Michael addition reaction.

\[
\text{R}^{1} \cdot \text{CH}_2 \cdot \text{NO}_2 + \text{R}^{2} \cdot \text{CHO} \rightarrow \text{R}^{1} \cdot \text{CH} \cdot \text{CH}(\text{OH}) \cdot \text{R}^{2} \quad \text{H}_2\text{O} \rightarrow \text{R}^{1} \cdot \text{C} = \text{CH} \cdot \text{R}^{2}
\]

\[
\text{R}^{1} \cdot \text{CH}_2 \cdot \text{NO}_2 + \text{CH}_2 = \text{CH} \cdot \text{CO}_2\text{Me} \rightarrow \text{R}^{1} \cdot \text{CH} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CO}_2\text{Me}
\]

Both reaction processes are base catalysed, and the use of alumina (Brockmann activity I) at room temperature is a particularly mild method leading to good yields of products.

The nitroaldol may be dehydrated to a nitroalkene; in the case of nitroaldols arising from aromatic aldehydes this dehydration reaction occurs spontaneously as is illustrated in the preparation of α-nitrostyrene (Expt 6.136). The nitroalkenes are important dienophiles in the Diels–Alder reaction (Section 7.6, p. 1117). An example of the Michael addition reaction is illustrated in the syn-
thesis of 1,4-dicarbonyl compounds (Section 5.9.3, p. 635) and γ-keto carboxylic acids (Section 5.14.3, p. 738); these examples exemplify the value of nitroalkanes as acyl anion equivalents.

Experiment 5.192 2-PHENYLNITROETHANE

\[
\begin{align*}
\text{Ph} & \text{CH} \quad \text{BF}_4^- \\
\text{Ph} & \text{O} \quad \text{Ph}
\end{align*}
\]

\[
\xrightarrow{\text{Ph-CH}_2 \cdot \text{NH}_2, \text{Ph}}
\]

\[
\begin{align*}
\text{Ph} & \text{CH} \quad \text{BF}_4^- \\
\text{Ph} & \text{CH}_2 \cdot \text{Ph}
\end{align*}
\]

\[
\xrightarrow{\text{MeNO}_2}
\]

\[
\begin{align*}
\text{Ph} & \text{CH}_2 \cdot \text{CH}_2 \cdot \text{NO}_2 + \\
\text{Ph} & \text{N} \quad \text{Ph}
\end{align*}
\]

Sodium hydride (0.72 g, 0.03 mol) is dissolved in ethanol (30 ml). Nitromethane (1.83 g, 0.030 mol) is added with stirring, followed by 1-benzyl-2,4,6-triphenylpyridinium tetrafluoroborate (Expt 8.31) (4.85 g, 0.01 mol). The solution is refluxed with stirring for 1 hour; the reaction is followed by t.l.c. (silica gel; chloroform). When no further pyridinium compound remains, the solution is cooled; the resulting crystalline by-product 2,4,6-triphenylpyridine is filtered off. The filtrate is added to water (50 ml), extracted with ether (3 x 25 ml) and the extract dried over magnesium sulphate. Dry hydrogen chloride is passed into the ethereal extract to remove residual 2,4,6-triphenylpyridine, and the solution is evaporated under reduced pressure (25 °C/15 mmHg). The crude product is distilled in vacuo (15 mmHg) to yield 2-phenylnitroethane, b.p. 120-130°C/15 mmHg, yield 78 per cent, pure by g.l.c. (Carbowax 220M, 200°C); p.m.r. (CDCl₃, TMS) δ 3.45 (t, 2H), 4.75 (t, 2H), and 7.50 (s, 5H).

5.16 ALIPHATIC AMINES

Amines are classified as primary (RNH₂), secondary (R₂NH), or tertiary (R₃N). The alkyl groups in secondary and tertiary amines can of course be the same or different. These latter classes of amines are usually prepared by alkylation at a nitrogen atom, as is also the case with quaternary ammonium salts (R₄N⁺X⁻). Quaternary ammonium salts having four different alkyl groups are chiral; tertiary amines with three different groups, although chiral, undergo rapid pyramidal inversion and hence automerisation, and enantiomeric forms are not isolable. Chirality in amines may arise from the presence of a chiral carbon atom in an alkyl chain (e.g. (+)-Ph-CH(NH₂)-Me).

Imines (e.g. R-CH₂-CH=N-R or R-CH₂-C(R)=N-R) are derived from the reaction of primary amines with aldehydes or ketones respectively, and may exist in tautomeric equilibrium with the corresponding enamine form, but in which the imine form predominates.
The reaction of carbonyl compounds with secondary amines gives the stable enamine form.

\[
\text{R-CH}_2\text{-CHO} + \text{HNR}_2 \rightarrow [\text{R-CH}_2\text{-CH(OH)-NR}_2]^+ \xrightarrow{\text{H}_2\text{O}} \text{R-CH=CH-NR}_2
\]

\[
\text{R-CH}_2\text{-CO-R} + \text{HNR}_2 \rightarrow [\text{R-CH}_2\text{-CR(OH)-NR}_2]^+ \xrightarrow{\text{H}_2\text{O}} \text{R-CH=C(R)-NR}_2
\]

The most important general methods for the preparation of aliphatic amines are as follows.

1. The reduction of alkyl azides, alkyl cyanides and amides (Expts 5.193 to 5.195).
2. The reduction of nitro compounds and oximes (Expt 5.196).
3. The reductive alkylation of ammonia or amines (Expt 5.197).
4. The alkylation of ammonia and its derivatives (Expts 5.198 and 5.199).
5. Imine and enamine formation (Expt 5.200 and 5.201).

Methods for the protection of the amino and imino groups are considered in Section 5.16.7, p. 784.

**SUMMARY OF RETROSYNTHETIC STRATEGIES**

**Functional group interconversion (FGI) (methods 1 and 2)**

**Primary amines**

\[
\text{R-CN} \xleftrightarrow{\text{TM}} \text{R-NH}_2 \xrightarrow{\text{TM}} \text{R-NH} \xrightarrow{\text{H}_2\text{O}} \text{R-O}
\]

\[
\text{R}^1\text{R}^2 \xleftrightarrow{\text{TM}} \text{R}^1\text{R}^2 \xrightarrow{\text{TM}} \text{R}^1\text{R}^2 \xrightarrow{\text{TM}} \text{R}^1\text{R}^2
\]

**Secondary and tertiary amines**

\[
\text{R}^1\text{NHR}_2 \xrightarrow{\text{TM}} \text{R}^1\text{NHR}_2 \xrightarrow{\text{TM}} \text{R}^1\text{NHR}_2 \xrightarrow{\text{TM}} \text{R}^1\text{NR}_2
\]
C–N Disconnection (method 4)

**Primary amines**

\[
\begin{align*}
R^1 & \text{-} \text{NH}_2 \quad \rightarrow \quad R^1 \text{-} \text{Br} + \text{[N-CN]}^{2\ominus} \text{Na}_2 \\
\text{(TM)} & \quad \text{(4)}
\end{align*}
\]

**Secondary amines**

\[
\begin{align*}
R^1 & \text{-} \text{NH}_2 \quad \rightarrow \quad 2 \left[ R^1 \text{-} \text{CH}_2 \right]^{2\ominus} \text{NH} \quad \rightarrow \quad R^1 \text{-} \text{Br} + \text{[N-CN]}^{2\ominus} \text{Na}_2 \\
\text{(TM)} & \quad \text{(4)}
\end{align*}
\]

FGI/C—N Disconnection (method 3)

\[
\begin{align*}
R^1 & \text{-} \text{NH}_3 \quad \text{FGI} \quad \rightarrow \quad R^1 \text{-} \text{Br} + \text{[N-CN]}^{2\ominus} \text{Na}_2 \\
\text{(TM)} & \quad \text{(3)}
\end{align*}
\]

**Rearrangement (method 6)**

\[
\begin{align*}
R^1 & \text{-} \text{NH}_2 \quad \rightarrow \quad \left[ R^1 \text{-} \text{N} \equiv \text{C} \equiv \text{O} \right] \quad \rightarrow \quad \left[ R^1 \text{-} \text{N} \equiv \text{C} \equiv \text{O} \right] \quad \rightarrow \quad R^1 \text{-} \text{NH}_2
\end{align*}
\]

**SPECTROSCOPIC FEATURES**

The characteristic i.r. absorption of the stretching vibration of the amino and imino groups of primary and secondary amines is clearly visible in the region of 3300 cm\(^{-1}\); the bending vibration and the out-of-plane deformation of the amino group are usually easily recognised, as the example of the spectrum of butylamine (Fig. 3.26) illustrates. The nitrogen-bound protons are frequently observed as broad signals in the p.m.r. spectrum of primary and secondary amines and their ready exchange with, for example, deuterium oxide is discussed on p. 348. The structure of the alkyl groups may be often assigned from the spin–spin splitting patterns (p. 341). In the m.s. of aliphatic amines the molecular ion is usually very weak or negligible (p. 368). The fragmentation reactions are noted in detail on p. 381 where the spectrum of diethylamine (Fig. 3.87) is given. The u.v.–visible absorption is not structurally informative. Further illustrative spectroscopic interpretations are given in appropriate preparative sections below.

**5.16.1 THE REDUCTION OF ALKYL AZIDES, ALKYL CYANIDES AND AMIDES**

As these compounds all possess a nitrogen-containing functional feature, it is worth pointing out that they arise from alkyl halides (or methanesulphonates) in the case of azides and cyanides, or from carboxylic acid chlorides (in the case of amides).
A one-pot PTC reaction procedure for the overall conversion of an alkyl halide into a primary amine via an azide is particularly illustrative. Thus the reduction of the azide is effected by the addition of sodium borohydride to a reaction mixture arising from the PTC displacement reaction of an alkyl halide with sodium azide (the preparation of 1-octylamine, Expt 5.193). The reaction appears to be applicable to primary and secondary alkyl halides, alkyl methanesulphonates and benzylic halides.

Alkyl cyanides in general are smoothly reduced to primary amines (giving a product having one carbon atom more than the alkyl halide starting material) by the action of sodium and ethanol (e.g. the preparation of pentylamine, Expt 5.194). The use of a metal–acid reducing medium is unsatisfactory since extensive hydrolysis of the cyano group occurs. Catalytic hydrogenation over a Raney nickel catalyst (Section 2.17.1, p. 87), in the presence of excess ammonia to suppress secondary amine formation, is illustrated by the preparation of 2-phenylethylamine (cognate preparation in Expt 5.194). The secondary amine may be formed by the following sequence.

\[
\begin{align*}
R\cdot\text{CN} & \rightarrow [R\cdot\text{CH} = \text{NH}] \rightarrow R\cdot\text{CH}_2\cdot\text{NH}_2 \\
R\cdot\text{CH} = \text{NH} & \xrightarrow{\text{R} \cdot \text{CH}_2\text{NH}_2} R\cdot\text{CH}_2\cdot\text{NH}_2 \xrightarrow{-\text{NH}_2} R\cdot\text{CH} \xrightarrow{\text{NH}} (R\cdot\text{CH}_2)_2\text{NH}
\end{align*}
\]

Lithium aluminium hydride has also been used for the reduction of nitriles to amines; a recommended procedure involves the slow addition of the nitrile to at least one molar proportion of the reducing agent in a cooled ethereal solution. The reduction of nitriles is also effected by the use of sodium trifluoroacetoxylborohydride (from sodium borohydride and trifluoroacetic acid) in tetrahydrofuran solution.

Amides may be reduced to the corresponding primary, secondary and tertiary amines with lithium aluminium hydride with a varying degree of success. The reagent sodium acetoxyborohydride (1) has been used to reduce a wide range of aliphatic and aromatic primary and secondary amides to the corresponding primary and secondary amines; in the case of tertiary amides (R·CO·NR₂) sodium trifluoroacetoxylborohydride is the reagent of choice. Amides may be reduced to the corresponding primary, secondary and tertiary amines with lithium aluminium hydride with a varying degree of success. The reagent sodium acetoxyborohydride (1) has been used to reduce a wide range of aliphatic and aromatic primary and secondary amides to the corresponding primary and secondary amines; in the case of tertiary amides (R·CO·NR₂) sodium trifluoroacetoxylborohydride is the reagent of choice. Amides may be reduced to the corresponding primary, secondary and tertiary amines with lithium aluminium hydride with a varying degree of success. The reagent sodium acetoxyborohydride (1) has been used to reduce a wide range of aliphatic and aromatic primary and secondary amides to the corresponding primary and secondary amines; in the case of tertiary amides (R·CO·NR₂) sodium trifluoroacetoxylborohydride is the reagent of choice.

\[
\begin{align*}
\text{Me} \cdot \text{CO}_2\text{H} + \text{NaBH}_4 & \rightarrow \text{NaBH}_3(\text{O} \cdot \text{CO} \cdot \text{Me}) \\
(1) \quad \text{R} \cdot \text{CO} \cdot \text{NH} \cdot \text{R}^2 + (1) & \rightarrow \text{R} \cdot \text{CH}_2 \cdot \text{NH} \cdot \text{R}^2
\end{align*}
\]

The reduction of benzamide to benzylamine is the illustrative example (Expt 5.195). Sodium borohydride with methanesulphonic acid is also a convenient and effective reductant for amides, and a general procedure is included in Expt 5.195.

**Experiment 5.193 OCTYLAMINE**

\[
\begin{align*}
\text{C}_6\text{H}_{13} \cdot \text{Br} & \xrightarrow{\text{NaN}_3 \text{ PTC}} \text{C}_6\text{H}_{13} \cdot \text{N}_3 \\
(\text{NaBH}_4 \text{ PTC}) & \rightarrow \text{C}_6\text{H}_{13} \cdot \text{NH}_2
\end{align*}
\]

A mixture of 1-bromo-octane (19.3 g, 0.1 mol), hexadecyltributylphosphonium bromide (5.1 g, 0.01 mol), sodium azide (16.2 g, 0.25 mol) and water (50 ml) is stirred at 80 °C for 8 hours. The aqueous phase is carefully removed,
the organic phase is diluted with toluene (15.5 ml), and then a solution of sodium borohydride (11.7 g, 0.3 mol) in water (30 ml) is added in 30 minutes. The mixture is stirred at 80 °C for 16 hours. The layers are separated and the organic phase is extracted with 10 per cent hydrochloric acid. The catalyst is recovered from the organic phase by removal of the solvent and is reused as isolated. Basification of the acid phase and extraction with ether affords octylamine, 11.4 g (88%), b.p. 172–174 °C.

**Experiment 5.194 PENTYLAMINE**

\[
\text{Pr-CH}_2\cdot\text{CN} \xrightarrow{\text{4HI}} \text{Pr-CH}_2\cdot\text{CH}_2\cdot\text{NH}_2
\]

Equip a three-necked 1-litre flask with a dropping funnel, an efficient mechanical stirrer and a reflux condenser. Place 55 g (2.4 mol) of clean sodium and 200 ml of sodium-dried toluene in the flask, heat the mixture until the toluene commences to boil and then stir the molten sodium vigorously thus producing an emulsion. Run in through the dropping funnel a mixture of 33 g (41.5 ml) of butyl cyanide (Expt 5.158) and 60 g (76 ml) of absolute ethanol during 1 hour. During the addition and the subsequent introduction of ethanol and of water, the stirring should be vigorous and the temperature adjusted so that the refluxing is continuous; the heat of reaction will, in general, be sufficient to maintain the refluxing. After the butyl cyanide solution has been added, introduce gradually a further 60 g (76 ml) of absolute ethanol. In order to destroy any residual sodium, treat the reaction mixture slowly with 40 g (50 ml) of rectified spirit and then with 20 g of water. Steam distil the contents of the flask (compare Fig. 2.102) (about 2 hours) and add 40 ml of concentrated hydrochloric acid to the distillate. Separate the toluene layer; evaporate the aqueous layer, which contains alcohol and amine hydrochloride, to dryness under reduced pressure (rotary evaporator). Treat the resulting amine hydrochloride with a solution of 40 g of sodium hydroxide in 200 ml of water. Separate the amine layer, dry it by shaking with sodium hydroxide pellets (prolonged contact is required for complete drying) and distil. Collect the fraction boiling at 102–105 °C as pure pentylamine. Dry the fraction of low boiling point again over sodium hydroxide and redistil; this gives an additional quantity of amine. The total yield is 30 g (86%).

**Cognate preparation. 2-Phenylethylamine.** Saturate commercial absolute methanol with ammonia (derived from a cylinder) at 0 °C; the resulting solution is c. 10 m. Dissolve 58 g (0.5 mol) of benzyl cyanide (Expt 5.157) (1) in 300 ml of the cold methanolic ammonia, and place the solution in a high-pressure hydrogenation bomb (Section 2.17.1, p. 95), add 10 ml of settled Raney nickel catalyst (Section 4.2.50, p. 450), securely fasten the cap and introduce hydrogen until the pressure is 500–1000 lb. Set the mechanical stirring device in motion, and heat at 100–125 °C until absorption of hydrogen ceases (about 2 hours). Allow the bomb to cool, open it and remove the contents. Rinse the bomb with two 100 ml portions of anhydrous methanol and pour the combined liquids through a fluted filter paper to remove the catalyst; do not permit the catalyst to become dry since it is likely to ignite. Remove the solvent and ammonia by distillation (fume cupboard), and fractionate the residue through a short column. Collect the 2-phenylethylamine at 92–93 °C/18 mmHg. The yield is 54 g (90%).
Note. (1) Minute amounts of halide have a powerful poisoning effect upon the catalyst; it is advisable to distil the benzyl cyanide from Raney nickel.

Experiment 5.195 BENZYLAMINE\(^{207}\)

\[
\text{Ph} \cdot \text{CONH}_2 \xrightarrow{\text{NaBH}_4(\text{O} \cdot \text{CO} \cdot \text{Me})} \text{Ph} \cdot \text{CH}_2 \cdot \text{NH}_2
\]

**CAUTION:** *Hydrogen gas is evolved in these reactions.*

To a stirred suspension of sodium borohydride (1.89 g, 50 mmol) and benzamide (1.21, 10 mmol) in dioxane (20 ml) is added acetic acid (3.0 g, 50 mmol) in dioxane (10 ml) over a period of 10 minutes at 10 °C; the reaction mixture is stirred at reflux for 2 hours. The reaction mixture is concentrated to dryness *in vacuo*, excess reagent is decomposed with water and the solution extracted with chloroform. The extract is washed with water and dried over anhydrous sodium sulphate. The chloroform layer is treated with dry hydrogen chloride, evaporated *in vacuo* and the residue recrystallised from methanol–ether to give benzylamine hydrochloride (1.09 g, 76.2%).

**Cognate preparation. General procedure for the reduction of amides with sodium borohydride/methanesulphonic acid in dimethyl sulfoxide.**\(^{208}\) To a vented 100-ml two-necked flask equipped with a magnetic stirrer, are added 16 mmol of amide, 1.61 g (40 mmol) of sodium borohydride, and 20 ml of dimethyl sulphoxide. Methanesulphonic acid (CAUTION) (freshly distilled prior to use, b.p. 112–114 °C/0.5 mmHg) (3.4 ml, 55 mmol) and 20 ml of dimethyl sulfoxide are mixed and added dropwise to the reaction mixture by means of an addition funnel over a 30-minute period. During this addition the reaction mixture is constantly stirred with the magnetic stirrer. Gas is evolved during the addition of acid and a gelatinous substance is formed, which dissolves when the acid comes to exceed the sodium borohydride on a molar basis. At the end of this time, if the reduction product is to be a primary or secondary amine, the reaction mixture is quenched by the addition of 20 ml of 10 per cent sodium hydroxide. If the product is to be a tertiary amine, the reaction mixture is kept at 70 °C for 2 hours to liberate the product from what appears to be a complex with borane. After this additional reaction period tertiary amines are isolated in the same way as primary and secondary amines. After the reaction is quenched, the product is extracted from the reaction mixture with three 10-ml portions of dichloromethane. The product solution is then washed with three 10-ml portions of 0.1 M sodium hydroxide to remove most of the residual dimethyl sulfoxide, and the product is extracted into three 10-ml portions of 10 per cent hydrochloric acid. Neutralisation with 10 per cent sodium hydroxide, followed by extraction with three 10-ml portions of dichloromethane, drying over calcium sulphate and fractional distillation affords the amine. In this way hexanamide gives hexylamine, b.p. 38–40 °C/25 mmHg, 74 per cent yield; acetonilide gives N-ethylaniline, b.p. 90–91 °C/15 mmHg, 77 per cent yield; N,N-dimethylbenzamide gives N,N-dimethylbenzylamine, b.p. 73–77 °C/22 mmHg, 59 per cent yield.

**5.16.2 THE REDUCTION OF NITRO COMPOUNDS AND OXIMES**

These methods are particularly useful for branched chain primary amines.
Although the reduction of nitro compounds is more widely applied in the aromatic series using procedures discussed in Section 6.5.1, p. 890, these are equally applicable to the reduction of primary or secondary nitroalkanes when these are readily available. \(\alpha,\beta\)- Unsaturated nitro compounds (arising for example from the Claisen–Schmidt reaction, Section 6.12.2, p. 1032) may be reduced to the saturated amine very effectively with sodium dihydrobis(2-methoxyethoxy)aluminate (‘Red-Al’).

The ready conversion of aldehydes and ketones into oximes and their subsequent reduction is more generally applicable to the synthesis of straight and branched chain primary aliphatic amines. Reduction with sodium and alcohol is convenient and effective and two examples of its use are given in Expt 5.196.

\[
\begin{align*}
\text{RNOH} & \quad \rightarrow \quad \text{R}^\prime\text{NH}_2 \\
\text{R}^2\text{NOH} & \quad \rightarrow \quad \text{R}^2\text{NH}_2
\end{align*}
\]

Other methods of reduction include the use of metal–acid systems, catalytic hydrogenation over Raney nickel or palladium-on-charcoal, and modified metal hydride reducing agents such as ‘Red-Al’.

**Experiment 5.196 HEPTYLAMINE**

\[
\text{Me} \cdot (\text{CH}_2)_5 \cdot \text{CH} = \text{NOH} \xrightarrow{[\text{HI}]} \text{Me} \cdot (\text{CH}_2)_5 \cdot \text{CH}_2 \cdot \text{NH}_2
\]

**Heptaldoxime.** Fit a 1-litre three-necked flask with an efficient mechanical stirrer, a double surface condenser and a thermometer. Place 115 g (141 ml, 1.25 mol) of heptanal (1) and a solution of 87 g of hydroxylamine hydrochloride in 150 ml of water in the flask, and stir the mixture vigorously (2). Introduce, from a separatory funnel down the reflux condenser, a solution of 67 g (0.63 mol) of anhydrous sodium carbonate in 250 ml of water at such a rate that the temperature of the reaction mixture does not rise above 45 °C. Continue the stirring for 1 hour at room temperature. Separate the upper layer and wash the oil with two 25 ml portions of water; dry with magnesium sulphate. Distil from a flask fitted with a short fractionating column. A small fraction of low boiling point (containing heptanenitrile and heptaldoxime) passes over first, and as soon as the temperature is constant the heptaldoxime is collected (e.g. at 103–107 °C/6 mmHg); the temperature of the oil bath is maintained at about 30 °C above the boiling point of the liquid. The yield is about 110 g, and the liquid slowly solidifies on cooling and melts at 44–46 °C; it is sufficiently pure for conversion into heptylamine. If required pure, the heptaldoxime may be recrystallised from 60 per cent ethanol (25 g of solid to 70 ml of solvent) and then melts at 53–55 °C (the m.p. depends somewhat upon the rate of heating).

**Heptylamine.** In a 3-litre round-bottomed flask, equipped with two large Liebig condensers (34/35 joints) joined in series, place a solution of 64.5 g (0.5 mol) of heptaldoxime in 1 litre of super-dry ethanol (Section 4.1.9, p. 401) and heat on a water bath. Immediately the alcohol boils, remove the flask from the water bath and introduce 125 g (5.4 mol) of sodium, cut in small pieces, as rapidly as possible through the condenser consistent with keeping the vigorous reaction under control. The last 30 g of sodium melts in the hot mixture and may be added very rapidly without appreciable loss of alcohol or
of amine. As soon as the sodium has completely dissolved (some warming may be necessary), cool the contents of the flask and dilute with 1250 ml of water. At once equip the flask with a condenser set for downward distillation and arrange for the distillate to be collected in a solution of 75 ml of concentrated hydrochloric acid in 75 ml of water contained in a 3-litre flask. Continue the distillation as long as amine passes over. Towards the end of the reaction considerable frothing sets in; then add a further 750 ml of water to the distillation flask. The total distillate is 2–2.2 litres and contains alcohol, water and some unreacted oxime as well as the amine hydrochloride. Evaporate the solution under reduced pressure using a rotary evaporator; the amine hydrochloride will crystallise out in the flask. Cool the flask, attach a reflux condenser and introduce 250 ml of 40 per cent potassium hydroxide solution. Rotate the flask to wash down the hydrochloride from the sides of the flask, cool the mixture to room temperature and transfer it to a separatory funnel. Run off the lower alkaline layer and add solid potassium hydroxide to the amine in the funnel. Again remove the lower aqueous layer, add more solid potassium hydroxide and repeat the process until no further separation of an aqueous layer occurs. Finally, transfer the amine to a small flask and leave it in contact with potassium hydroxide pellets for 24 hours. Decant the amine into a flask and distil through a well-lagged fractionating column. Collect the heptylamine at 153–157 °C. The yield is 40 g (70%).

Notes. (1) The heptanal should be dried and redistilled: b.p. 150–156 °C or 54–59 °C/16 mmHg.
(2) The solution may be rendered homogeneous by the addition of ethanol but the yield appears to be slightly diminished and more high boiling point material is produced.

Cognate preparation. Hexyl methyl ketoxime. From hexyl methyl ketone (octan-2-one) (Expt 5.86) in 90 per cent yield; b.p. 106–108 °C/12 mmHg.

1-Methylheptylamine. Reflux a solution of 50 g (0.35 mol) of the oxime in 200 ml of super-dry ethanol on a water bath while adding 75 g (3.25 mol) of sodium; introduce more alcohol (about 300 ml) to maintain a vigorous reaction. When all the sodium has passed into solution, cool, dilute with 250 ml of water and distil gently until the b.p. reaches 96 °C; add a further 200 ml of water and repeat the distillation to ensure the complete removal of the alcohol. The amine remains as a layer on the strongly alkaline solution: extract it with ether, dry the ethereal solution with sodium hydroxide or anhydrous calcium sulphate, remove the ether on a water bath, and distil the residue under diminished pressure. Collect the 1-methylheptylamine at 58–59 °C/13 mmHg; the b.p. under atmospheric pressure is 163–164 °C. The yield is 31 g (69%).

5.16.3 REDUCTIVE ALKYLATION OF AMMONIA OR AMINES

The process of reductive alkylation involves the treatment of ammonia or primary or secondary amines with an aldehyde or ketone under reducing conditions.

The conversion in the case of ammonia or primary amines and a carbonyl compound probably involves the following stages.
A retrosynthetic analysis for a target molecule of either a primary or secondary amine is therefore a two-stage process; first an FGI to reveal an imine, and then a disconnection to ammonia (or primary amine) and the carbonyl compound.

When secondary amines are used the intermediate aminol cannot give rise to an imine and the tertiary amine product is formed by a hydrogenolytic pathway.

The reduction is usually effected catalytically in ethanol solution using hydrogen under pressure in the presence of Raney nickel. As in the reduction of nitriles (Section 5.16.1, p. 771), which also involves the intermediate imine, ammonia or the amines should be present in considerable excess to minimise the occurrence of undesirable side reactions leading to the formation of secondary and tertiary amines. These arise from the further reaction of the carbonyl compound with the initially formed amine product. Selected experimental conditions for these reductive alkylation procedures have been well reviewed. Sodium borohydride has also been used as an in situ reducing agent and is particularly effective with mixtures of primary amines and aliphatic aldehydes and ketones.

A major variation is the use of formic acid or one of its derivatives as the reductant (the Leuckart reaction). In the synthesis of 1-phenylethylamine (Expt 5.197), ammonium formate is heated with acetophenone while the water formed in the reaction is carefully removed by fractional distillation to give the required amine as its N-formyl derivative, (1-phenylethyl)formamide. This is then hydrolysed with acid to yield the primary amine. The procedure has been satisfactorily applied to many aliphatic–aromatic, alicyclic and aliphatic–heterocyclic ketones, some aromatic ketones and aldehydes, and to some aliphatic aldehydes and ketones boiling at about 100 °C or higher.
Experiment 5.197 1-PHENYLETHYLAMINE (α-Methylbenzylamine)

\[
\text{Ph}+2\text{HCO}_2\text{NH}_4 \rightarrow \text{NH}\cdot\text{CHO}
\]

Place 126 g (2.0 mol) of ammonium formate, 72 g (0.6 mol) of acetophenone and a few chips of porous porcelain in a 250-ml flask fitted with a Claisen still-head carrying a short fractionating column; insert a thermometer extending nearly to the bottom of the flask, and attach a short condenser set for downward distillation to the side-arm. Heat the flask with a heating mantle or in an air bath; the mixture first melts to two layers and distillation occurs. The mixture becomes homogeneous at 150–155 °C and reaction takes place with slight frothing. Continue the heating, more slowly if necessary, until the temperature rises to 185 °C (about 2 hours); acetophenone, water and ammonium carbonate distil. Stop the heating at 185 °C, separate the upper layer of acetophenone from the distillate and return it without drying to the flask. Heat the mixture for 3 hours at 180–185 °C and then allow to cool; the acetophenone may be recovered from the distillate by extraction with 20 ml portions of toluene (1). Transfer the reaction mixture to a 250-ml separatory funnel and shake it with two 75 ml portions of water to remove formamide and ammonium formate. Transfer the crude (1-phenylethyl)formamide into the original reaction flask; extract the aqueous layer with two 20 ml portions of toluene, transfer the toluene extracts to the flask, add 75 ml of concentrated hydrochloric acid and a few chips of porous porcelain. Heat the mixture cautiously until about 40 ml of toluene are collected, and boil gently under reflux for a further 40 minutes; hydrolysis proceeds rapidly to 1-phenylethylamine hydrochloride except for a small layer of unchanged acetophenone. Allow the reaction mixture to cool, remove the acetophenone by extraction with four 20 ml portions of toluene (1). Transfer the aqueous acid solution to a 500-ml round-bottomed flask equipped for steam distillation, cautiously add a solution of 6.5 g of sodium hydroxide in 125 ml of water, and steam distil; heat the distillation flask so that the volume remains nearly constant. Most of the amine is contained in the first 500 ml of distillate; stop the operation when the distillate is only faintly alkaline. Extract the distillate with five 25 ml portions of toluene, dry the extract with sodium hydroxide pellets and fractionally distil (2). Toluene distils over at 111 °C, followed by the phenylethylamine. Collect the latter as a fraction of b.p. 180–190 °C (the bulk of the product distils at 184–186 °C (3); the yield is 43 g (59%).

Notes. (1) The acetophenone may be recovered by washing the toluene solution with dilute alkali, drying with anhydrous calcium sulphate and distilling; the fraction, b.p. 198–205 °C, is collected.
(2) Ground glass apparatus must be used as the amine attacks rubber (and cork). Since the product absorbs carbon dioxide from the air, attach the receiving flask to the condenser with a take-off adapter carrying a soda-lime guard-tube.
(3) The b.p. under diminished pressure is 80–81 °C/18 mmHg. To obtain a very pure sample of the amine, dissolve 1 part (by weight) of the above product in a solution of 1.04 parts of crystallised oxalic acid in 8 parts of hot water, add a little decolourising
carbon and filter. The filtered solution deposits crystals of the oxalate salt; about 5 g of this salt remains in each 100 ml of mother-liquor, but most can be recovered by evaporation and further crystallisation. The amine may be liberated from its oxalate salt with sodium or potassium hydroxide, steam distillation and purification as described above. The salt provides a convenient method of obtaining a known weight of the amine in water, since it can be weighed out and decomposed with alkali hydroxide.

5.16.4 THE ALKYLATION OF AMMONIA AND ITS DERIVATIVES

A C—N disconnection of a primary amine gives rise to the carbocation and amide anion synthons. It might be predicted therefore that treatment of an alkyl halide with ammonia (reagents equivalent to the above synthons) under pressure would constitute a suitable synthesis of a primary amine. In practice, however, the yield is poor since a mixture of all three classes of amines, together with some of the quaternary ammonium salt, is obtained, owing to more ready further alkylation of the sequentially formed products.

\[
\begin{align*}
RX + NH_3 & \leftrightarrow R\text{NH}_3\text{X} \leftrightarrow \text{RNH}_2 + NH_4X \\

RX + R_3\text{N} & \leftrightarrow R_4\text{NX}
\end{align*}
\]

A similar ammonolysis of alcohols in the presence of certain metallic oxide catalysts is, however, extensively used on the large scale for the manufacture of all classes of amines.

An alternative reagent equivalent for the amide anion synthon is the potassium salt of phthalimide which can only react with one molecular proportion of alkyl halide. The resulting N-alkylphthalimide is then cleaved to the primary amine (the Gabriel synthesis). The preliminary preparation of potassium phthalimide (from a solution of phthalimide in absolute ethanol and potassium hydroxide in 75% ethanol) may be avoided in some cases by boiling phthalimide with the halide in the presence of anhydrous potassium carbonate. The cleavage of the N-substituted phthalimide is best effected by reaction with hydrazine hydrate and then heating the reaction mixture with hydrochloric acid. The insoluble phthalhydrazide is filtered off, leaving the amine hydrochloride in solution from which the amine may be liberated and isolated in the appropriate manner.
The Gabriel synthesis is illustrated by the preparation of benzylamine and 2-phenylethylamine (Expt 5.198).

The preparation of pure symmetrical secondary amines (e.g. dibutylamine, Expt 5.199) is conveniently achieved by the hydrolysis of dialkylcyanamides with dilute sulphuric acid. The appropriate dialkyl cyanamide is prepared by treating sodium cyanamide (itself obtained from calcium cyanamide and aqueous sodium hydroxide solution) with an alkyl halide. In this case the reagent \([\text{:\text{N}—C≡N}]^{2-}\) may be regarded as a masked NH group.

\[

\end{align*}
\]

*N-Benzyllphthalimide.* Grind together 76 g (0.55 mol) of finely powdered, anhydrous potassium carbonate and 147 g (1 mol) of phthalimide (Expt 6.155) in a glass mortar, transfer the mixture to a round-bottomed flask and treat it with 151 g (1.2 mol) of redistilled benzyl chloride. Heat in an oil bath at 190 °C under a reflux condenser for 3 hours. While the mixture is still hot, remove the excess of benzyl chloride by steam distillation. The benzylphthalimide commences to crystallise near the end of the steam distillation. At this point, cool the mixture rapidly with vigorous swirling so that the solid is obtained in a fine state of division. Filter the solid with suction on a Buchner funnel, wash well with water and drain as completely as possible; then wash once with 200 ml of 60 per cent ethanol and drain again. The yield of crude product, m.p. 100–110°C, is 180 g (76%). Recrystallise from glacial acetic acid to obtain pure benzylphthalimide, m.p. 116°C: the recovery is about 80 per cent.

**Benzylamine.** Warm an alcoholic suspension of 118.5 g (0.5 mol) of finely powdered benzylphthalimide with 25 g (0.5 mol) of 100 per cent hydrazine hydrate (CAUTION: corrosive liquid, see Section 4.2.31, p. 436): a white, gelatinous precipitate is produced rapidly. Decompose the latter (when its formation appears complete) by heating with excess of hydrochloric acid on a steam bath. Collect the phthalylhydrazide which separates by suction filtration, and wash it with a little water. Concentrate the filtrate by distillation on a rotary evaporator to remove alcohol, cool, filter from the small amount of precipitated phthalylhydrazide, render alkaline with excess of sodium
hydroxide solution and extract the liberated benzylamine with ether. Dry the ethereal solution with potassium hydroxide pellets, remove the solvent (rotary evaporator) and finally distil the residue. Collect the benzylamine at 185–187 °C; the yield is 50 g (94%).

Cognate preparation. 2-Phenylethylamine. Prepare 2-phenylethlyphthalamide as above by substituting 2-phenylethyl bromide (Expt 5.55) for benzyl chloride: recrystallise the crude product from glacial acetic acid; m.p. 131–132 °C. Convert it into 2-phenylethylamine by treatment with hydrazine hydrate and hydrochloric acid as described for benzylamine. The yield of 2-phenylethylamine, b.p. 200–205 °C, is about 95 per cent.

Experiment 5.199 DIBUTYLAMINE

CaNCN + 2NaOH → Na₂NCN + Ca(OH)₂
Na₂NCN + 2BuBr → Bu₂NCN + 2NaBr
Bu₂NCN + 2H₂O → Bu₂NH + CO₂ + NH₄⁺

Dibutyl cyanamide. Equip a 2-litre three-necked flask with a reflux condenser and a sealed stirrer unit. Place 220 ml of water and 50 g of finely crushed ice in the flask and add slowly, with vigorous stirring, 70 g (0.46 mol) of commercial calcium cyanamide (1). As soon as the solid is thoroughly suspended, fit a separatory funnel into the third neck of the flask and introduce through it a cold solution of 34 g (0.85 mol) of sodium hydroxide in 70 ml of water; replace the funnel by a thermometer. Continue the vigorous stirring for 1 hour to complete the decomposition of the calcium cyanamide; if the temperature rises above 25 °C, add a little more ice. Add to the resulting solution of sodium cyanamide a solution of 134 g (195 ml, 1 mol) of butyl bromide (Expt 5.54) in 220 ml of rectified spirit. Heat the mixture, with stirring, on a water bath until it reflexes gently; continue the refluxing and stirring for 2.5 hours. Replace the reflux condenser by one set for downward distillation and distil the mixture until 165–170 ml of liquid are collected: stir during distillation. Cool the residue in the flask and filter it, with suction, through a Buchner or sintered glass funnel, and wash the residue with rectified spirit. Extract the filtrate, which separates into two layers, first with 90 ml and then with 45 ml of benzene. Dry the combined benzene extracts with anhydrous calcium sulphate, and remove the benzene on a rotary evaporator. Distil under reduced pressure and collect the dibutyl cyanamide at 147–161 °C/35 mm. The yield is 33 g (47%).

Dibutylamine. Into a 1-litre round-bottomed flask furnished with a reflux condenser place a solution of 34 g (18.5 ml) of concentrated sulphuric acid in 100 ml of water: add 33 g (0.2 mol) of dibutyl cyanamide and a few fragments of porous porcelain. Reflux gently for 6 hours. Cool the resulting homogeneous solution and pour in a cold solution of 52 g of sodium hydroxide in 95 ml of water down the side of the flask so that most of it settles at the bottom without mixing with the solution in the flask. Connect the flask with a condenser for downward distillation and shake it to mix the two layers; the free amine separates. Heat the flask, when the amine with some water distils: continue the distillation until no amine separates from a test portion of the distillate. Estimate the weight of water in the distillate and add about half this
amount of potassium hydroxide in the form of pellets so that it dissolves slowly. Cool the solution in ice while the alkali hydroxide is dissolving; some ammonia gas is evolved. When the potassium hydroxide has dissolved, separate the amine, and dry it for 24 hours over sodium hydroxide pellets. Filter and distil from a flask fitted with a Claisen still-head. Collect the dibutylamine at 157–160°C. The yield is 21 g (75%).

Note. (1) Also known as ‘nitrolim’. The fresh product contains approximately 55 per cent of calcium cyanamide, 90 per cent of lime, 12 per cent of graphite and small amounts of other impurities. It should be protected from moisture when stored in order to prevent slow polymerisation to dicyanodiamide.

5.16.5 IMINE AND ENAMINE FORMATION

Imines are formed by the reaction of a primary amine with aldehydes or ketones with the simultaneous removal of water, for example by azeotropic distillation, by the addition of anhydrous sodium sulphate, by the addition of molecular sieves or by the use of titanium(iv) chloride. When one, or both, of the reactants is aromatic, the imine is quite stable and usually known as a Schiff base (see Section 6.5.5, p. 902). In the case of wholly aliphatic reactants the imines tend to decompose or polymerise; in these cases their further reaction is carried out without delay.

\[
\begin{align*}
R^1\text{O} & \xrightarrow{R^2\text{NH}_2} R^1\text{NHR}^2 \\
R^3\text{O} & \xrightarrow{R^2\text{NH}_2} R^3\text{NHR}^2
\end{align*}
\]

A typical procedure involving water removal with anhydrous potassium carbonate is described in Expt 5.200 for the preparation of N-(1,1-methylethyl)-2-methylpropylimine. The imines are important synthetic intermediates and some of these aspects have been outlined in Section 5.16.3 above, Section 6.5.5, p. 902, and Section 5.7.8, p. 600.

Enamines are the stable products of a similar reaction between secondary amines (such as pyrrolidine or morpholine) and aldehydes and ketones. These vinylamines are reactive reagents of value in synthesis; they function as specific enol equivalents of carbonyl compounds, readily undergoing alkylation and acylation processes (e.g. Section 5.9.2, p. 632).

As with imines, enamine formation may be achieved using azeotropic distillation or with the aid of molecular sieves. The procedure described in Expt 5.201 for the preparation of the enamine from morpholine and diisobutyl ketone utilises titanium(iv) chloride as a catalyst and water scavenger.

The reaction of an amine with, principally, formaldehyde, followed by further reaction with compounds having active hydrogen atoms, give rise to the Mannich bases which are discussed in Sections 5.18.2, p. 801, and 6.12.7, p. 1050.
Experiment 5.200  N-(1,1-DIMETHYLETHYL)-2-METHYLPROPYLIMINE $^{217}$

\[
\begin{align*}
\text{Me} & \quad \text{H} \quad + \quad \text{Me} \\
\text{Me} & \quad \text{Me} \\
\text{O} & \\
& \to \\
\end{align*}
\]

2-Methylpropanal (72 g, 1.0 mol) is added dropwise and with stirring during 2 hours to 1,1-dimethylethylamine (t-butylamine) (73 g 1.0 mol). During the addition the temperature rises from 25 to 40 °C and an aqueous layer separates near the end of the addition. The organic layer is treated with anhydrous potassium carbonate (15 g), stirred at 25 °C for 17 hours, and then decanted on to barium oxide (12 g). After the mixture has been stirred for 10 hours, it is filtered and the organic filtrate is distilled to separate the imine as a colourless liquid, b.p. 56 °C/75 mmHg, 88.3 g (70%); i.r. (CCl₄) 1675 cm$^{-1}$ (C=N); p.m.r. (CCl₄, TMS) 1.05 [d, 6H, $J = 7$ Hz, (Me)$_2$CH], 1.10 [s, 9H, -C(Me)$_3$], 2.0-2.6 (m, 1H, CH), and 7.49 (d, 1H, $J = 4.5$ Hz, CH=N); m/z 127, 112, 72, 57, 56, 55, and 41.

Experiment 5.201  4-(2,6-DIMETHYL-3-HEPTEN-4-YL)MORPHOLINE $^{220}$

\[
\begin{align*}
\text{O} & \quad \text{NH} + \quad \text{O} \\
\text{Me} & \quad \text{Me} \\
\text{Me} & \quad \text{Me} \\
& \to \\
\end{align*}
\]

To a vigorously stirred, cold (0 °C) solution of morpholine (680 g, 7.8 mol) in 1500 ml of hexane is added a solution of titanium(IV) chloride (146 ml, 1.33 mol) in 300 ml of hexane. After the addition is complete diisobutyl ketone (142.2 g, 1.0 mol) is added in one portion. The cooling bath is removed and the reaction allowed to proceed under reflux for 2 hours. After cooling, the mixture is filtered through a sintered glass filter and the solvent removed under reduced pressure, giving a yellow oil which is distilled under reduced pressure. The yield of enamine is 171.4 g (87.7%), b.p. 106-108 °C/10 mmHg (1).

Note. (1) This method has been successfully applied to a very large range of straight and branched chain aliphatic ketones.

5.16.6 MOLECULAR REARRANGEMENTS OF THE HOFMANN TYPE

By treatment of an amide with sodium hypobromite or sodium hypochlorite solution (or with halogen admixed with aqueous alkali), a primary amine having one less carbon atom is produced. Good yields are obtained when the reaction is applied to most aliphatic and aromatic amides. Examples are provided by the preparation of anthranilic acid and 3-aminopyridine (Expt 6.53).

The conversion of an amide in this way is termed the Hofmann reaction or the Hofmann rearrangement. The mechanism of the reaction involves an intramolecular 1,2-carbon-to-nitrogen nucleophilic shift of the alkyl (or aryl) group.
in the bromo amide anion (2) to form an isocyanate, which is hydrolysed to the primary amine by the aqueous base present.

\[
R \cdot \text{CONH}_2 + \text{Br}_2 \xrightarrow{\text{OH}^-} \text{Br} \quad \xrightarrow{\text{R} - \text{CONH}_2 + \text{H}_2\text{O}} \quad \text{R} \cdot \text{NH}_2 + \text{CO}_2^2\text{OH}
\]

(2)

An important consequence of the mechanism of the rearrangement step is that if the migrating group R is attached to the amide carbonyl via a chiral carbon atom the configuration is retained in the product, thus generating a fully optically active amine from optically active starting material (e.g. 2-phenylpropanamide).

If the reaction is carried out by treating the amide with bromine and sodium methoxide in methanol, the alkyl isocyanate intermediate is trapped as the N-alkylurethane (3) which can subsequently be hydrolysed to the primary amine.

\[
R \cdot \text{N}=\text{C}=\text{O} \xrightarrow{\text{MeOH}} \text{R} \cdot \text{NH} \cdot \text{CO}_2\text{Me} \xrightarrow{\text{OH}^+ / \text{H}_2\text{O}} \text{R} \cdot \text{NH}_2
\]

(3)

With long chain (C > 8) alkanamides this modification gives better yields than those obtained by the standard procedure.221

A closely related reaction of general applicability is the Curtius rearrangement222 of acyl azides. The rearranging species in the Schmidt reaction (see p. 898) is in fact also a protonated acyl azide; these azides are readily prepared by the action of nitrous acid on acyl hydrazides which are themselves formed from esters and hydrazine (Section 9.6.17, p. 1269). On heating in aprotic solvents the acyl azides decompose to yield the corresponding isocyanates in good yield.

5.16.7 SOME METHODS FOR THE PROTECTION OF THE AMINO AND IMINO GROUPS

Only a restricted selection of the very great number of methods for the protection of the amino and imino groups is possible here. These have often been developed for the protection of the amino group in an amino acid for the purpose of peptide synthesis. Those considered below are: (a) N-acyl derivatives; (b) carbamates; and (c) phthalimides.

N-ACYL DERIVATIVES

The commonly encountered compounds in this class are the formyl, acetyl and benzoyl derivatives. The formation of the N-formyl compound is readily accomplished by heating the amino compound with formic acid in the presence of acetic anhydride.223 Alternatively, formic acid in the presence of dicyclohexylcarbodiimide (DCC) in pyridine solution is a suitable method for the protection of amino acid esters.224

**General procedure for the formation of N-formyl derivatives of \( \alpha \)-amino acids.**223

Acetic anhydride (83 ml) is added dropwise to a mixture of approximately 0.10 mol of the amino acid in 250 ml of 85 per cent formic acid at a rate to maintain the temperature of the mixture between 50 and 60 °C. After the addition is complete, the mixture is stirred at room temperature for 1 hour at the end of which time 80 ml of icewater is introduced, and the mixture is concentrated
under reduced pressure. The crystalline residue is recrystallised from water or aqueous ethanol.

The N-formyl group is stable providing hot aqueous acid or alkaline conditions are avoided. Deprotection is affected by prolonged hot alkaline hydrolysis, or in the case of protected amino acids, by oxidative\textsuperscript{225} or reductive procedures.\textsuperscript{226}

N-Acetyl and N-benzoyl derivatives may be readily prepared from the corresponding acid chloride or, in the case of acetyl derivatives, acetic anhydride. General procedures are detailed in Sections 9.6.21, p. 1273, and 9.6.23, p. 1279, and the use of N-acetyl derivatives in amino acid synthesis is to be found, for example, in Expts 5.183 and 5.184.

Deprotection may be effected by vigorous acidic or alkaline hydrolysis (p. 918). Alternative methods of deprotection are sodium hydride in refluxing dimethoxyethane,\textsuperscript{227} or by heating with 85 per cent hydrazine hydrate (hydrizinolysis).\textsuperscript{228}

**CARBAMATES**

The two commonest examples are the *benzyl carbamates* (CBZ derivatives) (4) and the *t-butyl carbamates* (BOC derivatives) (5) where the amino group is protected by the benzyloxy carbonyl or the t-butyloxy carbonyl groups respectively.

\[
\begin{align*}
\text{(4)} & \quad \text{R'}R''N\overset{O}{\text{O}}\overset{\text{Ph}}{\text{Ph}} \\
\text{(5)} & \quad \text{R'}R''N\overset{\text{Bu'}}{\text{O}}\overset{\text{Bu'}}{\text{O}}
\end{align*}
\]

An illustrative example of the introduction of the benzyloxy carbonyl group, and its removal by hydrogenolysis is given in the synthesis of L-prolylglycine (Expt 5.188). An alternative reagent for the removal of this protecting group is iodosiltrimethylsilane in acetonitrile at room temperature.\textsuperscript{229}

The conversion of the amino group in amino acids into a t-butyloxy carbonyl group is a process which is widely used in automated peptide synthesis carried out on solid (polymeric) supports (*solid phase synthesis*; the *Merrifield technique*).\textsuperscript{230}

T-Butyloxy carbonyl derivatives may be prepared by reacting the amino acid with t-butylox azidoformate while maintaining the pH at about 9.5 by the controlled addition of aqueous sodium hydroxide solution using an autotitrator (pH stat), and then liberating the product by careful acidification of the reaction mixture to pH 3 with citric acid.\textsuperscript{231}

\[
\text{NH}_2\cdot\text{CHR}\cdot\text{CO}_2\text{H} \xrightarrow{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{O}}{\text{OH}}} \text{Bu'O-CON}_3\overset{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{OH}}}{\text{Bu'O-CON}_3\overset{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{OH}}}}
\]

Although it has been on the market for some time, the reagent is no longer commercially available however. One convenient route for its preparation, starting from phenyl chloroformate, proceeds as formulated below; concise details have been published.\textsuperscript{232} The reagent is toxic and is best prepared as required and used in the crude state, since it may explode on distillation or storage.

\[
\text{ClCO\cdotOPh} \xrightarrow{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{OH}}} \text{Bu'O-CON}_3\overset{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{OH}}} \xrightarrow{\text{N}_2\text{H}_4} \text{Bu'O-CON}_3\overset{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{OH}}} \xrightarrow{\text{HNO}_3} \text{Bu'O-CON}_3\overset{\text{Bu'O-CON}_3\overset{\text{OH}}{\text{O}}{\text{OH}}}
\]
Alternatively, acylation with di-t-butyl pyrocarbonate\(^\text{233}\) has been recommended as a general procedure for the preparation of t-butylloxy carbonyl amino acids.\(^\text{234}\)

\[
\text{Bu'O-OCO-OCOOBu}^+ + \text{NH}_2\cdot\text{CHR-CO}_2\text{H} \xrightarrow{\text{Bu'OH}} \text{Bu'O-CONH-CHR-CO}_2\text{H}
\]

**Procedure for BOC-amino acids.** A solution of the amino acid (10 mol) in a mixture of dioxane (20 ml), water (10 ml) and 1 M sodium hydroxide (10 ml) is stirred and cooled in an ice-water bath. Di-t-butyl pyrocarbonate (1) (2.4 g, 11 mmol) is added and stirring is continued at room temperature for 30 minutes. The solution is concentrated *in vacuo* to about 10–15 ml, cooled in an ice-water bath, covered with a layer of ethyl acetate (30 ml) and acidified with dilute aqueous potassium hydrogen sulphate solution to pH 2–3 (Congo red). The aqueous phase is extracted with ethyl acetate (2 × 15 ml). The ethyl acetate extracts are pooled, washed with water (2 × 30 ml), dried over anhydrous sodium sulphate and evaporated *in vacuo*. The residue is recrystallised with a suitable solvent (e.g. ethyl acetate–hexane).

**Note.** (1) Commercially available, designated as di-t-butyl-dicarbonate. It melts at 20–22°C and should be stored in a refrigerator.

**Deprotection.** The BOC group is easily removed under quite mildly acidic conditions, a feature which underlines its value in selective deprotection in peptide synthesis. Typically, treatment at room temperature for 30–60 minutes with a 1 M solution of hydrogen chloride in acetic acid, or with neat trifluoroacetic acid, is used. It is of interest that after t.l.c. of BOC-amino acids, brief exposure of the plates to hydrogen chloride fumes enables the ninhydrin reaction to be used to detect the presence of the liberated free amino acids.

**PHTHALIMIDES**

These may be prepared from a primary amine by reaction with phthalic anhydride. The general procedure described in Section 9.6.21, p. 1276 uses glacial acetic acid; reaction conditions using chloroform as the solvent medium have been reported.\(^\text{235}\) Deprotection using hydrazine is described in Expt 5.198.

**5.17 ALIPHATIC SULPHUR COMPOUNDS**

The simpler aliphatic sulphur derivatives considered in this section are the sulphur analogues of oxygen compounds, e.g. the thiols (RSH), and the symmetrical or unsymmetrical thioethers (R·S·R or R\(^1\)·S·R\(^2\)). Compounds derived from these two groups, where the sulphur atom can attain a higher oxidation state, are the sulphinic and sulphonic acids (R·SO·OH and R·SO\(_2\)·OH), the sulphotides (R·SO·R), and the sulphones (R·SO\(_2\)·R). Other compounds of interest which are considered in the following discussion are:

the dialkyldisulphides (R·S·S·R: sulphur analogues of the peroxides);
sulphonium salts [e.g. trimethylsulphonium halides (1)];
thioacetals [e.g. 2-ethyl-1,3-dithiane (2)];
\(\text{O,S-dialkyldithiocarbonates (xanthate esters, e.g. O-ethyl S-ethyl dithiocarbon-}
\text{ate (3))].

786
The chirality exhibited by the pyramidal sulphur compounds (e.g. sulphonium salts, sulfoxides and sulphinic esters) should be noted, but cannot be considered within the scope of this book.

\end{array}
\end{align*}
\]

**SPECTROSCOPIC FEATURES**

The characteristic absorption frequencies of this varied group of sulphur compounds may be inferred by reference to the data given in Appendices 2, 3 and 4.

### 5.17.1 THIOLS AND THIOACETALS

The thiols are the sulphur analogues of the alcohols and were formerly called the *mercaptans*. Although they may be prepared by the interaction of an alkyl halide and sodium hydrosulphide in ethanolic solution, a better method involves the interaction of an alkyl bromide and thiourea to form an S-alkylisothiouronium salt, followed by hydrolysis of the latter with sodium hydroxide solution.

\[
\begin{align*}
\text{RBr} + \text{NaSH} & \rightarrow \text{RSH} + \text{NaBr} \\
2\text{RBr} + 2\text{S}=\text{C}(\text{NH}_2)_2 & \rightarrow \\
2\text{RS}\cdot\text{C}(\text{=NH}_2)\cdot\text{NH}_2\text{Br} & \xrightarrow{\text{NaOH}} 2\text{RSH} + \text{H}_2\text{N}\cdot\text{C}(\text{=NH})\cdot\text{NH}\cdot\text{CN}
\end{align*}
\]

This preparative method is quite general as indicated by the range of examples included in Expt 5.202.

In many cases it is not necessary to prepare the alkyl bromide; the S-alkylisothiouronium salt may be prepared directly from the alcohol by heating with thiourea and concentrated aqueous hydrobromic acid.\(^{236}\)

The lower members of the thiol series have remarkably disagreeable odours, but the offensive odour diminishes with increasing carbon content; for example, dodecane-1-thiol is not noticeably unpleasant.

The preparation and isolation of S-benzylisothiouronium chloride by the interaction of benzyl chloride and thiourea is described in Expt 5.203. On recrystallisation the compound separates in either, or sometimes as both, of two dimorphic forms, m.p. 150 and 175 °C respectively. The former may be converted into the higher m.p. form by dissolving it in ethanol and seeding with crystals of the form, m.p. 175 °C: the low m.p. form when warmed to 175 °C gives, after solidification, a m.p. of 175 °C. The compound is of particular interest as a reagent for the characterisation of carboxylic acids or sulphonic acids with which it forms the S-benzylisothiouronium carboxylate (or sulphonate) salts (Sections 9.6.15, p. 1264, and 9.6.26, p. 1285). Both dimorphic forms give identical derivatives.

Thioacetals, arising from the reaction of an aldehyde or ketone with either two moles of a thiol or one mole of a 1,2- or 1,3-dithiol, are useful both as a means of protection of a carbonyl group (Section 5.8.8, p. 625) and as important intermediates in organic synthesis.
In particular, 1,3-dithiane prepared from dimethoxymethane (methylal) and propane-1,3-dithiol in the presence of boron trifluoride-etherate\textsuperscript{237} and 2-alkyl-1,3-dithianes prepared similarly from aldehydes\textsuperscript{238a} are important acyl anion equivalents. These and other uses are discussed in Sections 5.7.5, p. 596, and 6.6.1, p. 909. A wide-ranging review of the reversal of polarity of the carbonyl group through the formation of these sulphur-containing reagents has emphasised their value in organic synthesis\textsuperscript{238b}

Experiment 5.202 HEXANE-1-THIOL

\[
2\text{Me} \cdot (\text{CH}_2)_4 \cdot \text{CH}_2 \cdot \text{Br} + 2\text{H}_2\text{N} \cdot \text{CS} \cdot \text{NH}_2 \rightarrow 2[\text{Me} \cdot (\text{CH}_2)_4 \cdot \text{CH}_2 \cdot \text{S} \cdot \text{C(} \text{NH}_2)\text{NH}_2] \cdot \text{Br} \stackrel{\text{NaOH}}{\rightarrow} 2\text{Me} \cdot (\text{CH}_2)_4 \cdot \text{CH}_2 \cdot \text{SH} + \text{H}_2\text{N} \cdot \text{C(} \text{NH}) \cdot \text{NH} \cdot \text{CN}
\]

**CAUTION:** *This preparation must be carried out in an efficient fume cupboard; disposable plastic gloves should be worn when handling thiourea.*

Into a 500-ml two-necked flask, equipped with a sealed stirrer unit and a reflux condenser, place 62.5 g (53.5 ml, 0.38 mol) of 1-bromohexane (Expt 5.55) and a solution of 35 g (0.5 mol) of thiourea in 25 ml of water. Connect a tube from the top of the condenser leading to an inverted funnel just immersed in potassium permanganate solution in order to prevent the escape of unpleasant odours. Stir the mixture vigorously and heat under reflux for 2 hours; the mixture becomes homogeneous after about 30 minutes and the additional heating ensures the completeness of the reaction. Add a solution of 30 g of sodium hydroxide in 300 ml of water and reflux, with stirring, for a further 2 hours; during this period the thiol separates since it is largely insoluble in the alkaline medium. Allow to cool and separate the upper layer of almost pure hexane-1-thiol (35 g). Acidify the aqueous layer with a cold solution of 75 ml of concentrated sulphuric acid in 50 ml of water, and extract it with 75 ml of ether. Combine the ethereal extract with the crude thiol, dry with anhydrous sodium sulphate and remove the ether on a water bath. Distil the residue using an air bath (Fig. 2.46(a) and (b)) and collect the hexane-1-thiol at 150–152 °C. The yield is 37.5 g (84%).

**Cognate preparation. Butane-1-thiol.** Use 51 g (40 ml, 0.372 mol) of butyl bromide (Expt 5.54), 38 g (0.5 mol) of thiourea and 25 ml of water. Reflux, with stirring, for 3 hours; the mixture becomes homogeneous after 1 hour. Allow to cool and separate the upper layer of the thiol (A). Acidify the aqueous layer with a cold solution of 7 ml of concentrated sulphuric acid in 50 ml of water, cool and saturate with salt; remove the upper layer of butane-1-thiol (B) and combine it with (A). Extract the aqueous liquid with 75 ml of ether, dry the ethereal extract with sodium sulphate or calcium sulphate and distil off the ether from a water bath through a fractionating column. Combine the residue with (A) and (B), and distil. Collect the butane-1-thiol at 97–99 °C. The yield is 24 g (72%).
General remarks on the preparation of thiols. The above method is of quite general application. If the bromoalkane is inexpensive, the extraction with ether may be omitted, thus rendering the preparation of thiols a comparatively easy and not unduly unpleasant operation. The following thiols may be prepared in yields of the same order as hexane-1-thiol and butane-1-thiol; ethanethiol, b.p. 35–36 °C; propane-1-thiol, b.p. 66–67 °C; propane-2-thiol, b.p. 51–52 °C; 2-methylpropane-1-thiol, b.p. 87–88 °C; pentane-1-thiol, b.p. 124–125 °C; heptane-1-thiol, b.p. 175–176 °C; octane-1-thiol, b.p. 198–200 °C or 98–100 °C/22 mmHg; nonane-1-thiol, b.p. 220–222 °C or 98–100 °C/15 mmHg; decane-1-thiol, b.p. 96–97 °C/5 mmHg or 114 °C/13 mmHg; undecane-1-thiol, b.p. 103–104 °C/3 mmHg; dodecane-1-thiol, b.p. 111–112 °C/3 mmHg or 153–155 °C/24 mmHg; tetradecane-1-thiol, b.p. 176–180 °C/22 mmHg; phenylmethanethiol, b.p. 195 °C.

Experiment 5.203 S-BENZYLISOTHIOURONIUM CHLORIDE

\[ \text{Ph} \cdot \text{CH}_2\text{Cl} + (\text{NH}_2)_2\text{C}=\text{S} \rightarrow \text{Cl}^\oplus \text{NH}_2=\text{C} (\text{NH}_2)\cdot \text{S} \cdot \text{CH}_2 \cdot \text{Ph} \]

Dissolve 76 g (1 mol) of thiourea in 200 ml of warm water in a 1-litre round-bottomed flask. Dilute the solution with 135 ml of rectified spirit and add 126.5 g (1 mol) of benzyl chloride. Heat the mixture under reflux on a water bath until the benzyl chloride dissolves (about 15 minutes) and for a further 30 minutes taking care that the mixture is well shaken from time to time. Cool the mixture in ice: there is a tendency to supersaturation so that it is advisable to stir (or shake) the cold solution vigorously, when the substance crystallises suddenly. Filter off the solid at the pump. Evaporate the filtrate to about half bulk in order to recover a further small quantity of product. Dry the compound upon filter paper in the air. The yield of S-benzylisothiouronium chloride, m.p. 174 °C, is 200 g (99%). Recrystallise the salt from 400 ml of 0.2 M hydrochloric acid; filter off the solid which separates on cooling. The yield of recrystallised salt, m.p. 175 °C, is 185 g (91%); some of the dimorphic form, m.p. 150 °C, may also separate.

5.17.2 DIALKYL SULPHIDES (THIOETHERS) AND TRIALKYSULPHONIUM SALTS

Retrosynthetic C—S disconnection reveals two possible routes to dialkyl sulphides.

(a) \[ R^1 \cdot S^1 \cdot R \rightarrow 2R^\ominus + S^2\ominus \]

(b) \[ R^1 \cdot S^1 \cdot R^2 \rightarrow R^1 \cdot S^\ominus + ^\ominus R^2 \]

Formation of a symmetrical sulphide (a) (e.g. dipropyl sulphide, Expt 5.204), is conveniently effected by boiling an alkyl halide (the source of carbocations) with sodium sulphide in ethanolic solution. Mixed sulphides (b) are prepared by alkylation of a thiolate salt (a mercaptide) with an alkyl halide (cf. Williamon’s ether synthesis, Section 5.6.2, p. 583). In the case of an alkyl aryl sulphide (R·S·Ar) where the aromatic ring contains activating nitro groups (see Section 6.5.3, p. 900), the aryl halide is used with the alkyl thiolate salt. The alternative alkylation of a substituted thiophenol is described in Section 8.3.4, p. 1160. The former procedure is illustrated by the preparation of isobutyl 2,4-dinitrophenyl sulphide (Expt 5.205) from 1-chloro-2,4-dinitrobenzene and 2-methylpropane-1-thiol.
A variant of this procedure is provided by the preparation of S-benzyl-L-cysteine (Expt 5.206). The required thiolate salt is prepared by the reductive cleavage with sodium in liquid ammonia of the disulphide linkage in the amino acid, (S)-cystine, and is alkylated in situ with benzyl chloride. The preparation of this S-benzyl derivative constitutes a method of protection of the thiol grouping in cysteine.

The use of a cyanooethylolation procedure (Section 5.13.3, p. 717) or related Michael type addition reactions for the synthesis of functionalised sulphides should be noted as an important preparative route.

\[
\begin{align*}
\text{R-S-S-S} & \xrightarrow{\text{Me}-\text{CH}_2\text{CH}_2\text{Br} + \text{Na}_2\text{S}} \text{Me}_2\text{S} + [\text{CH}_2] \\
\end{align*}
\]

Example of its use are to be found in Expt 8.4.

Dialkyl disulphides, of which (S)-cystine above is an example, may be prepared from thiols by mild oxidation, usually with iodine in the presence of alkali. A convenient synthesis of unsymmetrical analogues results when a symmetrical disulphide is heated with thiol to establish an equilibrium mixture. By careful choice of the reactants, fractional distillation then removes the more volatile thiol leaving the mixed disulphide as a residue.

\[
\begin{align*}
\text{R}^1\cdot\text{S}\cdot\text{S} \cdot \text{R}^1 + \text{R}^2\text{SH} & \xrightarrow{\text{distillation}} \text{R}^1\cdot\text{S}\cdot\text{S} \cdot \text{R}^2 + \text{R}^1\text{SH} \\
\end{align*}
\]

**Experiment 5.204 DIPROPYL SULPHIDE**

2 Me\cdot\text{CH}_2\cdot\text{CH}_2\text{Br} + \text{Na}_2\text{S} \xrightarrow{\text{2NaBr}} (\text{Me}\cdot\text{CH}_2\cdot\text{CH}_2)_2\text{S} + 2\text{NaBr}

**CAUTION:** This preparation must be carried out in an efficient fume cupboard.

Place 56 g (0.5 mol) of finely powdered, fused sodium sulphide and 100 ml of rectified spirit in a 500-ml round-bottomed flask equipped with a reflux condenser. To the boiling mixture add 46 g (34 ml, 0.374 mol) of propyl bromide slowly and reflux for 6 hours. Distil off the ethanol on a water bath, and add a large excess of water to the distillate. Separate the upper layer of crude sulphide, wash it with three 40-ml portions of 5 per cent sodium hydroxide solution, then with water until the washings are neutral, and dry over anhydrous calcium chloride or anhydrous calcium sulphate. Distil, and collect the dipropyl sulphide at 141–143°C. The yield is 20 g (91%). If the sulphide is required perfectly pure, it should be redistilled from a little sodium.

**Cognate preparation. Dibenzyl sulphide.** Heat a solution of 63 g (0.5 mol) of benzyl chloride in 160 ml of rectified spirit on a steam bath and stir while...
adding a solution of 29 g (0.25 mol) of fused sodium sulphide in about 50–60 ml of water. Continue stirring and heating for 3 days, remove the ethanol on a rotary evaporator and pour the residue on to 350 g of crushed ice. Separate the oil and triturate with a little 70 per cent ethanol to crystallise the product. Recrystallise from the same solvent; the yield of dibenzyl sulphide is 26 g (83%), m.p. 49 °C.

Experiment 5.205 ISOBUTYL 2,4-DINITROPHENYL SULPHIDE

\[ 2,4-(\text{NO}_2)\text{C}_6\text{H}_3\text{Cl} + \text{HS-CH}_2\text{CHMe}_2 \rightarrow 2,4-(\text{NO}_2)\text{C}_6\text{H}_3\cdot\text{S-CH}_2\cdot\text{CHMe}_2 \]

Dissolve 1 g (0.005 mol) of 1-chloro-2,4-dinitrobenzene in 5 ml of rectified spirit with warming and add a solution of 0.5 ml (0.005 mol) of 2-methylpropane-1-thiol in 5 ml of rectified spirit containing 2 ml of 10 per cent aqueous sodium hydroxide. Heat under reflux for 10 minutes and decant the hot solution from any insoluble material into a clean conical flask. Allow the solution to cool, filter and recrystallise the sulphide twice from methanol. The product is obtained as yellow flakes, m.p. 75–76 °C; the yield is 440 mg (35%).

Experiment 5.206 S-BENZYL-L-CYSTEINE [L-2-Amino-3-(benzylthio)propanoic acid]

\[ [\text{NH}_2\cdot\text{CH(CO}_2\text{H)}\cdot\text{CH}_2\cdot\text{S}]_2 \xrightarrow{\text{Na/NH}_3} 2\text{NH}_2\cdot\text{CH(CO}_2\text{Na)}\cdot\text{CH}_2\cdot\text{SNa} \xrightarrow{(i)\text{ Ph-CH}_2\text{Cl}} 2\text{NH}_2\cdot\text{CH(CO}_2\text{H)}\cdot\text{S-CH}_2\cdot\text{Ph} \]

Collect about 750 ml of liquid ammonia (Section 2.17.7, p. 116) in a 1-litre three-necked flask, surrounded by a lagging bath of cork chips and fitted with a sealed stirrer unit, a soda-lime guard-tube and a stopper. Weigh out 24 g (0.1 mol) of L-cystine (Expt 5.187), and add about 10 g (0.48 mol) of sodium cut into small pieces under dry light petroleum. Start the stirrer, add about 2 g of the sodium followed by L-cystine in small portions until the blue colour has disappeared. Repeat this addition sequence until all of the cystine has been added and a permanent blue colour remains. Discharge the blue colour by gradually adding powdered ammonium chloride, and then add dropwise 25.3 g (23 ml, 0.2 mol) of benzyl chloride. Remove the stirrer and lagging bath and allow the ammonia to evaporate overnight. Dissolve the residue in 100 ml of cold water and add concentrated hydrochloric acid until the resulting mass is acid to Congo red. Heat the mixture gradually to boiling to dissolve the precipitated product and allow to cool. Filter off the long needles of S-benzyl-L-cysteine which separate, wash with a little cold water and allow to dry in the air. The yield is 38 g (90%), m.p. 214 °C (decomp.).

5.17.3 SULPHOXIDES AND SULPHONES

Dialkyl sulphides may be oxidised to the sulfoxides (4) (alkylsulphinylalkanes), and thence to the sulphones (5) (alkylsulphonylalkanes).

\[ \text{R-S-R} \xrightarrow{\text{101}} \text{R-SO-R} \xrightarrow{\text{101}} \text{R-SO}_2\cdot\text{R} \]

(4) (5)
Sulphoxides are obtained by using a variety of mild oxidising agents; hydrogen peroxide has been widely used, but aqueous sodium metaperiodate and sodium perborate have the advantage of being easily handled reagents. The use of the former reagent is described in Expt 5.207.

More vigorous oxidising agents yield sulphones; an excess of potassium permanganate in aqueous acetic acid is often employed. The preparation of isobutyl 2,4-dinitrophenyl sulphone (Expt 5.208) may be regarded as typical. Frequently the vigour of this oxidant (and indeed others such as organic peracids) results in other functional groups which may be present in the sulphide (e.g. carbon–carbon multiple bonds) being oxidatively degraded. A reagent which is chemoselective for the sulphide to sulphone conversion is potassium hydrogen persulphate.

The simplest sulphoxide, dimethyl sulphoxide, is an important aprotic solvent (Section 4.1.33, p. 412). Its use as a reagent in carbon–carbon forming reactions and as a reagent for the oxidation of alcohols to carbonyl compounds (p. 608) (the Pfitzner–Moffatt and Swern oxidations) has been extensively reviewed. An illustrative example of carbon–carbon bond formation using dimethyl sulphoxide is noted in Expt 7.3.

**Experiment 5.207 DIBENZYL SULPHOXIDE**

\[(\text{Ph} \cdot \text{CH}_2)_2 \text{S} \xrightarrow{\text{NaIO}_4} (\text{Ph} \cdot \text{CH}_2)_2 \text{SO}\]

Stir 2.35 g (0.011 mol) of sodium metaperiodate (Section 4.2.55, p. 454) in 45 ml of a 1:1 mixture of water and methanol held at 0°C. Add portionwise 2.14 g (0.01 mol) of dibenzyl sulphide (Expt 5.204) and continue to stir the mixture at 0°C for several hours, preferably overnight. Extract the reaction mixture (which contains precipitated sodium iodate) with three 20 ml portions of chloroform. Dry the combined chloroform extracts over magnesium sulphate and remove the solvent on a rotary evaporator. Recrystallise the product from ethanol. The yield of dibenzyl sulphoxide is 2.2 g (96%), m.p. 135°C.

**Experiment 5.208 ISOBUTYL 2,4-DINITROPHENYL SULPHONE**

\[2,4-(\text{NO}_2)_2\text{C}_6\text{H}_3 \cdot \text{S} \cdot \text{CH}_2 \cdot \text{CHMe}_2 \xrightarrow{\text{KMnO}_4} 2,4-(\text{NO}_2)_2\text{C}_6\text{H}_3 \cdot \text{SO}_2 \cdot \text{CH}_2 \cdot \text{CHMe}_2\]

Dissolve 340 mg of isobutyl 2,4-dinitrophenyl sulphide (Expt 5.205) in 10 ml of acetic acid, warm to about 50°C and add dropwise 8 ml of 3 per cent aqueous potassium permanganate solution. Maintain the solution at about 50°C for 20 minutes, and then pass through the solution a stream of sulphur dioxide to decompose excess potassium permanganate. Add crushed ice to the yellow solution to precipitate the crude sulphone. Filter the precipitate, dry and recrystallise from rectified spirit to give the yellow crystalline product, m.p. 105–106°C; the yield is 190 mg (50%).

### 5.17.4 O,S-DIALKYL DITHIOCARBONATES (XANTHATE ESTERS)

Alkali metal salts of the O-alkyl dithiocarbonates (e.g. RO·CS·S\(^{\ominus}\)K\(^{\ominus}\), the xanthates) are prepared by the reaction of carbon disulphide with an alcohol and an alkali metal hydroxide.
KOH + CS₂ + R'OHIR → R'O·CS·SK + H₂O

Alkylation of this xanthate salt with an alkyl halide in absolute ethanol leads to an O,S-dialkyl dithiocarbonate.

R'O·CS·S⁻→R²⁻I → R'O·CS·SR² + I⁻

The xanthate esters are of interest in that if the O-alkyl group contains at least one α-hydrogen atom, pyrolysis produces an olefin, a thiol and carbon oxysulphide (the Chugaev reaction, Section 5.2.1, p. 489).

Isolation of the intermediate xanthate salts in the preparation of the xanthate esters is not essential. The formation of the latter may be achieved, in one step, by converting the alcohol into the corresponding alkoxide by reaction with a potassium derivative of a tertiary alcohol (e.g. potassium t-pentoxide), followed by reaction successively with carbon disulphide and the alkyl halide. Both preparative procedures are illustrated in the following section.

**Experiment 5.209 O-ETHYL S-ETHYL DITHIOCARBONATE**

EtO⁻K⁻ + CS₂ → EtO·C(=S)·S⁻K⁻ → EtO·C(=S)·S·Et

**CAUTION:** These preparations must be conducted in an efficient fume cupboard.

**Potassium O-ethyl dithiocarbonate.** Into a 500-ml round-bottomed flask, fitted with a reflux condenser, place 42 g (0.75 mol) of potassium hydroxide pellets and 120 g (152 ml) of absolute ethanol. Heat under reflux for 1 hour. Allow to cool and decant the liquid from the residual solid into another dry 500-ml flask; add 57 g (45 ml, 0.75 mol) of carbon disulphide (1) slowly and with constant shaking. Filter the resulting almost solid mass, after cooling in ice, on a sintered glass funnel at the pump, and wash it with three 25 ml portions of ether. Dry the potassium O-ethyl dithiocarbonate in a vacuum desiccator over silica gel. The yield is 74 g. If desired, it may be recrystallised from absolute ethanol but this is usually unnecessary.

**O-Ethyl S-ethyl dithiocarbonate.** Place 32 g (0.2 mol) of potassium O-ethyl dithiocarbonate and 50 ml of absolute ethanol in a 500-ml round-bottomed flask provided with a double surface condenser. Add 32 g (16.5 ml, 0.205 mol) of ethyl iodide. No reaction appears to take place in the cold. Heat on a water bath for 3 hours: a reaction sets in within 15 minutes and the yellow reaction mixture becomes white owing to the separation of potassium iodide. Add about 150 ml of water, separate the lower layer and wash it with water. Dry it with anhydrous calcium chloride or anhydrous calcium sulphate and distil collecting O-ethyl S-ethyl dithiocarbonate at 196–198 °C. The yield is 23 g (77%).

**Note.** (1) Carbon disulphide is toxic and has a dangerously low flash point (Section 2.3.2, p. 40).

**Cognate preparation. O-Ethyl S-butyl dithiocarbonate.** Use 32 g (0.2 mol) of potassium O-ethyl dithiocarbonate, 37 g (23 ml, 0.2 mol) of butyl iodide (Expt 5.58) and 50 ml of absolute ethanol. Reflux on a water bath for 3 hours. Pour
into 150 ml of water, saturate with salt (in order to facilitate the separation of the upper layer), remove the upper xantheate layer, wash it once with 25 ml of saturated salt solution and dry with anhydrous calcium chloride or anhydrous calcium sulphate. Distil under reduced pressure and collect the pale yellow O-ethyl S-butyl dithiocarbonate at 90–91 °C/4 mmHg. The yield is 34 g (95%).

O-[1,2,2-Trimethylpropyl] S-methyl dithiocarbonate. In a 2-litre three-necked flask equipped with a stirrer, reflux condenser and dropping funnel, prepare potassium t-pentoxide by dissolving 48.5 g (60 ml, 0.55 mol) of 2-methylbutan-2-ol (t-pentyl alcohol) in 750 ml of dry toluene and adding in portions 21.5 g (0.55 mol) of potassium metal (1) and refluxing gently until reaction is complete. Then add 51 g (63 ml, 0.5 mol) of 3,3-dimethylbutan-2-ol to the hot solution slowly and with stirring. Cool and add slowly 57 g (0.75 mol) of carbon disulphide. When the reaction has subsided, cool the resulting orange xantheate suspension to room temperature, add 78 g (34 ml, 0.55 mol) of methyl iodide and heat on a water bath for 4–5 hours. Filter, remove toluene and the residual alcohols on a rotary evaporator (fume cupboard) and distil the product under reduced pressure collecting the xantheate ester at 85–87 °C/6 mmHg (2). The yield is 63 g (70%).

Note. (1) Great care must be taken in the handling of potassium (see Section 4.2.62, p. 460) and of methyl iodide (Section 2.3). (2) Use a 500-ml flask fitted with a short fractionating column; the distillation is accompanied by considerable frothing.

5.18 UNSATURATED COMPOUNDS

This section reviews some of the further important methods of synthesis of (i) unsaturated alcohols, (ii) unsaturated carbonyl compounds, and (iii) unsaturated carboxylic acids. It also provides an opportunity to consider those methods which were not conveniently included elsewhere, but which are of great importance and interest.

The importance of these three classes of unsaturated compounds is that they contain many naturally occurring examples having specific biological activity. For this reason their general methods of synthesis are of interest. Furthermore, their particular functional features are to be found embedded in the structures of more complex acyclic, alicyclic and polycyclic molecules. Thus the incorporation of the simpler structures as 'building blocks' in multistage syntheses of, for example, antibiotics has been one of the synthetic challenges of recent decades.

5.18.1 UNSATURATED ALCOHOLS

The two important groups of unsaturated alcohols are the allylic alcohols [e.g., (1)], and the homoallylic alcohols [e.g., (2)]. The (E)-isomers are formulated for (1) and (2) but the (Z)-isomers are of course also known; the hydroxyl-carrying carbon may also be chiral [(R)- and (S)-isomers].
A synthetic survey embracing all these structural and isomeric features cannot be attempted here, and the discussion is restricted to the allylic alcohols.

Retrosynthetic strategies, limited to the more obvious but widely used FGI and disconnection transforms in the case of an allylic alcohol target molecule, are summarised below.

The synthetic method (a) is the regioselective reduction of an \(\alpha,\beta\)-unsaturated aldehyde or ketone (Section 5.18.2, p. 798), which is most conveniently effected by the Meerwein–Ponndorf–Verley procedure (Section 5.4.1, p. 520). The further disconnection shown of the \(\alpha,\beta\)-carbonyl compound is a retro-aldol condensation (Section 5.18.2, p. 799); however it should be emphasised that other routes to the unsaturated carbonyl compound, such as the Horner–Emmons reaction (Section 5.18.2, p. 799), may also be feasible.

Asymmetric reduction of \(\alpha,\beta\)-unsaturated carbonyl compounds using chiral complexes (Section 5.4.1, p. 521) could feasibly lead to optically active allylic alcohols. Other reducing agents which have some merit of regioselectivity, but not stereoselectivity, are sodium cyanoborohydride, and sodium borohydride in the presence of lanthanide salts.

The synthetic method (b) combines the formation of a primary or secondary alkynol [from formaldehyde or an aldehyde respectively and an organometallic acetylenic reagent (Section 5.4.2, p. 532)] with the semihydrogenation of the triple bond to a double bond. As noted in Section 5.2.2, p. 493, appropriate selection of catalyst is necessary in the hydrogenation step to ensure the formation of either the (\(E\))- or the (\(Z\))-isomer. The specific formation of the allylic alcohol, \(\text{CH}_2\equiv\text{CH-CH(OH)-R}\), is from a vinylmagnesium halide (Expt 6.41) and an aldehyde.

The synthetic method (c) is a base-catalysed ring opening of an oxirane. Since the oxirane may be formed by the epoxidation of an olefin (Section 8.1.3, p. 1132), or by a methylene insertion reaction into a carbonyl group (Section 8.1.2, p. 1131), this method is of some versatility.
This reaction is used as one step [(7) to (6)] of the multistage synthesis of the monocyclic sesquiterpenic hydrocarbon, dehydro-α-curumene (3) [6-methyl-2-(4-methylphenyl)hepta-1,5-diene]. The overall strategy is revealed from a retrosynthetic analysis for this compound, and is of interest since it emphasises the logic of the disconnection approach and draws together a number of important reactions which are relevant to this discussion of unsaturated compounds.

Thus the initial disconnection of (3) reveals the ylide, isopropylidenetriphenylphosphorane, and the γδ-unsaturated aldehyde (4) (see the Wittig reaction, Sections 5.2.3, p. 495). A retro-Claisen–Cope rearrangement (a [3,3] sigmatropic shift, see also the Claisen rearrangement, Section 6.9.2, p. 978) of the aldehyde (4) discloses the allyl vinyl ether (5). Disconnection of this ether reveals the allylic alcohol and an alkyl vinyl ether. The forward synthetic step [(6) to (5)] is a transetherification reaction with ethyl vinyl ether. Reconnection of (6) gives the epoxide (7). Various retrosynthetic strategies for epoxides are considered in Section 8.1, but the most suitable in the case of (7) is disconnection to p-methylacetophenone and a carbene insertion reagent. The methodology of the synthesis of dehydro-α-curumene is formulated in Expt 5.210.
Experiment 5.210 2-(4-METHYLPHENYL)-PROP-2-EN-1-OL AND 6-METHYL-2-(4-METHYLPHENYL)HEPTA-1,5-DIENE

1,2-Epoxy-2-(4-methylphenyl)propane. To a solution of dimethyloxosulphonium methylium [prepared from sodium hydride (1.5 g, 50% dispersion), finely powdered trimethyloxosulphonium iodide (6.6 g) and dimethyl sulphoxide (30 ml) under a nitrogen atmosphere] is added with stirring, a solution of p-methylacetophenone (3.4 g) in dimethyl sulphoxide (10 ml). The reaction mixture is left overnight at room temperature and then heated to 50 °C for 1 hour. After cooling and adding water (60 ml), the mixture is extracted with ether, the combined ethereal extracts washed with water and then dried over anhydrous sodium sulphate. Evaporation of the solvent followed by chromatography over neutral alumina using light petroleum (b.p. 40–60 °C) as eluant, affords the epoxide (3.3 g, 90%).

2-(4-Methylphenyl)prop-2-en-1-ol. To a solution of diisopropylamine (3 g) in ether is added with stirring butyllithium (15 ml, 2.1 m in ether) under a nitrogen atmosphere. After 30 minutes, the solution of the foregoing epoxide (3 g) in ether (40 ml) is added slowly with stirring and the mixture left overnight at room temperature. The mixture is refluxed for 4 hours and the disappearance of epoxide is monitored by t.l.c. The solution, after cooling, is partitioned between ether and water, the organic phase washed successively with water and brine and then dried over anhydrous sodium sulphate. Solvent evaporation followed by chromatography over neutral alumina affords 2-(4-methylphenyl)prop-2-en-1-ol (2.6 g, 85%), pure by t.l.c. analysis; b.p. 105–107 °C/5–7 mmHg; i.r. (film) 3380, 1050 (OH), 3070, 1650, 890 (>C=CH<2), and 820 cm⁻¹ (para-substituted benzene).

Conversion into 6-methyl-2-(4-methylphenyl)hepta-1,5-diene. 2-(4-methylphenyl)prop-2-enyl vinyl ether. A mixture of the foregoing allylic alcohol (2.5 g), ethyl vinyl ether (75 ml) and freshly crystallised mercury(II) acetate (600 mg) is refluxed continuously for 12 hours on a water bath. The reaction mixture is chilled in ice and mixed with 10 per cent aqueous sodium carbonate solution (25 g) and stirred well for 30 minutes at 0 °C. The organic layer is
5.18 PRACTICAL ORGANIC CHEMISTRY

separated, washed with water and dried over anhydrous potassium carbonate. Evaporation of the solvent and chromatography of the residue on neutral alumina (50 g) furnished, on elution with light petroleum (b.p. 40–60 °C), the allyl vinyl ether which is further purified by distillation under reduced pressure, b.p. 90–92 °C/5–7 mmHg; yield 2.0 g (80%); 1630, 1610 (C==C), 1200 (vinyl ether), 900 (> C==H₂) and 820 cm⁻¹ (para-substituted benzene).

Claisen-Cope rearrangement of the allyl vinyl ether. The ether (1.1 g) is heated for 30 minutes at 180–185 °C under nitrogen in a fully immersed half-filled sealed Pyrex glass tube (CAUTION). After cooling, the product is distilled under reduced pressure to furnish 4-(4-methylphenyl)pent-4-enal (850 mg, 87%), b.p. 100–102 °C/5–7 mmHg; i.r. (film) 2700, 1710 (CHO), 3070, 1650, 890 (> C==CH₂), and 825 cm⁻¹ (para-substituted benzene).

Wittig reaction. To the phosphorane [prepared from isopropyltriphenylphosphonium iodide (2.6 g) in dimethyl sulfoxide (6 ml) and sodium hydride (300 mg, 50% dispersion) under a nitrogen atmosphere], is added the foregoing aldehyde (700 mg) in tetrahydrofuran (1 ml). The contents are stirred for 2 hours and then left overnight at room temperature and warmed to 50 °C for 2 hours. The cooled reaction mixture is poured on to crushed ice and extracted with light petroleum (b.p. 40–60 °C). The organic extract is dried over anhydrous sodium sulphate, the solvent removed and the residue chromatographed over neutral alumina (20 g) when elution with light petroleum (b.p. 40–60 °C) gives 6-methyl-2-(4-methylphenyl)hepta-1,5-diene (450 mg, 66%). This is further purified by distillation under reduced pressure, b.p. 110–113 °C/5–7 mmHg; p.m.r. (CCL₄, TMS) δ 1.52 (s, 6H, C==C(Me)₂), 2.34 (s, 3H, Ar.Me), 5.05 (t, 1H, =CH–C–), 5.24 (broad s, 2H, > C==CH₂), and 7.23 (4H, aromatic protons).

5.18.2 UNSATURATED CARBONYL COMPOUNDS

By far the most important compounds of this type are the α,β-unsaturated aldehydes and ketones, of which the simplest general representation is (8) and (9) respectively. Branching may be present at either or both of the α- or β-positions as for example in 2-ethylhex-2-enal (10) and 4-methylpent-3-en-2-one (11). Compounds where the carbon–carbon double bond is terminal are acraldehyde [(8), R=H], and the alkyl (or aryl) vinyl ketones [(9), R' = H, R = alkyl, aryl etc.].

![Diagram of unsaturated carbonyl compounds](attachment:image)

The preparation of α,β-unsaturated aldehydes and ketones is exemplified by the following four important methods: (a) the oxidation of the corresponding unsaturated primary or secondary alcohol; (b) the Horner–Emmons or Wadsworth–Emmons modification of the Wittig reaction²⁴⁸; (c) the aldol con-
densation followed by dehydration; and (d) the specific formation of alkyl (or aryl) vinyl ketones from Mannich bases.

**THE OXIDATION OF α,β-UNSATURATED PRIMARY OR SECONDARY ALCOHOLS.**
This method is of value when the alcohol is readily available from natural sources, or when it can be prepared, for example, by the reaction of an alkenyl-organometallic reagent with an aldehyde. An example of the former is the oxidation of the terpenoid alcohol carveol to carvone (Expt 5.88) using pyridinium chlorochromate-on-alumina reagent.

**THE HORNER-EMMONS OR WADSWORTH-EMMONS MODIFICATION OF THE WITTIG REACTION**
This reaction is discussed in Section 5.2.3, p. 496, where the broad mechanism of the reaction and its preparative value is considered. The example included here is the preparation of 2-oxoundec-3-ene from octanal and diethyl 2-oxopropanephosphonate,249 (Expt 5.211). The interest of the procedure is that the reaction is carried out under heterogeneous liquid–liquid conditions using a high concentration of potassium carbonate, but in the absence of an organic solvent and a phase transfer catalyst. This may be contrasted with the conditions which employ an aprotic solvent and a base such as sodium hydride (cf. Expt 5.17).

**THE ALDOL REACTION FOLLOWED BY DEHYDRATION**
A retrosynthetic analysis of an α,β-unsaturated aldehyde or ketone involves an initial functional group interconversion into a β-hydroxy carbonyl compound, followed by a disconnection into the carbocation (12) and the carbanion (13) synthons. The reagent equivalents of these two synthons are the corresponding carbonyl compounds.

$$\begin{align*}
R^1 & \quad O^+ \\
R^2, R^3 & = H \text{ or alkyl}
\end{align*}$$

The forward synthetic reaction is a base-catalysed condensation reaction between two carbonyl compounds, the *aldol condensation* leading to β-hydroxyaldehydes or β-hydroxyketones followed by dehydration. This sequence is one of the most important carbon–carbon bond forming reactions, and *aldol-type* condensation reactions are considered in a number of other sections of the text, for example, the Doebnner reaction (Section 5.18.3, p. 805), the Knoevenagel reaction (Section 5.11.6, p. 681), the Perkin reaction (Section 6.12.3, p. 1036) and the Robinson annelation reaction (Section 7.2).

The mechanism is illustrated in the simple case of the self-condensation of an aldehyde in the presence of base. Here the nucleophilic, mesomerically stabilised α-carbanion (the enolate ion) formed by the action of base, attacks the electrophilic carbonyl carbon of a second aldehyde molecule to form, after proton exchange with the solvent, the β-hydroxyaldehyde.
All the steps of this reaction are reversible but the position of the equilibrium is significantly in favour of the aldol, which generally may be obtained when the reaction is carried out at room temperature or below, followed by extraction and careful distillation under reduced pressure. When the required product is the unsaturated aldehyde the reaction is carried out at a higher temperature, and dehydration of the aldol occurs readily (e.g. 2-ethylhex-2-enal, Expt 5.212). In the case of aldehydes with only one \( \alpha \)-hydrogen atom, aldol formation occurs but the resulting \( \beta \)-hydroxyaldehyde cannot undergo the dehydration step.

In a similar way a ketone may undergo a self-condensation reaction to give a ketol, which may be dehydrated in a separate reaction to an \( \alpha,\beta \)-unsaturated ketone.

In this case however the position of equilibrium is not in favour of the condensation product (which rapidly dissociates into the ketone in the presence of base), and a technique has to be employed which continuously removes the ketol product, as it is formed, from the presence of base. A satisfactory procedure for converting acetone into diacetone alcohol is described in Expt 5.213. The dehydration step to give mesityl oxide is subsequently effected by the presence of a trace of iodine.

'Mixed' aldol reactions may be broadly classified as the reaction between two different aldehydes or ketones, or the reaction of an aldehyde with a ketone. Apart from the concomitant self-condensation, not less than two possible 'crossed' products can be envisaged. Such reactions are therefore only preparatively useful either if appropriate structural conditions are present, or if certain experimental conditions are used to effect a directed aldol condensation.

In the former instance, the major structural condition is that one of the carbonyl components (either the aldehyde or the ketone) has no \( \alpha \)-hydrogen and thus is unable to form an enolate ion, but is nevertheless sufficiently electrophilic at its carbonyl carbon that it reacts with the carbanion of the second carbonyl component. Examples are provided in the formation of 4-phenylbut-3-en-2-one from benzaldehyde (no \( \alpha \)-hydrogens) and acetone in the presence of base, and the formation of benzylideneacetophenone from benzaldehyde and acetophenone (Expt 6.135).

Recent decades have seen the enormous development of a great range of procedures for the achievement of directed self- or cross-coupling reactions. The interested reader should consult the relevant review articles which cover the field comprehensively.\(^{250}\) One example is used here to illustrate, in part, the com-
plexity and interest of these reactions. This is the reaction between cyclohexanone and benzaldehyde where a conventional aldol-type reaction is unlikely to be successful owing to the low concentration of carbanions arising from the ketone. However, if the cyclohexanone is first converted into the corresponding silyl enol ether (14), and then treated with the aldehyde in the presence of titanium chloride, the reaction gives a chelated titanium complex of 2-(1'-hydroxybenzyl)cyclohexanone (15); hydrolysis with water gives the aldol\(^{251}\) (16) (Expt 5.214).

\[
\begin{align*}
\text{O} & \quad \text{TMS, Li}_2\text{S} \quad \text{Et}_3\text{H} \\
\text{OSiMe}_3 & \quad \text{Ph} \quad \text{CHO} \quad \text{TiCl}_4 \\
\text{O} & \quad \text{TiCl}_3
\end{align*}
\]

The stereoisomeric features of the intermediates and of the product of this reaction should be noted. Thus the silyl enol ether (14) can only have the \((E)\)-configuration. The product (16) has two chiral sites (*) and the aldol is therefore a mixture of \textit{erythro/threo} ketols; in this case the ratio is 23:69.

It should be noted that several procedures are available for the preparation of 1-(trimethylsilyloxy)cyclohexene. In an original report\(^{252}\) it was prepared by heating a dimethylformamide solution of cyclohexanone under reflux with chlorotrimethylsilane in the presence of triethylamine. This procedure is generally satisfactory for aldehydes and symmetrical ketones, or ketones which can enolise in one direction only. The method described in Expt 5.214 employs lithium sulphide as an additive to increase the silylating power of the chlorotrimethylsilane, so that the reaction proceeds at room temperature; acetonitrile is used as the solvent.\(^{253}\)

**THE MANNICH REACTION**

The mechanism of the reaction is considered in Section 6.12.7, p. 1050, where acetophenone, which can only enolise in one direction, reacts with the formaldehyde equivalent (17) formed from formaldehyde and dimethylamine hydrochloride, to give the Mannich base (18), which in this case is isolated as the hydrochloride. The free Mannich bases are obtained by treatment with base and solvent extraction or crystallisation (e.g. gramine, Expt 6.147).

\[
\begin{align*}
\text{Ph} & \quad \text{Me} \quad \text{OH} \quad \text{CH}_2 & \text{CH}_2 & \text{NMe}_2 \\
\text{Ph} & \quad \text{NHMe}_2
\end{align*}
\]

Conversion of a Mannich base hydrochloride into an \(\alpha,\beta\)-unsaturated carbonyl compound, is illustrated by the formation of phenyl vinyl ketone, which is obtained directly by steam distillation (Expt 6.147). Alternatively the Mannich base may be treated with methyl iodide to form the quaternary salt, which then gives the \(\alpha,\beta\)-unsaturated carbonyl compound by a base-catalysed elimination reaction.

\[
\begin{align*}
\text{Ph} & \quad \text{NHMe}_2 \quad \text{(i)} \quad \text{OH} \\
\text{Ph} & \quad \text{NHMe}_2 \quad \text{MeI} \\
\text{Ph} & \quad \text{NMe}_3 \\
\text{O} & \quad \text{CH}_2
\end{align*}
\]
Experiment 5.211 2-OXOUNDEC-3-ENE$^{249}$

\[
\text{Me}^+(\text{CH}_2)_5\text{CH}_2\cdot\text{CHO} + (\text{EtO})_2\text{P(O)}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{Me} \rightarrow \text{Me}^+(\text{CH}_2)_5\text{CH}_2\cdot\text{CH}==\text{CH}\cdot\text{CO}\cdot\text{Me}
\]

Potassium carbonate (8.3 g, 60 mmol) in water (10 ml) is added to a vigorously stirred mixture of octanal (3.84 g, 30 mmol) and diethyl 2-oxopropanephosphonate (7.0 g, 36 mmol) at room temperature. The mixture is stirred for 18 hours at room temperature, water (15 ml) is then added, and the organic phase is extracted with hexane (3 x 25 ml). The extract is dried with magnesium sulphate (1 g), evaporated, and the residue distilled to give 2-oxoundec-3-ene; 4.4 g (87%), b.p. 80–83 °C/0.7 mmHg.

Experiment 5.212 2-ETHYLHEX-2-ENAL

\[2\text{Et} \cdot \text{CH}_2 \cdot \text{CHO} \xrightarrow{\text{EtOH}} \text{Et} \cdot \text{CH}_2 \cdot \text{CH}==\text{C} \cdot (\text{Et}) \cdot \text{CHO}\]

Place 100 ml of 1 M sodium hydroxide solution in a 500-ml three-necked flask fitted with a sealed stirrer unit and an efficient reflux condenser. Heat the solution to 80 °C and attach to the flask a dropping funnel containing 216 g (264 ml, 3.0 mol) of redistilled butyraldehyde (compare Expt 5.74). With vigorous stirring, add the butyraldehyde as rapidly as the efficiency of the reflux condenser will allow and then boil the reaction mixture under reflux for 1 hour. Cool, separate the organic layer and distil it without further treatment under reduced pressure through a fractionating column (e.g. of the Vigreux type). Collect the pure 2-ethylhex-2-enal as a fraction of b.p. 66–67 °C/25 mmHg; the yield is 160 g (85%).

Cognate preparation. 2-Methylpent-2-enal. Add 174 g (215 ml, 3.0 mol) of propionaldehyde with vigorous stirring to 100 ml of 1 M sodium hydroxide solution, but without initial heating, during 15 minutes. Cool rapidly in an ice bath, isolate the organic product with the aid of a little ether and fractionally distil. The yield is 70 per cent; b.p. 38–39 °C/25 mmHg, 136–137 °C/760 mmHg.

Experiment 5.213 MESITYL OXIDE (4-Methylpent-3-en-2-one)

\[\text{Me}_2\text{CO} + \text{Me} \cdot \text{CO} \cdot \text{Me} \xrightarrow{\text{Ba(OH)}_2} \text{Me}_2\text{C(OH)} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{Me} \]

\[\text{Me}_2\text{C(OH)} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{Me} \xrightarrow{\text{heat}} \text{Me}_2\text{C}==\text{CH} \cdot \text{CO} \cdot \text{Me} + \text{H}_2\text{O}\]

4-Methyl-4-hydroxypentan-2-one (diacetone alcohol). Fit a 1-litre round-bottomed flask with a large Soxhlet extractor (Fig. 2.96) and attach an efficient double surface condenser to the latter. Place 595 g (750 ml, 10.25 mol) of commercial acetone, preferably dried over anhydrous potassium carbonate, and a few fragments of porous porcelain in the flask. Select as large a Soxhlet thimble as the extractor will accommodate and three-quarters fill it with barium hydroxide (1). Fill the remaining space in the thimble with glass wool. Insert the charged thimble into the extractor. Heat the flask on a water bath or steam bath so that the acetone refluxes back into the extractor rather rapidly. Continue the heating until the acetone no longer refluxes when the
flask is almost completely immersed in the boiling water bath (72–120 hours). The refluxing may be interrupted at any time for as long as desired without influencing the preparation. Equip the flask with a fractionating column attached to an efficient double surface condenser set for downward distillation. Immerse the flask in an oil bath and raise the temperature gradually to 125°C; maintain this temperature as long as acetone distils over. The recovery of acetone is complete when the temperature at the top of the column is about 70°C. Distil the residue (2) under diminished pressure (3); a little acetone passes over first, followed by the diacetone alcohol at 71–74°C/23 mmHg (or 62–64°C/13 mmHg). The yield is 450 g (75%).

**Mesityl oxide.** Fit a 750-ml round-bottomed flask with a fractionating column attached to a condenser set for downward distillation. Place 400 g (3.44 mmol) of diacetone alcohol (the crude product is quite satisfactory), 0.1 g of iodine and a few fragments of porous porcelain in the flask. Distil slowly with a small free flame (best in an air bath) and collect the following fractions: (a) 56–80°C (acetone and a little mesityl oxide); (b) 80–126°C (two layers, water and mesityl oxide); and (c) 126–131°C, which is almost pure mesityl oxide. Separate the water from fraction (b), dry with anhydrous potassium carbonate or anhydrous sodium sulphate and fractionate from a small flask. A further quantity of mesityl oxide is thus obtained. The total yield is about 320 g (95%).

**Notes.** (1) If crystallised barium hydroxide [Ba(OH)₂·8H₂O] is employed, this becomes dehydrated after one run; the anhydrous compound is just as satisfactory and may be used repeatedly.
(2) The residual liquid contains about 95 per cent of diacetone alcohol and is satisfactory for the preparation of mesityl oxide.
(3) Diacetone alcohol partially decomposes when distilled under normal pressure.

**Experiment 5.214 ERYTHRO- AND THREO-2-(1'-HYDROXYBENZYL) CYCLOHEXANONES**

\[
\text{O} \quad \overset{\text{TMS, Li}_2\text{S}}{\text{Et}_3\text{N}} \quad \text{OSiMe}_3 \quad \overset{(i) \text{TiCl}_4, \text{Ph-CHO}}{\text{(i) H}_2\text{O}} \quad \text{O} \quad \text{OH} \quad \text{Ph}
\]

**1-Trimethylsilyloxy cyclohexene.** To a well-stirred suspension of lithium sulphide (1.5 g, 30 mmol) (1) in dry acetonitrile (25 ml) in a 100-ml round-bottomed flask, fitted with a water condenser and a nitrogen inlet, is added chlorotrimethylsilane (6.3 ml, 50 mmol). To this mixture are added cyclohexanone (1.96 g, 20 mmol) and triethylamine (3 ml, 20 mmol) in succession, and the solution is allowed to stir at room temperature (25°C). The progress of the reaction is monitored by removing aliquots periodically and analysing them after work-up by t.l.c. (silica gel plates with hexane as an eluant). Soon after the completion of the reaction (c. 16 hours), the mixture is taken up in ether (50 ml) and washed thoroughly with ice-cold aqueous 5 per cent hydrochloric acid solution (4 × 50 ml) to remove all basic and water-soluble materials. The ethereal extract is washed with ice-cold aqueous 5 per cent sodium hydrogen carbonate solution (50 ml), water (50 ml), and brine (25 ml). It is dried over anhydrous sodium sulphate and subjected to distillation under
reduced pressure to obtain the crude enol silyl ether. The product is further purified by distillation (b.p. 70–71°C/12 mmHg) to obtain spectrally (p.m.r. and i.r.) pure 1-trimethylsilyloxycyclohexene (95%).

**Erythro- and Threo-2-(1'-Hydroxybenzyl)cyclohexanones.** A dichloromethane (10 ml) solution of 1-trimethylsilyloxycyclohexene (0.426 g, 2.5 mmol) is added dropwise into a mixture of benzaldehyde (0.292 g, 2.75 mmol) and titanium(IV) chloride (0.55 g, 2.75 mmol) (2) in dry dichloromethane (20 ml) under an argon atmosphere at −78°C, and the reaction mixture is stirred for 1 hour. After hydrolysis (with water) at that temperature, the resulting organic layer is extracted with ether, and the extract is washed with water and dried over anhydrous sodium sulphate. The extract is evaporated under reduced pressure, and the residue is purified by column chromatography (silica gel). Elution with dichloromethane affords 115 mg (23%) of erythro-2-(1'-hydroxybenzyl)cyclohexanone, m.p. 103°C (recrystallised from propan-2-ol, m.p. 103.5–104.5°C); i.r. 3530 (OH), 1700 (C=O) cm⁻¹; p.m.r. (CDCl₃, TMS) 1.1–2.7 (broad, 9H, aliphatic CH), 3.05 (s, 1H, OH, exchangeable with D₂O), 5.40 (d, 1H, J = 2.5 Hz, O—CH), and 7.27 (s, 5H, aryl CH).

From the last fraction, 346 mg (69%) of theo-2-(1'-hydroxybenzyl)cyclohexanone are obtained, m.p. 74°C (recrystallised from hexane–ether, m.p. 75°C); i.r. 3495 (OH), 1695 (C=O) cm⁻¹; p.m.r. (CCl₄, TMS) 1.1–2.9 (broad, 9H, aliphatic CH), 3.77 (s, 1H, OH, exchangeable with D₂O), 4.83 (d, 1H, J = 9.0 Hz, O—CH), 7.29 (s, 5H, aryl CH).

**Notes.** (1) Lithium sulphide is obtained from Alfa Ventron. Acetonitrile is purified and stored over molecular sieves.

(2) Titanium(IV) chloride is distilled under an argon atmosphere before use (CAUTION).

### 5.18.3 Unsaturated Acids and Esters

As for the unsaturated carbonyl compounds, the most significant groups are the α,β-unsaturated acids or esters. Some of their methods of formation are closely analogous, for example, (a) the Horner–Emmons or Wadsworth–Emmons reaction, and (b) the aldol-type reactions. Rather more specific methods are considered below for the formation of α,β-acetylenic acids, and for the conversion of the unsaturated dicarboxylic acid, maleic acid, into its anhydride or into fumaric acid.

**The Horner–Emmons or Wadsworth–Emmons Reaction**

This reaction is considered in Sections 5.2.3, p. 496, and 5.18.2, p. 799, and the specific examples that are included in this section are: (i) the formation of ethyl cyclohexyldieneacetate from cyclohexanone and triethyl phosphonoacetate in the solvent 1,2-dimethoxyethane and using sodium hydride as the base for the formation of the phosphoryl-stabilised anion; and (ii) the formation of ethyl (E)-but-2-enoate from acetaldehyde and triethyl phosphonoacetate under PTC conditions (Expt 5.215). In the latter example the (E)-configuration is to be expected from the general features of the reaction that are summarised in Section 5.2.3, p. 496.
THE ALDOL-TYPE REACTIONS
This reaction type leading to \(\alpha,\beta\)-unsaturated acids and esters is exemplified in the Perkin reaction (Section 6.12.3, p. 1036) and the Knoevenagel reaction (Section 5.11.6, p. 681). The Doebner reaction, which is illustrated in this section, is the condensation of an aldehyde with malonic acid in pyridine solution, often in the presence of a trace of piperidine. The reaction mechanism involves the addition of a malonate anion to the aldehydeic carbonyl carbon atom followed by the elimination of water accompanied by decarboxylation.

\[
\begin{align*}
\text{R} & \text{H} \quad \text{CH}_2(\text{CO}_2\text{H})_2 \quad \rightarrow \quad \text{R} \quad \text{OH} \quad \text{CO}_2\text{H} \quad \text{H}_2\text{O} \quad \rightarrow \quad \text{R} \quad \text{CO}_2\text{H}
\end{align*}
\]

Examples given in Expt 5.216 include the preparation of non-2-enoic acid starting from hexanal, but-2-enoic acid (crotonic acid) from acetaldehyde, and also hexa-2,4-dienoic acid (sorbic acid) starting from the conjugated aldehyde crotonaldehyde.

MISCELLANEOUS METHODS
A useful route to \(\alpha,\beta\)-acetylenic acids, illustrated by the preparation of but-2-ynoic acid (Expt 5.217), involves the base-induced decomposition of the dibromopyrazolone which is obtained by brominating pyrazol-5-one, which is itself prepared by the reaction of a \(\beta\)-keto ester with hydrazine.

\[
\begin{align*}
\text{R} \quad \text{CO}_2\text{H} \quad \text{Et} \quad \rightarrow \quad \text{N} \quad \text{H} \quad \text{O} \quad \text{Br} \quad \rightarrow \quad \text{N} \quad \text{H} \quad \text{O} \quad \text{Br} \quad \rightarrow \quad \text{R} \quad \text{C} \equiv \text{C} \quad \text{CO}_2\text{H}
\end{align*}
\]

A likely mechanism for the last stage may be formulated as follows:

\[\text{R} \quad \text{Br} \quad \rightarrow \quad \text{R} \quad \text{Br} \quad \rightarrow \quad \text{R} \quad \text{C} \equiv \text{C} \quad \text{CO}_2\text{H} + \text{N}_2\]

If the bromination of the pyrazol-5-one is interrupted when only one of the methylenic hydrogens has been substituted, and the monobromopyrazol-5-one is similarly treated with alkali, the \(\alpha,\beta\)-ethylenic acid is obtained.

The simplest unsaturated dicarboxylic acids are maleic acid and fumaric acid, both of which are cheap, commercially available, materials. They are geometric isomers; maleic acid is the (Z) isomer (19), and fumaric acid is the (E) isomer (20). Maleic acid forms an internal anhydride, maleic anhydride (21), which is widely used to form adducts with conjugated dienes (the Diels–Alder reaction, Section 7.6). The formation of the anhydride from maleic acid and the conversion of maleic acid into fumaric acid are described in Expt 5.218. The hydrogenation of maleic acid to succinic acid is of value as a means of evaluating the activity of a catalyst for use in hydrogenations at atmospheric pressure; the experimental procedure is given in Section 2.17.1, p. 87.
Experiment 5.215 ETHYL CYCLOHEXYLIDENEACETATE

\[ \text{CAUTION: } \text{Hydrogen gas is evolved in the first part of this experiment, hence the apparatus should be sited in an efficient fume-cupboard.} \]

Triethyl phosphonoacetate (11.2 g, 0.05 mol) is added dropwise at 20 °C to a slurry of 50 per cent sodium hydride (2.4 g, 0.05 mol) in 100 ml of dry 1,2-dimethoxyethane. After the addition, the reaction mixture is stirred for 1 hour at room temperature until gas evolution has ceased. Cyclohexanone (4.9 g, 0.05 mol) is added dropwise at such a rate that the temperature is maintained below 30 °C. After the addition, the solution is stirred for 15 minutes at room temperature during which time a viscous semi-solid appears. The mixture is taken up in a large excess of water, and the aqueous solution extracted with ether. The ether layer, after being dried over magnesium sulphate and evaporated, gives a liquid residue, b.p. 88–90 °C/10 mmHg, 5.8 g (70%), \( n_0^{\text{D}} 1.4704 \). The i.r. spectrum shows a strong absorption band at 1660 cm \(^{-1} \).

Cognate preparation. Ethyl (E)-but-2-enoate \(^{255} \) (PTC procedure). A solution of triethyl phosphonoacetate (35 mmol) and acetaldehyde (35 mmol) in dichloromethane (5 ml) is added dropwise to a stirred two-phase system consisting of dichloromethane (35 ml), aqueous sodium hydroxide (20 ml, 50%), and tetrabutylammonium iodide (0.7 g) (1). The strongly exothermic reaction is complete in 15 minutes. The organic layer is separated, washed with water (5 ml), and dried with magnesium sulphate. Evaporation of the solvent and distillation of the residue affords the product, b.p. 51–52 °C/25 mmHg, in 54 per cent yield.

Note. To avoid undesirable reactions of the aldol-type, both substrates should be added simultaneously to the reaction mixture.

Experiment 5.216 3-HEXYLACRYLIC ACID (Non-2-enoic acid)

\[ \text{Me} \cdot (\text{CH}_2)_5 \cdot \text{CHO} + \text{CH}_2(\text{CO}_2\text{H})_2 \xrightarrow{\text{pyridine}} \text{Me} \cdot (\text{CH}_7)_5 \cdot \text{CH} = \text{CH} \cdot \text{CO}_2\text{H} + \text{CO}_2 + \text{H}_2\text{O} \]

Dissolve 57 g (0.55 mol) of malonic acid in 92.5 ml of dry pyridine contained in a 500-ml round-bottomed flask, cool the solution in ice and add 57 g (70 ml, 0.5 mol) of freshly distilled heptanal with stirring or vigorous shaking. After a part of the aldehyde has been added, the mixture yields a semi-solid slurry of crystals. Insert a calcium chloride tube into the mouth of the flask and allow the mixture to stand at room temperature for 60 hours with periodic shaking. Finally, warm the mixture on a water bath until the evolution
of carbon dioxide ceases (about 8 hours) and then pour into an equal volume of water. Separate the oily layer and shake it with 150 ml of 25 per cent hydrochloric acid to remove pyridine. Dissolve the product in benzene, wash with water, dry with anhydrous sodium sulphate and distil under reduced pressure. Collect the nonenoic acid at 130–132 °C/2 mmHg. The yield is 62 g (79%).

Cognate preparations. Crotonic acid [(E)-But-2-enoic acid]. Mix together in a 250-ml flask carrying a reflux condenser and a calcium chloride drying tube 25 g (32 ml, 0.57 mol) of freshly distilled acetaldehyde with a solution of 59.5 g (0.57 mol) of dry, powdered malonic acid in 67 g (68.5 ml, 0.85 mol) of dry pyridine to which 0.5 ml of piperidine has been added. Leave in an ice chest or refrigerator for 24 hours. Warm the mixture on a steam bath until the evolution of carbon dioxide ceases. Cool in ice, add 60 ml of 1:1 sulphuric acid (by volume) and leave in the ice bath for 3–4 hours. Collect the crude crotonic acid (c. 27 g) which has separated by suction filtration. Extract the mother-liquor with three 25 ml portions of ether, dry the ethereal extract, and evaporate the ether; the residual crude acid weighs 6 g. Recrystallise from light petroleum, b.p. 60–80 °C; the yield of crude crotonic acid, m.p. 72 °C, is 20 g (41%).

Sorbic acid (Hexa-2,4-dienoic acid). Place 40 g (46.5 ml, 0.57 mol) of crotonaldehyde (b.p. 101–103 °C), 60 g (0.575 mol) of malonic acid and 60 g (61 ml, 0.76 mol) of dry pyridine (b.p. 113–115 °C) in a 500-ml round-bottomed flask, attach a reflux condenser and heat on a water bath for 3 hours. At the end of this period the vigorous evolution of carbon dioxide will have ceased. Cool the mixture in ice and cautiously acidify it by the addition of a solution of 21.3 ml of concentrated sulphuric acid in 50 ml of water with shaking. Most of the sorbic acid separates out immediately; a more complete separation is obtained by cooling the solution in ice for 3–4 hours. Filter the acid at the pump and wash it with a little ice-cold water. Recrystallise from about 125 ml of boiling water; the maximum recovery of purified acid is achieved by leaving the solution in an ice chest or a refrigerator overnight and then filtering. The yield of sorbic acid, m.p. 134 °C, is 20 g (31%).

Experiment 5.217 BUT-2-YNOIC ACID

\[
\text{MeC}==\text{C}==\text{O} \xrightarrow{\text{NH}_2\cdot\text{NH}_3} \text{Me} \xrightarrow{\text{Br}_2} \xrightarrow{\ominus\text{OH}} \text{Me} \cdot \text{C}==\text{C} \cdot \text{CO}_2\text{H} \]

3-Methylpyrazol-5-one. Place 65 g (0.5 mol) of ethyl acetoacetate in a conical flask and stir magnetically during the slow dropwise addition of a solution of 25 g (0.5 mol) of hydrazine hydrate (98–100%) in 40 ml of absolute ethanol. The temperature rises during this addition which should be regulated so that a temperature of about 60 °C is maintained; a crystalline deposit separates.
After further stirring for 1 hour at room temperature, cool the reaction mixture in an ice bath to complete the crystallisation, and filter. Wash the product with ice-cold ethanol; it is then pure enough for use in the next stage. The yield is 43 g (90%), m.p. 222°C (phase change at 195°C; microscope m.p. apparatus).

**4,4-Dibromo-3-methylpyrazol-5-one.** Dissolve 20.0 g (0.2 mol) of 3-methylpyrazol-5-one in 80 ml of glacial acetic acid and stir magnetically during the slow dropwise addition of a solution of 32 g (0.2 mol) of bromine in 20 ml of glacial acetic acid (1). On completion of this addition, add 50 ml of water and continue the dropwise addition of a further 32 g (0.2 mol) of bromine dissolved in 20 ml of glacial acetic acid. On completion of this second addition of bromine solution allow the mixture to stand at room temperature overnight. Add water to precipitate the dibromopyrazolone, filter and wash the solid product under suction with distilled water until the washings are neutral. The air-dried product, sufficiently pure for use in the next stage, has m.p. 130–132°C, the yield is 41 g (79%).

**But-2-ynoic acid.** Prepare a solution of 20 g of sodium hydroxide in 500 ml of water and stir magnetically in an ice bath until the temperature reaches 0–5°C. Add portionwise over 10 minutes 34 g (0.132 mol) of 4,4-dibromo-3-methylpyrazol-5-one. The bromoketone dissolves to give an orange–red solution which evolves nitrogen gas; the temperature of the solution during the addition shows only a slight tendency to rise. Stir the reaction mixture for 1 hour at 0–5°C and then at room temperature for 1 hour. Cool the solution again and acidify it with concentrated hydrochloric acid. Continuously extract the acidified solution with ether overnight (Section 2.22), dry the ethereal extract with magnesium sulphate and remove the solvent on a rotary evaporator. Place the flask containing the orange oil in a vacuum desiccator and allow to stand until it solidifies. Extract the orange crystalline deposit with successive portions of boiling light petroleum (b.p. 60–80°C) and concentrate the combined extracts to about 50 ml. Filter the slightly off-white product, m.p. 74–75°C; recrystallise by dissolving in the minimum volume of light petroleum (b.p. 80–100°C), adding an equal volume of light petroleum (b.p. 40–60°C) and allowing to cool. The pure but-2-ynoic acid has m.p. 75–76°C, the yield is 5.9 g (54%). The i.r. spectrum shows absorption at 2950 (broad, —OH), 2240 (sharp, disubstituted —C==C—), 1690 cm⁻¹ (broad, —C==O in carboxylic acid).

**Note.** (1) Removal of a portion of the reaction mixture when 1 mol of bromine has been added and addition to it of water results in the precipitation of the monobromo compound, m.p. 180–182°C.

**Experiment 5.218 FUMARIC ACID AND MALEIC ANHYDRIDE**

![Diagram of Fumaric Acid and Maleic Anhydride conversion](image)

**Conversion of maleic acid into fumaric acid.** Dissolve 10 g of maleic acid in
10 ml of warm water, add 20 ml of concentrated hydrochloric acid and boil gently under reflux for 30 minutes. Crystals of fumaric acid soon crystallise out from the hot solution. Allow to cool, filter off the fumaric acid and recrystallise it from hot 1 m hydrochloric acid. The m.p. in a sealed capillary tube is 286–287°C.

**Conversion of maleic acid into maleic anhydride. CAUTION:** All operations must be conducted in an efficient fume cupboard, owing to the highly toxic nature of the solvent. Mix 100 g of maleic acid with 1,1,2,2-tetrachloroethane (100 ml) in a distillation flask fitted with a Claisen still-head, a thermometer and a condenser set for downward distillation. Heat the mixture on an air bath; when the temperature reaches 150°C, 75 ml of 1,1,2,2-tetrachloroethane and between 15 and 15.5 ml of water are present in the receiver. Continue the distillation using an air condenser and change the receiver flask when the temperature reaches 190°C. Collect the maleic anhydride at 195–197°C. Recrystallise the crude anhydride from chloroform. The yield of pure maleic anhydride, m.p. 54°C, is 70 g (83%).

### 5.19 Resolution of Racemates

The development of the various strategies for the synthesis of optically active compounds in high enantiomeric excess has made great advances over the last decade or so (p. 15). Nevertheless, resolution is still necessary to prepare optically pure chiral auxiliaries, to purify products of low enantiomeric excess and as a valid strategy for chiral synthesis in its own right. The most important general procedure for such resolutions, originally proposed and explored by Pasteur, involves the conversion of the mixture of enantiomers into a pair of diastereoisomeric derivatives by reaction with a pure, optically active, reagent, e.g.

\[
2(\pm)-X + 2(+-)-Y \rightarrow (+-)-X(+-)Y + (-)-X(+-)Y
\]

(1) (2) (3)

It should be recalled that whereas the enantiomers in the mixture (or racemate) (1) have identical physical properties (except for their action on the plane of polarised light), the diastereoisomers (2) and (3) have physical properties (e.g. solubility, boiling points, chromatographic behaviour, etc.) which are frequently significantly different. Resolution of the mixture (or racemate) can then be achieved provided that one of the diastereoisomers may be obtained in a pure state, and that regeneration from it of the pure enantiomorphous form is not accompanied by any degree of racemisation.

Pasteur's original chemical method of resolution, which is still widely used at the present time, involves the formation of diastereoisomeric salts from racemic acids or bases by neutralisation with available optically pure bases or acids respectively. The required optically pure reactants are often available from natural sources and include tartaric, malic and mandelic acids, and alkaloids such as brucine, strychnine, morphine and quinine. Ideally, by appropriate choice of the resolving reagent, the diastereoisomeric salts are crystalline and have solubilities sufficiently different to permit the separation and ready purification of the less soluble salt by fractional crystallisation from a suitable solvent. The regeneration of the optically pure enantiomorph, and incidentally the recovery of the resolving reagent, normally presents no problems.
The procedure is illustrated in Expt 5.219 by the resolution of $(\pm)$-α-methylbenzylamine (1-phenylethylamine) with the aid of tartaric acid.

The Pasteur method can also be applied to the resolution of neutral racemates, if these can be first converted into an acidic or basic derivative from which eventually a mixture of crystalline diastereoisomeric salts may be prepared by appropriate neutralisation. Thus, a racemic alcohol (e.g. $(\pm)$-octan-2-ol, Expt 5.220) may be converted into the corresponding racemic hydrogen phthalate ester by heating with phthalic anhydride, and the ester is then resolved by the Pasteur procedure using an optically active base. The resulting optically active hydrogen phthalate ester is then carefully hydrolysed with aqueous sodium hydroxide to regenerate one of the optically active forms of the alcohol.

\[
\begin{align*}
\text{H}_3\text{C}_6\text{O} & \quad \text{Me} \\
\text{Me} & \quad \text{OH} \\
\rightarrow & \quad \text{C}_6\text{H}_{13}\text{Me} \\
\text{Me} & \quad \text{CO}_2\text{H} \\
\end{align*}
\]

A racemic aldehyde or ketone may similarly be resolved by conversion into a diastereoisomeric mixture of hydrazones (or semicarbazones) using, for example, the optically active 1-phenylethyldrazine.$^{256}$

The most important development in the last decade for the resolution of mixtures of enantiomers is in the application of g.l.c. and h.p.l.c. techniques. These techniques have been used in the analytical mode to determine the ratio of enantiomers, for example in the case of products arising from an asymmetric synthesis. Indeed this method of analysis has several advantages over the conventional procedure of optical rotation measurement and comparison with the maximum known rotation of one of the pure enantiomers (p. 34). Thus the analysis is rapid and is feasible on quantities of sample which would be inadequate for measurement of optical rotation. These chromatographic methods may also be used in the preparative mode for the realistic isolation of the pure enantiomers. Furthermore, by a close study of the chromatographic behaviour (i.e. elution times) of a series of enantiomeric pairs of compounds having like functionality and known configurations, some judgement is possible for the assignment of configuration to a similar member of the series but of unknown configuration.
Both techniques can be applied in two ways. In the first method the enantiomeric mixture (or racemate) is converted into a diastereoisomeric mixture with a suitable optically pure reagent, and this mixture chromatographed on a column having an achiral stationary phase. Separation then depends on the differential molecular interactions of the diastereoisomers with the stationary phase. In the second method, the stationary phase on the support material (usually chemically bonded) contains a chiral, optically pure residue. In this case the mixture of enantiomers which is loaded directly on to the column is separated by virtue of differential diastereoisomeric molecular interactions between each enantiomer and the optically pure stationary phase.

Research in this area of resolution methods was first in g.l.c. However, the need to derivatise many of the compounds of interest to make them sufficiently volatile for analysis tended to increase the complexity of sample preparation. High performance liquid chromatography does not have this drawback (p. 232) and research activity in this field is now extensive. One illustrative example of the elegance of this technique is noted here257 but the reader’s attention is directed to an excellent summary to 1983 of both these chromatographic methods.258

A commercially packed h.p.l.c. column (25 cm × 4.6 mm) of γ-aminopropyl silanised silica [e.g. 5 μm Spherisorb (Regis Chemical Co.), or 7 μm Zorbax (Dupont Co.), or 10 μm Lithosorb (Merck), or 5 μm irregular (J. T. Baker Chemical Co.)] was sequentially treated, at a pumping rate of 2 ml/min, with the following solutions: 2 ml of triethylamine in 40 ml of dry tetrahydrofuran, 2 g of (R)-N-(3,5-dinitrobenzoyl)phenylglycine in 40 ml of dry tetrahydrofuran, 20 ml of dry tetrahydrofuran, and finally 10 per cent propan-2-ol in hexane, until the base line stabilises. The chiral amino acid derivative (which is available from Aldrich Chemical Co.) becomes ionically bonded to the amino residues on the stationary phase.

This chiral column has been shown successfully to resolve enantiomeric mixtures (or racemates) of aromatic alcohols including 1,1′-bi-2-naphthol and its analogues (p. 836), aromatic hydroxy (or alkoxy) carboxylic esters and amides, amino acid derivatives, sulphoxides, cyclic imides and amides, lactones, etc. Even this list should not be regarded as limiting. The potential of this method, coupled with the simplicity of operation will undoubtedly be extensively developed and explored in the coming years.

Other chiral immobilised stationary phases are available commercially, for example covalently bonded bovine serum albumin or chemically bonded L-hydroxyproline–Cu²⁺ complexes to wide-bore Nucleosil (both from Macherey-Nagel).

Several useful methods of resolution, which are particularly applicable to the x-amino acids, involve the use of enzymes. Their success depends upon the fact that enzyme-catalysed reactions are stereospecific, only one of the enantiomorphous forms (actually the form having the ‘natural’, L, configuration) taking
part in the reaction. For example, the conversion of an acyl-L-amino acid (best results are usually obtained with the benzoyl derivative) into the corresponding anilide by reaction with aniline in a buffered medium* is catalysed by the enzyme papain which occurs in papaya latex. Therefore, if the racemic acylamino acid is used, only the L-form is converted into the neutral anilide which can be readily separated from the unreacted acidic D-form.

\[
\begin{align*}
2 \text{H}_2\text{N}\text{CO}_2\text{H} \quad (\text{DL}-) & \quad + \quad \text{PhNH}_2 \quad \xrightarrow{\text{papain}} \quad 2 \text{H}_2\text{N}\text{CO}_2\text{H} \quad (\text{L}-) \\
& \quad + \quad \text{R}^1\text{R}^2\text{NH}_2\text{CO}_2\text{H} \quad (\text{D}-)
\end{align*}
\]

This method represents a resolution by asymmetric enzymic synthesis (e.g. L-alanine, \(\text{H}_2\text{N}\text{CH(CH}_3\text{)}\text{CO}_2\text{H}\), Expt 5.221). Related procedures involve other types of enzymic reactions (e.g. hydrolysis, oxidation, etc.). Asymmetric enzymic hydrolysis, for example, proceeds according to the following reaction sequence.

\[
\begin{align*}
2 \text{H}_2\text{N}\text{CO}_2\text{H} \quad (\text{DL}-) & \quad \xrightarrow{(\text{MeCO})_2\text{O}} \quad 2 \text{Me}\text{CO}_2\text{H} \quad (\text{DL}-) \\
& \quad + \quad \text{R}^1\text{R}^2\text{NH}_2\text{CO}_2\text{H} \quad (\text{L}-) \\
& \quad + \quad \text{Me}\text{NH}_2\text{CO}_2\text{H} \quad (\text{D}-)
\end{align*}
\]

**Experiment 5.219** RESOLUTION OF (±)-α-METHYLBENZYLAMINE [(±)-1-Phenylethylamine]

(−)-α-Methylbenzylamine. Add 450 ml of methanol to 31.5 g (0.21 mol) of (+)-tartaric acid in a 1-litre conical flask and heat the mixture almost to boiling on a water bath. Then add cautiously with swirling 24.2 g (0.20 mol) of (±)-α-methylbenzylamine (Expt 5.197); too rapid an addition may cause the mixture to boil over. Allow the mixture to cool to room temperature and then to stand for 24 hours to allow slow separation of the (−)-amine-(+)-hydrogen tartrate as prismatic crystals (1). Filter off the product (17.9 g); concentrate the filtrate to 225 ml under reduced pressure on a rotary evaporator and allow it to stand at room temperature for 24 hours to obtain a second crop. The total yield of the (−)-amine-(+)-hydrogen tartrate is about 21 g (77%).

Shake the total product with 90 ml of water in a 250-ml separating funnel and basify the mixture by cautiously adding 50 per cent aqueous sodium hydroxide. Extract out the liberated amine with three 40 ml portions of ether, dry the extract over anhydrous sodium sulphate, filter and concentrate to about 25 ml using a rotary evaporator. Remove the remainder of the ether in

* The optimum pH of the buffer varies within the approximate range 4.5–5.5 depending upon the substrate used.
a distillation apparatus and fractionally distil the residue at atmospheric pressure (2), collecting the (+)-α-methylbenzylamine as a fraction of b.p. 184–186 °C; the yield is about 5 g (53%). Measure the optical rotation of the neat liquid and calculate the specific rotation (Section 2.36). Pure (+)-α-methylbenzylamine has $d^2_2 0.950$, $[\alpha]_B^2 - 40.3^\circ$ (neat); $[\alpha]_B^{20} - 31.5^\circ$ (c 3.2 in EtOH).

(+)-α-Methylbenzylamine. This enantiomer may be recovered using the following procedure. Evaporate the methanolic filtrate from the isolation of the (-)-amine salt to dryness using a rotary evaporator. Convert the residual salt to the free amine by treatment with sodium hydroxide solution followed by ether extraction as described above. Do not distil the recovered amine but remove the last traces of ether completely by warming under reduced pressure. Weigh the resulting product (x g), measure its optical rotation and calculate the specific rotation. The ratio of this value to that of pure (+)-amine is the optical purity of the sample; the weight of (+)-amine in the sample in excess of that present in the racemic modification is given by:

$$\text{excess (+)-amine} = \frac{x \times \text{observed } [\alpha]_B \text{ for neat liquid}}{40.3} \text{ grams}$$

For each gram of excess (+)-amine present add firstly 10.0 ml of rectified spirit, bring to the boil and then add, for each gram, a hot solution of 0.44 g of 98 per cent sulphuric acid (1.03 times the theoretical amount) in 21.5 ml of rectified spirit. Allow the solution to cool slowly to room temperature, filter off the crystalline (+)-amine sulphate and wash it with cold rectified spirit. The yield is about 1 g of sulphate per gram of (+)-amine (71%). Liberate the free (+)-amine from the sulphate as described for the (-)-amine from the tartrate, but use 4 ml of water and 0.5 ml of 50 per cent aqueous sodium hydroxide for each gram of sulphate. The yield of (+)-amine, b.p. 184–186 °C, is 60 per cent of theory; its optical purity is 95 per cent.

Notes. (1) If fine needles separate, the mixture should be warmed until they redissolve, and the solution allowed to cool. The solution should be seeded with the prismatic crystals if these are available.

(2) The free amine rapidly absorbs carbon dioxide. It is therefore essential to protect the distillation apparatus from the atmosphere with a guard-tube filled with soda-lime. As the product tends to foam excessively during distillation, the apparatus used should be larger than is customary for the volume of liquid to be distilled.

**Experiment 5.220** RESOLUTION OF (±)-OCTAN-2-OL*

Heat a mixture of 65 g (0.5 mol) of dry octan-2-ol (b.p. 178–180 °C), 74 g (0.5 mol) of pure phthalic anhydride (1) and 40 g of dry pyridine (CAUTION) on a water bath for 1 hour, and allow to cool. Dissolve the resulting viscous mass in an equal volume of acetone. Add slowly, preferably with stirring, 55 ml of concentrated hydrochloric acid diluted with an approximately equal volume of crushed ice: if an oil separates before all the hydrochloric acid has been added, introduce more acetone to render the mixture homogeneous. Add ice-water until the oil is completely precipitated; this usually sets to a hard mass within 1–2 hours. If the resulting mass is semi-solid or pasty (2),

* The following experimental details were kindly supplied by the late Dr J. Kenyon F.R.S.
transfer it to a large flask and pass steam through it until the octan-2-one is removed, i.e. until the steam distillate is clear; pour the contents of the flask while still warm into a beaker. The \( (\pm)-2 \)-octyl hydrogen phthalate solidifies on cooling. Filter the octyl hydrogen phthalate at the pump, wash it with water, grind it thoroughly in a mortar with water, filter again and dry in the air. The crude material is quite satisfactory for the subsequent resolution (3).

Introduce 197 g (0.5 mol) of anhydrous brucine (CAUTION: poisonous) or 215 g of the air-dried dihydrate (4) into a warm solution of 139 g of \( (\pm)-2 \)-octyl hydrogen phthalate in 300 ml of acetone and warm the mixture under reflux on a water bath until the solution is clear. Upon cooling, the brucine salt \((+)-A\), \((-)-B\) separates as a crystalline solid. Filter this off on a sintered glass funnel, press it well to remove mother-liquor and wash it in the funnel with 123 ml of acetone. Set the combined filtrate and washings (W) aside. Cover the crystals with acetone and add, slowly and with stirring, a slight excess (to Congo red) of dilute hydrochloric acid (1:1 by volume; about 60 ml); if the solution becomes turbid before the introduction of the acid is complete, add more acetone to produce a clear liquid. Add ice-water until the precipitation of the active 2-octyl hydrogen phthalate [crude \((+)-A\)] is complete; filter (5), wash with cold water and dry in the air. The yield is about half that of the \((\pm)-\)ester originally taken (6).

Concentrate the combined filtrate and washings (W) to about half the original volume, and pour it into slightly more than the calculated amount of dilute hydrochloric acid (use a mixture of 30 ml of concentrated hydrochloric acid and 30 ml of ice-water); then add about 300 ml of water. Collect the active 2-octyl hydrogen phthalate (crude \((-)-A\)) as above (5). The weight of the air-dried solid is about half that of the \((\pm)-\)ester originally used (7).

Crystallise the two lots of crude active 2-octyl hydrogen phthalates separately twice from 90 per cent acetic acid; use 2 g of acetic acid to each gram of solid. The recrystallised esters, if optically pure (8), will melt sharply at 75°C; if the melting points are below 75°C, further recrystallisation is necessary. The yields of optically pure products, m.p. 75°C, are 48 g and 49 g respectively.

To obtain optically pure \((+)-\) and \((-)-\)octan-2-ol, steam distil the respective esters with 30 per cent sodium hydroxide solution; use the proportions 1 mol of ester to 2 mols of sodium hydroxide. Separate the alcohols from the steam distillate, dry over anhydrous potassium carbonate and distil under diminished pressure. Both samples boil at 86°C/20 mmHg (9) and have the following rotations:

\[ \alpha^\circ_{D} = 9.9°, \alpha^\circ_{D} = 11.8°, \alpha^\circ_{D} = 9.9°, \alpha^\circ_{D} = 11.8°. \]

The yields from the 2-octyl hydrogen phthalates are almost quantitative.

Notes. (1) If the presence of phthalic acid is suspected, it may be readily removed by mixing with cold chloroform; phthalic anhydride dissolves readily, but the acid is insoluble.

(2) This is due to octan-2-one in the original octan-2-ol; it is most easily separated by steam distillation as described.

(3) The inactive 2-octyl hydrogen phthalate may be recrystallised from light petroleum, b.p. 60–80°C, or from glacial acetic acid, and then melts at 55°C. If the octan-2-ol is pure, the yield of pure material is almost quantitative.
(4) Commercial brucine is usually the tetrahydrate C_{23}H_{26}O_{4}N_{2},4H_{2}O; upon air drying, this loses two molecules of water of crystallisation and passes into the dihydrate.

(5) The filtrates from the decomposition of the brucine salts with dilute hydrochloric acid should be carefully preserved. The brucine is recovered by the addition of an excess of dilute ammonia solution (1:4); if the solution becomes turbid before all the ammonia solution is added, introduce a little ethanol until the solution becomes clear.

After several hours in an open beaker, filter off the brucine, wash it well with cold water and dry it in the air.

(6) The rotation in absolute ethanol is about \([\alpha]_D +44^\circ, [\alpha]_{5461} +47^\circ\).

(7) The rotation in absolute ethanol is about \([\alpha]_D -44^\circ, [\alpha]_{5461} -47^\circ\).

(8) The optically pure esters have rotations in ethanol of \([\alpha]_D -48.4^\circ, [\alpha]_{5461} -58.5^\circ\), and \([\alpha]_D +48.4^\circ, [\alpha]_{5461} +58.5^\circ\) respectively. A preliminary check of the optical purity is, however, more simply made by a m.p. determination; the rotation is determined, if desired, when the m.p. is 75°C.

(9) The boiling point under atmospheric pressure is 179°C.

Experiment 5.221 RESOLUTION OF DL-ALANINE

Benzoyl DL-alanine. Dissolve 100 g (1.1 mol) of DL-alanine (Expt 5.180) in 400 ml of water containing 44.5 g (1.1 mol) of sodium hydroxide and cool the solution in an ice bath. Add 175 g (1.2 mol) of benzoic chloride and a solution of 49 g (1.2 mol) of sodium hydroxide in 200 ml of water to the stirred, cooled, amino acid solution, alternately and in portions during 2 hours; continue to stir for a further 2-hour period. Boil the reaction mixture with 10 g of decolourising charcoal, filter, cool the clear yellow filtrate to 0°C and acidify carefully to Congo red with concentrated hydrochloric acid. Triturate a portion of the oil which separates with water to induce crystallisation and then seed the bulk of the acidified solution with crystals and leave in an ice bath to complete the crystallisation process. Filter off the product, wash the filter cake with 500 ml of ice-cold water and recrystallise from about 3.5 litres of boiling water. The yield of benzoyl-DL-alanine, m.p. 162–164°C, is 194.5 g (90%).

Benzoyl-L-alanine anilide. Use freshly boiled, cooled, distilled water throughout this stage. Prepare an 0.1 M citrate buffer solution by dissolving 48 g of anhydrous citric acid and 16.5 g of sodium hydroxide in 2.5 litres of water. Stir together 50 g of technical powdered papain (1) and 4 g of potassium cyanide in 500 ml of the buffer solution, adjust the pH to 5 (narrow range pH paper) with glacial acetic acid, and stir for a further 75 minutes. Filter this enzyme extract through a Celite filter bed. Dissolve 193 g (1 mol) of benzoyl-DL-alanine by warming it in 300 ml of the citrate buffer to which has been added 120 ml of 2.5 molar sodium hydroxide, 360 ml of 3 M sodium acetate solution and 93 g (91 ml, 1 mol) of redistilled aniline; adjust the pH of this solution to 5 with sodium hydroxide solution. Cool the solution to 45°C, add the filtered enzyme extract and transfer the mixture to several conical flasks of suitable size such that each is filled to the neck and tightly stoppered with a rubber bung to exclude air. Leave the flasks in an incubator held at 37°C, shaking them occasionally during the early stages.

Product begins to separate within 5 minutes and the contents of the flasks becomes almost immobile within 2 hours. After 24 hours filter the mixture and return the filtrate to the incubator for a further 24 hours and remove the additional crop of solid which separates. Wash the combined solids with
250 ml of water and recrystallise from 1 litre of 50 per cent aqueous ethanol with the aid of decolourising charcoal. The yield of benzyol-L-alanine anilide is 122 g (91%), m.p. 175–176 °C, [α]D 18° = 7.8° (c 5 in Me-CO₂H).

L-Alanine. Heat a mixture of 50 g (0.187 mol) of benzyol-L-alanine anilide and 250 ml of 6 M hydrochloric acid under reflux for 5 hours. Leave the mixture at room temperature overnight, remove the precipitated benzoic acid by filtration and evaporate the filtrate to dryness under reduced pressure (rotary evaporator). Dissolve the brown oily residue in 100 ml of water and boil it with decolourising charcoal. Filter and pass the filtrate through 450 g of a weakly basic anion exchange resin, e.g. Amberlite IR4B (which has been washed free from soluble colour with dilute hydrochloric acid and regenerated with dilute aqueous ammonia) in the form of a column 60 cm long. Collect the effluent (in all about 2 litres) until it gives no colour when boiled with ninhydrin (Expt 5.99). Evaporate the effluent to dryness under reduced pressure (rotary evaporator) and boil the yellow solid residue with 20 ml of water and a little decolourising charcoal. Add ethanol to the hot filtered solution until crystallisation begins and cool in ice to complete the separation of the L-alanine. The yield is 13.9 g (76%), [α]D 18° + 12.0° (c 4 in 1 M HCl).

Note. (1) An inexpensive crude commercial product (dried papaya latex) was used; the activity was not determined. Purified highly active enzyme preparations may, however, be obtained²⁸⁹ (e.g. Koch–Light, Sigma, etc.).

6.1 AROMATIC HYDROCARBONS

Benzene (1) is the simplest aromatic hydrocarbon upon which our knowledge of aromatic chemistry is based. This hydrocarbon, the alkylbenzenes (2), the arylmethanes [e.g. diphenylmethane (3)], the biphenyls [e.g. biphenyl (4)] and the condensed polycyclic systems [e.g. naphthalene (5) and anthracene (6)] all exhibit chemical reactivity and spectroscopic features which are markedly different from their aliphatic and alicyclic hydrocarbon counterparts. Indeed the term aromatic character was introduced to specify the chemistry of this group of hydrocarbons and their substituted functional derivatives, and it was soon used to summarise the properties of certain groups of heterocyclic compounds having five- and six-membered ring systems and the associated condensed polycyclic analogues (Chapter 8).

The crucial structural feature which underlies the aromatic character of benzenoid compounds is of course the cyclic delocalised system of six $\pi$-electrons. Other carbocyclic systems similarly possessing this 'aromatic sextet' of electrons include, for example, the ion C$_5$H$_5^-$ formed from cyclopentadiene under basic conditions. The cyclopentadienide anion is centrosymmetrical and strongly resonance stabilised, and is usually represented as in (7). The analogous cycloheptatrienylum (tropylium) cation (8), with an aromatic sextet delocalised over a symmetrical seven-membered ring, is also demonstrably aromatic in character. The stable, condensed, bicyclic hydrocarbon azulene (C$_{10}$H$_8$) possesses marked aromatic character; it is usually represented by the covalent structure (9). The fact that the molecule has a finite dipole moment, however, suggests that the ionic form (10) [a combination of (7) and (8)] must contribute to the overall hybrid structure.
SPECTROSCOPIC FEATURES

Aromatic hydrocarbons give rise to spectra which differ markedly from those of aliphatic and alicyclic hydrocarbons owing to the mesomeric stabilisation of the aromatic ring system. In the i.r. absorption spectrum of an aromatic hydrocarbon there are four wavenumber regions which should be inspected to provide definitive evidence for the presence of an aromatic nucleus, and for the possible state of substitution: (a) at c. 3050 cm\(^{-1}\) (C\(_{\text{AR}}\)—H stretching); (b) at 1600, 1590, 1500 and 1450 cm\(^{-1}\) (ring-breathing vibrations); (c) at 650–820 cm\(^{-1}\) (C\(_{\text{AR}}\)—H out-of-plane vibrations); and (d) at 2000–1600 cm\(^{-1}\) (summation bands) (p. 278). The p.m.r. spectrum (e.g. Fig. 3.42 of toluene) also provides definitive evidence of the presence of an aromatic nucleus, since the aromatic protons are deshielded by the induced ring current sustained by the \(\pi\)-electrons and they appear as signals at c. \(\delta\) 7.00 (p. 325). The \(^{13}\)C-n.m.r. is discussed on p. 329 (see also Fig. 3.43). The u.v.–visible spectrum is more useful in the aromatic field than the aliphatic, since the energy associated with the \(\pi\)-electron transitions is markedly affected by the presence of a fused ring system or of substituent interaction in a mesomeric or inductive manner (p. 390). The profile of the m.s. of an aromatic compound also provides invaluable confirmation of the presence of an aromatic nucleus in that the relative abundance of the molecular ion and closely associated fragment ions is usually high compared to the low relative abundance found in the aliphatic series (p. 368).

The isomeric xylenes provide a useful illustration of these spectroscopic features. Thus the i.r. spectrum of o-xylene (Fig. 3.16) shows absorption bands at c. 3050 cm\(^{-1}\) and c. 2950 cm\(^{-1}\) for the stretching vibrations of the aromatic and aliphatic carbon-bound hydrogens respectively. The ring-breathing vibrations are found at 1600, 1590, 1500 cm\(^{-1}\) (the 1450 cm\(^{-1}\) band is obscured by the methyl deformation absorption). The meta and para isomers show almost identical absorptions in these regions. However, the absorption in the 700–800 cm\(^{-1}\) region clearly defines the state of substitution; for the ortho isomer the band at c. 740 cm\(^{-1}\) indicates four adjacent hydrogens; for the meta isomer the bands are at c. 690 and 770 cm\(^{-1}\) for three adjacent hydrogens and at c. 870 cm\(^{-1}\) for one lone hydrogen; for the para isomer the band at c. 790 cm\(^{-1}\) indicates two adjacent hydrogens. The three isomers each give a characteristic pattern in the summation band region when the spectra are appropriately recorded. The p.m.r. spectra of the three isomers do not clearly define the substitution pattern, the aromatic protons appearing as a four-proton singlet in the spectra of the ortho and para isomers, and as a multiplet in the case of the meta isomer. The m.s. of these isomers are very similar (ortho isomer, Fig. 3.76) and may be interpreted as m/z 106 (M), 105 (M – H), 91 (M – Me, base peak), 65 (91 – C\(_2\)H\(_2\)), 77 (91 – CH\(_2\)), 51 (77 – C\(_2\)H\(_2\)) and 39 (65 – C\(_2\)H\(_2\)).
The synthesis of aromatic hydrocarbons (arenes) is for convenience organised under the following five headings.

1. Alkylbenzenes (Expts 6.1 to 6.5).
2. Di- and triarylmethanes (Expts 6.6 and 6.7).
3. Biphenyl systems (Expts 6.8 to 6.10, see also Expt 6.79).
5. Some non-benzenoid systems (Expts 6.15 and 6.16).

### 6.1.1 ALKYLBENZENES

The synthesis of alkylbenzenes may be classified under: (a) the Wurtz–Fittig reaction; (b) the reduction of aryl aldehydes and ketones; and (c) and Friedel-Crafts alkylation reaction.

#### SUMMARY OF RETROSYNTHETIC STRATEGIES

\[
\begin{align*}
R^\ominus CH_2 & \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ Ph^\ominus CH_2,Na + RX \\
R^\ominus CH_2X + Ph^\ominus Na^\ominus & \ \ \ \ \ \ \ \ \ Ph\cdot CH_2Na + RX \\
R^\ominus CH_2 & \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ PhH + R\cdot COCl
\end{align*}
\]

**The Wurtz–Fittig reaction** (cf. the Wurtz reaction, Section 5.1.4, p. 478). The interaction of an aryl halide, an alkyl halide and sodium gives a reasonable yield of an alkylbenzene.

\[
ArBr + RBr + 2Na \rightarrow Ar\cdot R + 2NaBr
\]

The by-products of the reaction, e.g. R—R and Ar—Ar, can usually readily be separated by distillation.

A likely mechanism for this reaction involves the formation of an arylsodium and its subsequent reaction with the alkyl halide.

\[
ArBr + 2Na \rightarrow Ar^\ominus Na^\ominus + NaBr
\]

\[
Ar^\ominus R^\ominus Br \rightarrow Ar\cdot R + :Br
\]

The reaction of the arylsodium with the more reactive alkyl bromide occurs in preference to reaction with the less reactive aryl bromide, which would lead to
the biaryl Ar—Ar. Furthermore, the formation of the aryl anion, which is likely to be stabilised by electron delocalisation, probably occurs more readily than the formation of the alkyl anion by reaction of the sodium with the alkyl bromide. For these reasons acceptable yields of the alkylbenzene are usually obtained.

Better yields of alkylbenzenes result if the arylsodium is first prepared and then subjected to a suitable alkylation reaction. In the preparative example of butylbenzene (Expt 6.1), benzylsodium is conveniently obtained by first forming phenylsodium by reaction between sodium and chlorobenzene in a toluene medium, and then heating the toluene suspension of the phenylsodium at 105 °C for about 35 minutes when a transmetalation process occurs (formulated at the beginning of Expt 6.1).

The Grignard reagent derived from benzyl chloride undergoes ready alkylation with an alkyl toluene-p-sulphonate, a reaction which provides a further useful synthesis of an alkylbenzene (e.g. penty1benzene, Expt 6.2).

\[
\text{Ph} \cdot \text{CH}_2 \cdot \text{Cl} \xrightarrow{\text{Mg}} \text{Ph} \cdot \text{CH}_2 \cdot \text{MgCl} \xrightarrow{2 \text{i} \cdot \text{Me} \cdot \text{C}_6 \text{H}_4 \cdot \text{SO}_2 \cdot \text{R}} \text{Ph} \cdot \text{CH}_2 \cdot \text{R} + \text{RCl}
\]

The reduction of aldehydes and ketones. Aromatic hydrocarbons are the main products when aromatic aldehydes or ketones are reduced with amalgamated zinc and concentrated hydrochloric acid (the Clemmensen reduction, e.g. hexylbenzene, Expt 6.3).

\[
\text{Ar} \cdot \text{CO} \cdot \text{R} \rightarrow \text{Ar} \cdot \text{CH}_2 \cdot \text{R}
\]

Some features of the Clemmensen reduction are discussed in Section 5.1.3, p. 476. Purely aromatic ketones generally do not give satisfactory results: pinacols and resinous products often predominate. The reduction of ketonic compounds of high molecular weight and very slight solubility is facilitated by the addition of a solvent, such as ethanol, acetic acid or dioxane, which is miscible with aqueous hydrochloric acid. With some carbonyl compounds, notably keto acids, poor yields are obtained even in the presence of ethanol, etc., and the difficulty has been ascribed to the formation of insoluble polymolecular reduction products, which coat the surface of the zinc. The addition of a hydrocarbon solvent, such as toluene, is beneficial because it keeps most of the material out of contact with the zinc and the reduction occurs in the aqueous layer at such a high dilution that polymolecular reactions are largely inhibited (see Expt 6.123).

Aryl alkyl ketones are readily prepared by the Friedel–Crafts acylation process (see Section 6.11.1, p. 1006) and their Clemmensen reduction constitutes a more efficient procedure for the preparation of monoalkylbenzenes than the alternative direct Friedel–Crafts alkylation reaction (see below). Alternatively aldehydes and ketones may be reduced to the corresponding hydrocarbon by the Wolff–Kishner method which involves heating the corresponding hydrazone or semicarbazone with potassium hydroxide or with sodium ethoxide solution.

\[
\text{Ar} \cdot \text{CO} \cdot \text{R} \xrightarrow{\text{NH}_2} \text{Ar} \cdot \text{(R)C} = \text{N} \cdot \text{NH}_2 \xrightarrow{\text{KOH}} \text{Ar} \cdot \text{CH}_2 \cdot \text{R}
\]

The Huang–Minlon modification of the reaction has the following advantages: (i) the actual isolation of the hydrazone is unnecessary; (ii) the reaction time is considerably reduced; (iii) the reaction can be carried out at atmospheric pressure and on a large scale and; (iv) the yields are usually excellent. The
Hydrazone is first formed *in situ* by refluxing a solution of the carbonyl compound in a moderate amount of diethylene glycol or triethylene glycol with the commercial 85 or 90 per cent hydrazine hydrate and about 3 equivalents of potassium hydroxide for 1 hour; the water and excess of hydrazine are removed by distillation until a favourable temperature for the decomposition of the hydrazone is attained (170–190°C) and the solution is refluxed for 3–5 hours longer.

An alternative milder procedure is the reduction of the corresponding toluene-<s>p-sulphonylhydrazones</s> with catecholborane, followed by decomposition of the intermediate with sodium acetate in the presence of dimethyl sulphoxide, or with tetrabutylammonium acetate. These methods, which do not have the disadvantages of the Clemmensen reduction, are illustrated by the preparation of ethylbenzene from acetophenone (Expt 6.4, Methods A and B).

Outline mechanisms for these reactions are given below.

\[
\begin{align*}
R_2C=NH_2 & \xrightarrow{-H^+} [R_2C=N-NH]^+ \xrightarrow{-H^++H^=} R_2CH-N=N^\ominus \\
R_2CH-N=N^\ominus & \xrightarrow{-N_2} R_2CH^\ominus \xrightarrow{+H^=} R_2CH_2 \\
R_2C=N-NHTs & \xrightarrow{\text{O,BH}} \xrightarrow{\text{Ts} = O_2S\cdot C_6H_4\cdot Me} R_2C-N-NHTs \xrightarrow{\text{AcO}} R_2CH-N-NHTs \xrightarrow{\text{O,BH}} R_2CH-N-NHTs \\
& \xrightarrow{-\text{Ts}} R_2CH-N=N-H \xrightarrow{-N_2} R_2CH^\ominus \xrightarrow{+H^=} R_2CH_2
\end{align*}
\]

The Friedel–Crafts alkylation reaction. An alkyl halide reacts with an aromatic hydrocarbon in the presence of aluminium chloride to yield in the first instance a hydrocarbon, thus:

\[
\text{ArH} + \text{RX} \xrightarrow{\text{AlCl}_3} \text{Ar-R} + \text{HX}
\]

The reaction does not, however, stop at the stage of mono-substitution, since the alkylbenzene (Ar-R) initially produced undergoes alkylation more easily than the original hydrocarbon ArH, owing to the electron-releasing effect of the alkyl group. Mixtures of substances therefore often result and extensive purification may be required in order to isolate the monosubstituted compound. Some mono-alkylbenzenes may be prepared by using an excess of the hydrocarbon, which also acts as a diluent in moderating the violence of the reaction and prevents the undue formation of poly-alkylbenzenes.

The mechanism of the reaction is generally considered to proceed by way of carbocations which attack the aromatic nucleus:

\[
\begin{align*}
\text{R-X:} \xrightleftharpoons{\text{AlCl}_3} & \xrightarrow{\ominus} \text{R}^\ominus[\text{XAlCl}_3]^\ominus \xrightleftharpoons{\ominus} \xrightarrow{\ominus} \text{R}^\ominus + [\text{XAlCl}_3]^\ominus \\
\xrightarrow{\ominus} & \xrightarrow{[\text{XAlCl}_3]^\ominus} \text{R}^\ominus + \text{HX} + \text{AlCl}_3
\end{align*}
\]
In many cases the alkyl group may undergo extensive skeletal rearrangement under the reaction conditions employed. For example, when benzene is alkylated with propyl chloride in the presence of aluminium chloride over a wide temperature range, a mixture of propylbenzene and isopropylbenzene, in approximately 1:2 ratio, is obtained. On the other hand isobutyl bromide or chloride with benzene in the presence of aluminium chloride gives exclusively t-butylbenzene. This alkylbenzene is, however, more conveniently prepared by using t-butyl chloride as the alkylating reagent (Expt 6.5).

The rearrangement processes mentioned above involve a 1,2-nucleophilic shift of a hydride ion to form a more stable secondary or tertiary carbocation.

\[
\begin{align*}
\text{Me}^+\text{CH}_2\text{CH}_2\text{H} & \rightarrow \text{Me}^+\text{C}^\circ\text{Me} \\
\text{Me}^+\text{CH}_2\text{CH}_2\text{H} & \rightarrow \text{Me}^+\text{C}^\circ\text{Me}
\end{align*}
\]

Other catalysts which may be used in the Friedel–Crafts alkylation reaction include iron(III) chloride, antimony pentachloride, zirconium tetrachloride, boron trifluoride, zinc chloride and hydrogen fluoride but these are generally not so effective in small-scale preparations. The alkylating agents include alkyl halides, alcohols and alkenes.

Experiment 6.1 BUTYLBENZENE (2-Phenylbutane)

\[
\text{PhCl} + 2\text{Na} \rightarrow \text{PhNa} + \text{Ph}^+\text{CH}_2\text{Na} + \text{PrBr} \rightarrow \text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{Pr}
\]

Equip a 500-ml three-necked flask as detailed for p-toluic acid (Expt 6.158, Method A) and pass a slow stream of nitrogen through the apparatus. Charge the flask with 150 ml of sodium-dried, sulphur-free toluene (Section 4.1.3, p. 398) and 13.8 g (0.6 mol) of sodium wire. Place 34 g (31 ml, 0.3 mol) of chlorobenzene in the dropping funnel and add it dropwise through the condenser during 1 hour, with vigorous stirring, while maintaining the temperature inside the flask at 30–35°C. The start of the reaction is indicated by the appearance of black specks on the sodium surface. (If the reaction is slow to start, it may be instantly initiated by a few drops of butanol.) Complete the formation of phenylsodium by stirring for 2–3 hours at 30°C. Attach a calcium chloride tube to the top of the reflux condenser and reflux the mixture for 40 minutes. The reflux temperature, initially 107°C, gradually falls to 103°C as benzene is formed by the exchange reaction. Remove the heating bath and add 27.6 g (20.5 ml, 0.224 mol) of redistilled propyl bromide during 20–25 minutes at 103–105°C; the reaction is strongly exothermic. Allow the reaction mixture to cool to room temperature: maintain the stirring and the slow stream of nitrogen. Add water slowly to destroy the excess of sodium. Separate the toluene layer, dry it (magnesium sulphate) and distil it through a short, jacketed column filled with glass helices (19 cm packed length, 14 mm diameter; compare Fig. 2.104). After removal of the toluene (up to 111°C) and a small intermediate fraction (111–179°C), pure butylbenzene passes over at 179.5–181°C/752 mmHg (23 g, 77%). A brown residue (4 g) remains in the flask.

The i.r. spectrum shows absorptions at c. 3050 and 2950 cm\(^{-1}\) for the aromatic and alkyl carbon–hydrogen stretching vibrations respectively, at
1600, 1590 and 1500 cm\(^{-1}\) for the ring breathing vibrations (the 1450 cm\(^{-1}\) absorption is obscured by the alkyl carbon–hydrogen deformation vibrations), at c. 700 and 750 cm\(^{-1}\) characteristic of monosubstitution, and well-defined summation bands at 1600–2000 cm\(^{-1}\). The p.m.r. spectrum (CCl\(_4\), TMS), shows signals at \(\delta\) 0.92 (t, 3H, Me), 1.10–1.80 (m, 4H, \(-\text{CH}_2\text{CH}_2\)-), 2.58 (t, 2H, ArCH\(_2\)) and 7.09 (s, 5H, C\(_{\text{Ar}}\)-H). The m.s. shows significant fragment ions at \(m/z\) 134 (M), 105 (M – C\(_2\)H\(_5\)), 91 (M – C\(_3\)H\(_7\), base peak), and 65 (91 – C\(_2\)H\(_2\)).

**Experiment 6.2 PENTYLBENZENE (1-Phenylpentane)**

\[
\text{Ph}\cdot\text{CH}_2\text{Cl} \xrightarrow{\text{Mg}} \text{Ph}\cdot\text{CH}_2\text{MgCl} \xrightarrow{2\{p\text{-Me}\cdot\text{C}_6\text{H}_4\cdot\text{SO}_3\text{Bu}\}} \text{Ph}\cdot\text{CH}_2\cdot\text{Bu} + \text{BuCl}
\]

In a 1500-ml three-necked flask equipped with a dropping funnel, a sealed stirrer unit and a double surface condenser to which is attached a guard-tube filled with a mixture of calcium chloride and soda-lime, prepare an ethereal solution of benzylmagnesium chloride from 24.3 g (1 mol) of clean, dry magnesium turnings (under 100 ml of anhydrous ether) and a solution of 126.5 g (115 ml, 1 mol) of freshly distilled benzyl chloride in 500 ml of anhydrous ether. Use a crystal of iodine as a catalyst and proceed as described under the general procedure noted in Expt 5.39. Finally, cool the flask by immersion in a bath of ice-water. Place a solution of 456 g (2 mol) of butyl toluene-\(p\)-sulphonate (Expt 6.46) in about twice the volume of anhydrous ether in the dropping funnel, and add it slowly to the vigorously stirred benzylmagnesium chloride solution, at such a rate that the ether just boils; a white solid soon forms. The addition is complete after about 2 hours. Pour the reaction product slowly into a mechanically stirred mixture of 1 kg of finely crushed ice, 1 litre of water and 125 ml of concentrated hydrochloric acid contained in a 4- or 5-litre beaker; the precipitated magnesium toluene-\(p\)-sulphonate will ultimately pass into the solution. Separate the ether layer, extract the aqueous layer with 250 ml of ether and wash the combined ether solutions with about 100 ml of water. Dry the ether solution with about 10 g of anhydrous potassium carbonate. Distil off the ether on a rotary evaporator, add to the mixture 5–7 g of sodium cut into small pieces and heat under reflux for about 2 hours in order to remove any benzyl alcohol which may have formed by atmospheric oxidation of benzylmagnesium chloride. Decant the solution and distil it from an air bath through a well-lagged and efficient fractionating column; collect the fraction, b.p. 190–210\(^\circ\)C. Redistil and collect the pentylnzene at 198–203\(^\circ\)C. The yield is 90 g (61%).

Record the i.r. spectrum and the p.m.r. spectrum and assign the absorptions using the spectra quoted above for butylbenzene (Expt 6.1) as a guide. Interpret the m.s. which shows principal fragment ions at \(m/z\) 148, 105, 91, 77 and 65.

**Experiment 6.3 HEXYLBENZENE (1-Phenylhexane)**

\[
\text{Ph} \xrightarrow{\text{Zn/Hg}} \text{Ph} \xrightarrow{\text{HCl}} \text{Pr}
\]

Clemmensen reduction. Prepare 200 g of amalgamated zinc in a 2-litre three-necked flask as detailed in Section 4.2.80, p. 467. Fit the flask with a reflux
condenser, a sealed stirrer and a gas entry tube reaching to within 1 cm of the bottom; connect the last-named through an intermediate empty wash bottle to a Kipp's apparatus supplying hydrogen chloride gas (Section 4.2.38, p. 438). Place a mixture of 500 ml of concentrated hydrochloric acid and 100 ml of water in the flask and introduce 100 g (0.57 mol) of 1-phenylhexan-3-one (Expt 5.93). Stir the mixture and pass a slow stream of hydrogen chloride gas while warming the flask on a suitable wire gauze by means of a small flame. If the reaction becomes unduly vigorous, stop the supply of hydrogen chloride until it subsides somewhat. Most of the zinc dissolves after 6 hours, by which time the reaction is almost complete; allow to stand overnight. Arrange the apparatus for steam distillation (Fig. 2.102) and pass steam into the flask, heated by means of a small flame, until the distillate is clear. Separate the upper hydrocarbon layer, wash it with 5 per cent sodium hydroxide solution, then with water and dry over magnesium sulphate. Distil from a 100 ml flask and at 218–230°C collect the crude hexylbenzene, which contains some unsaturated compounds. These can be removed by repeated shaking with 5 per cent of the volume of concentrated sulphuric acid until the latter is colourless or, at most, very pale yellow. The hydrocarbon is then washed with 5 per cent sodium carbonate solution, then with water and dried over magnesium sulphate. It is then distilled twice from sodium when pure hexylbenzene, b.p. 220–225°C is obtained. The yield is 40 g (43%).

**Experiment 6.4 ETHYLBENZENE**

\[
\text{Ph} \cdot \text{CO} \cdot \text{Me} + \text{NH}_2 \cdot \text{NHX} \xrightarrow{\text{Method (A)}} \text{Ph} \cdot \text{C}(= \text{N} \cdot \text{NHX}) \cdot \text{Me} \xrightarrow{\text{Method (B); KOH, HI}} \text{Ph} \cdot \text{CH}_2 \cdot \text{Me}
\]

**Method A. Huang–Minlon modification of the Wolff–Kishner reduction.** Place 36.0 g (0.3 mol) of redistilled acetophenone, b.p. 201°C, 300 ml of diethylene glycol, 30 ml of 90 per cent hydrazine hydrate (CAUTION) and 40 g of potassium hydroxide pellets in a 500-ml two-necked round-bottomed flask fitted with a reflux condenser; insert a thermometer supported in a screwed-capped adapter in the side-neck so that the bulb dips into the reaction mixture. Warm the mixture on a boiling water bath until most of the potassium hydroxide has dissolved and then heat under reflux for 1 hour either by means of a free flame or by using a heating mantle. Remove the reflux condenser and fit a still-head and condenser for downward distillation. Distil until the temperature of the liquid rises to 175°C (1). Separate the upper hydrocarbon layer from the distillate and extract the aqueous layer twice with 20 ml portions of ether. Dry the combined upper layer and ethereal extracts with magnesium sulphate, remove the ether on a water bath and distil the residue. Collect ethylbenzene at 135–136°C; the yield is 20 g (62.5%).

The i.r. spectrum shows absorptions at c. 3050 and 2950 cm⁻¹ for the stretching of the aromatic and alkyl carbon–hydrogen bonds respectively. Monosubstitution is confirmed from the absorption at c. 690 and 745 cm⁻¹ arising from five adjacent hydrogens. The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 1.19 (q, 3H, Me), 2.53 (t, 2H, CH₂) and 7.07 (s, 5H, C₅H₅—H). The ¹³C-n.m.r. spectrum (CDCl₃, TMS) shows signals at δ 15.8, 29.1, 125.8, 127.9, 128.4 and 144.1.
Note. (1) The reduction takes place at a comparatively low temperature and is fairly rapid for acetophenone. With higher ketones, the upper layer of the distillate should be returned to the contents of the flask and the heating under reflux continued for 3–5 hours. The reaction mixture and the aqueous distillate are then combined, extracted with ether and the ether extract treated as described above.

Method B. The toluene-$p$-sulphonylhydrazone of acetophenone (0.721 g, 2.5 mmol) (1), m.p. 140–141.5°C, is placed in a flame-dried, nitrogen-filled flask containing 5 ml of chloroform. Catecholborane (0.52 ml, 5.0 mmol) (Section 4.2.7, p. 420) is added and the reduction allowed to proceed for 2 hours at room temperature (2). Methanol (1 ml) is added to destroy the excess of hydride followed by the addition of tetrabutylammonium acetate (0.7 g, 2.5 mmol). The reaction mixture is stirred for 4 hours when g.l.c. analysis indicates a 94 per cent yield of ethylbenzene. The product is isolated by distillation, yield 0.21 g (79%), b.p. 132–136°C.

Notes. (1) The general procedure for the preparation of toluene-$p$-sulphonylhydrazones is given in Expt 5.6.
(2) The reaction may be monitored by removing aliquot portions with a syringe, mixing with deuterochloroform in an n.m.r. tube, and recording the spectra.

Experiment 6.5 t-BUTYLBENZENE (2-Methyl-2-phenylpropane)

$$\text{Me}_3\text{CCl} + \text{PhH (excess)} \xrightarrow{\text{AlCl}_3} \text{Ph}\cdot\text{CMe}_3$$

**CAUTION:** This preparation should be conducted in an efficient fume cupboard.

Into a 1-litre three-necked flask, equipped as in Expt 6.121, place 50 g (0.33 mol) of anhydrous aluminium chloride (1) and 200 ml (2.25 mol) of dry benzene (CAUTION); cool in a bath of crushed ice. Stir the mixture and add 50 g (59 ml, 0.54 mol) of t-butyl chloride (Expt 5.49) from the dropping funnel during 4–5 hours; the first addition should be 3–4 ml in order to prevent the benzene from freezing. Maintain the mixture at a temperature of 0–5°C by the addition of salt to the ice, if necessary. When all the t-butyl chloride has been run in, continue the stirring for 1 hour longer. Remove the separatory funnel and add 200 g of finely crushed ice in small portions with stirring; finally add 100 ml of cold water to complete the decomposition of the intermediate addition compound. Arrange the flask for steam distillation (Fig. 2.102) and steam distil the resulting reaction mixture. Transfer the steam distillate to a separatory funnel, remove the upper hydrocarbon layer, extract the water layer with two 50 ml portions of ether and combine the extracts with the upper layer. Dry with magnesium sulphate, distil off the ether on a water bath and fractionally distil the residue twice, using a well-lagged column (Fig. 2.104). Collect the t-butylbenzene at 165–170°C. The yield is 45 g (62%). Pure t-butylbenzene boils at 168.5°C.

Note. The characteristic absorptions for the aromatic system at c. 3050 cm$^{-1}$, at 1600, 1590 and 1500 cm$^{-1}$ and at c. 700 and 765 cm$^{-1}$ for a monosubstituted nucleus. The t-butyl group shows characteristic carbon–hydrogen stretching absorptions at c. 2950 cm$^{-1}$.

Note. In an alternative procedure 25 g of anhydrous iron(III) chloride replace the aluminium chloride, the mixture is cooled to 10°C and the 50 g of t-butyl chloride are added. The mixture is slowly warmed to 25°C and maintained at this temperature until no more hydrogen chloride is evolved. The reaction mixture is then washed with...
dilute hydrochloric acid and with water, dried and fractionally distilled. The yield of t-butyl benzene, b.p. 167–170 °C, is 60 g.

### 6.1.2 DI- AND TRIARYLMETHANES

Alkylation with benzyl chloride by the Friedel–Crafts procedure yields diphenylmethane (Expt 6.6). The reactive nature of the halide obviates the need for heating the reaction mixture, and a smaller proportion of aluminium chloride is employed compared to the standard conditions as illustrated by Expt 6.5.

A Friedel–Crafts reaction between chloroform and an excess of benzene affords a convenient route to triphenylmethane (cognate preparation in Expt 6.6).

$$3\text{PhH} + \text{CHCl}_3 \rightarrow \text{Ph}_3\text{CH}$$

The synthesis of the triptycene system illustrates a synthetic use of the important reactive intermediate benzyne (13) which is generated by the thermal decomposition of benzenediazonium-2-carboxylate (see Section 6.5.3, p. 900). The latter is produced when anthranilic acid (11) is treated with an alkyl nitrite in an aprotic solvent, and probably exists mainly as the zwitterionic form (12).

The benzyne functions as a dienophile towards reactive diene systems. The reactivity of the 9,10-positions in anthracene is well known (Diels–Alder reaction, Section 7.6), and addition of benzyne to 9-bromoanthracene yields the interesting cage-ring alkyl halide: 9-bromotriptycene (9-bromo-9,10-o-benzoanthracene). The reaction is incomplete and some unreacted 9-bromoanthracene remains in the crude reaction products, but may be removed by virtue of its ready conversion into a maleic anhydride adduct in a further Diels–Alder-type reaction.

The environment of the halogen in the ring structure renders it almost unreactive in displacement reactions by nucleophiles.

#### Experiment 6.6 DIPHENYL METHANE

$$\text{Ph} \cdot \text{CH}_2\text{Cl} + \text{PhH} \text{ (excess)} \xrightarrow{\text{AlCl}_3} \text{Ph} \cdot \text{CH}_2 \cdot \text{Ph}$$

**CAUTION:** This preparation should be conducted in an efficient fume cupboard.

Fit a 500-ml three-necked round-bottomed flask with a sealed mechanical stirrer, attach a gas absorption device to one of the side-necks and stopper the third neck. Place 38 g (35 ml, 0.3 mol) of redistilled benzyl chloride and 150 ml of dry benzene (CAUTION) (Section 4.1.2, p. 398) in the flask. Weigh out 2 g (0.015 mol) of anhydrous aluminium chloride (Section 4.2.3, p. 416) into a dry capped specimen tube with the minimum exposure to the atmosphere. Cool the flask in a bath of crushed ice and add about one-fifth of the aluminium chloride. Stir the mixture; a vigorous reaction will set in within a few minutes and hydrogen chloride is evolved. When the reaction has subsided, add a
further portion of the aluminium chloride and repeat the process until all has been introduced. The mixture should be kept well shaken and immersed in the ice bath during the addition. After 15 minutes cautiously add 100 g of crushed ice, followed by 100 ml of water in order to decompose the aluminium complex. Shake the mixture well, transfer to a separatory funnel and run off the lower aqueous layer. Wash the upper layer successively with dilute hydrochloric acid and water and dry it with anhydrous calcium chloride. Remove the benzene with the aid of the apparatus shown in Fig. 2.101. Distil the remaining liquid through an air condenser either with a free flame or from an air bath. Collect the diphenylmethane at 250–275 °C (the pure substance boils at 262 °C) (1). The distillate should solidify on cooling in ice and scratching with a glass rod, or by seeding with a crystal of the pure material. If it does not crystallise, redistil from a small flask and collect the fraction, b.p. 255–267 °C; this generally crystallises on cooling and has m.p. 24–25 °C. The yield is 25 g (50%).

Note. (1) Alternatively the distillation may be conducted under diminished pressure; the fraction, b.p. 125–130 °C/10 mmHg, is collected.

Cognate preparation. Triphenylmethane. The apparatus is similar to that described above, but incorporating a reflux condenser to the outlet of which is fitted the gas absorption device. Place a mixture of 200 g (230 ml, 2.57 mol) of dry benzene (CAUTION) and 40 g (26 ml, 0.33 mol) of dry chloroform (CAUTION) (Section 4.1.6, p. 399) in the flask, and add 35 g (0.26 mol) of anhydrous aluminium chloride in portions of about 6 g and at intervals of 5 minutes with constant stirring. The reaction sets in upon the addition of the aluminium chloride and the liquid boils with the evolution of hydrogen chloride. Complete the reaction by refluxing for 30 minutes on a water bath. When cold, pour the contents of the flask very cautiously on to 250 g of crushed ice and 10 ml of concentrated hydrochloric acid. Separate the upper benzene layer, dry it with anhydrous calcium chloride or with magnesium sulphate and remove the benzene by flash distillation (Fig. 2.101). Attach a Claisen still-head connected to a short air condenser and distil the remaining oil under reduced pressure; collect the fraction, b.p. 190–215 °C/10 mmHg. This is crude triphenylmethane which solidifies on cooling. Recrystallise it from about four times its weight of ethanol; triphenylmethane separates in needles and melts at 92 °C. The yield is 30 g (37%).

Experiment 6.7 9-BROMOTRIPTYCENE

Place 2.3 g (0.02 mol) of isopentyl nitrite (isoamyl nitrite), 2.6 g (0.01 mol) of 9-bromoanthracene and 25 ml of 1,2-dimethoxyethane (‘glyme’, Section
4.1.18, p. 406) in a 250-ml round-bottomed flask fitted with a reflux condenser. Heat the mixture to gentle reflux on an electric mantle and add down the condenser, dropwise during 30 minutes, a solution of 3.4 g (0.025 mol) of anthranilic acid in 15 ml of glyme. Remove the mantle, cool the mixture to about 40°C and add 2.3 g more of isopentyl nitrite dissolved in 5 ml of glyme. Resume the gentle refluxing and add during 15 minutes another solution of 3.4 g of anthranilic acid in 10 ml of glyme. Heat for an additional 15 minutes, add 10 ml of 95 per cent ethanol and pour the reaction mixture into a solution of 3.0 g of sodium hydroxide in 100 ml of water. Cool the resulting brown suspension thoroughly in ice-water and filter under suction. Wash the residue with a chilled methanol/water mixture (4:1 v/v) and transfer to a 100-ml round-bottomed flask which is then evacuated (rotary evaporator) on a steam bath until the weight is constant.

To the flask containing the crude product, add 2.0 g (0.02 mol) of maleic anhydride and 25 ml of triethyleneglycol dimethyl ether ('triglyme', b.p. 222°C), fit a reflux condenser and boil under reflux for 10 minutes over a Bunsen flame. Cool the solution to about 100°C, add 10 ml of 95 per cent ethanol and pour into a solution of 3.0 g of sodium hydroxide in 75 ml of water. Stir for a few minutes, then cool in ice-water and filter under suction. Wash the residue with chilled methanol/water (4:1 v/v) and recrystallise from methylecyclohexane or a chloroform/methanol mixture to give colourless plates of 9-bromotriptycene, m.p. 251–256°C; yield is 1.5 g (45%). Further recrystallisation gives the pure product, m.p. 258–262°C.

### 6.1.3 BIPHENYL SYSTEMS

A reaction which is reminiscent of the Wurtz coupling procedure, and which is particularly valuable in the synthesis of biphenyl and its symmetrically substituted derivatives, is that of Ullmann. It involves heating an aryl halide with copper powder, or better, with activated copper bronze.

\[
2\text{ArX} + 2\text{Cu} \rightarrow \text{Ar} - \text{Ar} + 2\text{CuX}
\]

Aryl iodides and bromides are more reactive than the corresponding chlorides but the latter may be used when activating substituents (e.g. the nitro group) are present, as for example in the synthesis of 2,2'-dinitrobiphenyl (Expt 6.8). The coupling reaction can be effectively carried out in the absence of a solvent, but the use of dimethylformamide as a solvent and diluent often results in an increase of yield, particularly in the case of reactive halides, when the vigour of the exothermic reaction is moderated.

The symmetrically substituted biphenyl system is also formed when aryl radicals generated from an appropriate precursor are allowed to undergo a self-coupling process. An interesting reaction involving the use of the diazonium salt derived from anthranilic acid affords an excellent method of preparing biphenyl-2,2'-dicarboxylic acid (diphenic acid, Expt 6.9). The diazotised anthranilic acid is reduced with the aid of a cupro-ammonia reagent obtained by dissolving copper(II) sulphate in aqueous ammonia and treating the solution with hydroxylamine hydrochloride.

\[
2\text{Ar}^\cdot \quad +2e^- \quad \rightarrow \quad 2\text{Ar}^\cdot + 2\text{N}_2
\]

\[
2\text{Ar}^\cdot \rightarrow \quad \text{Ar} - \text{Ar}
\]
Unsymmetrically substituted biphenyls may be prepared from diazonium salts by means of the Gomberg–Bachmann–Hey reaction. Some preparative examples of the classical method and of a PTC procedure are described in Expt 6.79.

Reactive aromatic systems, in particular phenols, readily undergo oxidation by a single electron transfer process, leading to a mesomerically stabilised radical species, which then dimerises. The coupling of phenols in this way is frequently encountered in biogenetic pathways leading to naturally occurring molecules. A reaction illustrative of the process is the oxidation of 2-naphthol with iron(III) chloride (Expt 6.12) to give 2,2'-dihydroxy-1,1'-binaphthyl (1,1'-bi-2-naphthol).

\[
\begin{align*}
\text{OH} & \xrightarrow{-e} \text{O} \\
\text{O} & \xrightarrow{-2H^+ + 2H^+} \text{OH} \\
\end{align*}
\]

This compound, in common with other suitable substituted biphenyls, possesses a chiral axis (p. 6) and is isolated from the reaction as a racemate. Although several resolution procedures have been reported, the superior method to date is that in which the binaphthol is first converted by treatment with phosphorus oxychloride into the binaphthyl phosphoric acid (14). Resolution is then effected by formation of diastereoisomeric salts with (+)-cinchonine, appropriate fractional crystallisation and recovery of the (S)-(+-)-binaphthyl phosphoric acid. Suitable hydrolysis gives (S)-(+-)-1,1'-bi-2-naphthol (15).

Earlier attempts to effect an asymmetric coupling to mimic biological coupling reactions by using chiral copper(II)–amine complexes gave only low enantiomeric excesses. The use of (S)-(+-)-amphetamine sulphate \([\text{Ph-CH}_2\cdot\text{CH(NH}_3\cdot\text{Me})\cdot\text{HSO}_4]\) with copper(II) nitrate was more successful in that the (S)-(+-)-enantiomer (15) was formed in 85 per cent chemical yield and 95 per cent optical purity. (S)-(+-)-10,10'-Dihydroxy-9,9'-biphenanthryl has been similarly prepared from the coupling of 9-phenanthrol, using (R)-(+-)-1,2-diphenylethylamine and copper(II) nitrate. Enantioselective syntheses of
binaphthyls using chiral oxazolines in the coupling reaction have also been reported. These chiral biaryls may be complexed with metal hydrides and used in the chiral reduction of, for example, the carbonyl group (p. 521).

Experiment 6.8 2,2’-DINITROBIPHENYL

\[ \text{NO}_2 \text{Cl} \xrightarrow{\text{Cu bronze}} \text{NO}_2 \text{NO}_2 \]

Place 50 g (0.32 mol) of o-chloronitrobenzene and 75 g of clean dry sand in a 250-ml three-necked flask equipped with a mechanical stirrer and an air reflux condenser. Heat the mixture in an oil or fusible metal bath to 215–225°C and add, during 40 minutes, 50 g (0.78 mol) of copper bronze or, better, of activated copper bronze (Section 4.2.19, p. 426) (1). Maintain the temperature at 215–225°C for a further 90 minutes and stir continuously. Pour the hot mixture into a Pyrex beaker containing 125 g of sand and stir until small lumps are formed; if the reaction mixture is allowed to cool in the flask, it will set to a hard mass, which can only be removed by breaking the flask. Break up the small lumps by powdering in a mortar, and boil them for 10 minutes with two 400 ml portions of ethanol; filter after each extraction. Cool the filtered extracts in ice, and collect the crude product on a Buchner funnel. Concentrate the filtrate to about half the original volume and thus obtain a second crop of crystals. The total yield of crude solid should be about 24 g; if it is less than this, a third extraction of the reaction product should be made. Dissolve the crude solid in about 400 ml of hot ethanol, add a little decolourising charcoal, boil for a few minutes, filter and cool in ice. Recrystallise again from hot ethanol. The yield of pure 2,2’-dinitrobiphenyl, m.p. 123–124°C, is 20–22 g (54%).

The experimental conditions for conducting the above reaction in dimethylformamide as solvent are as follows. In a 250-ml three-necked flask, equipped with a reflux condenser and a tantalum wire Hershberg-type stirrer, place 20 g of o-chloronitrobenzene and 100 ml of dimethylformamide (dried over anhydrous calcium sulphate). Heat the solution to reflux and add 20 g of activated copper bronze in one portion. Heat under reflux for 4 hours, add another 20 g portion of copper powder and continue refluxing for a second 4-hour period. Allow to cool, pour the reaction mixture into 2 litres of water and filter with suction. Extract the solids with three 200 ml portions of boiling ethanol; alternatively, use 300 ml of ethanol in a Soxhlet apparatus. Isolate the 2,2’-dinitrobiphenyl from the alcoholic extracts as described above: the yield of product, m.p. 124–125°C, is 11.5 g (75%).

**Note.** (1) If the temperature is allowed to rise above 240°C, reduction of the nitro groups will occur and carbazole will be formed.

Experiment 6.9 BIPHENYL-2,2’-DICARBOXYLIC ACID (Diphenic acid)

\[
\begin{align*}
2 \text{CO}_2\text{H} & \xrightarrow{\text{NaNO}_2, \text{HCl}} 2 \text{N}=\text{N}\text{Cl} \\
& \xrightarrow{2\text{Cu}^{II}, \text{NH}_3} \text{HO}_2\text{C} & \text{CO}_2\text{H}
\end{align*}
\]
The reducing agent (a solution containing cupro-ammonia ions) is first prepared. Dissolve 63 g (0.25 mol) of crystallised copper(ii) sulphate in 250 ml of water in a 1-litre beaker, add 100 ml of concentrated ammonium hydroxide solution (d 0.88) and cool the solution to 10 °C. Dissolve 17.8 g (0.256 mol) of hydroxylammonium chloride or 21 g (0.256 mol) of hydroxylammonium sulphate in 60 ml of water, cool to 10 °C and add 42.5 ml of 6 m sodium hydroxide solution; if the resulting solution of hydroxylamine is not clear, filter it at the pump. Without delay add the hydroxylamine solution, with stirring, to the ammoniacal copper(ii) sulphate solution. Reduction occurs at once, a gas is evolved and the solution assumes a pale blue colour. Protect the reducing agent from the air if it is not used immediately.

Grind 25 g (0.18 mol) of anthranilic acid (Expt 6.53) with 46 ml of concentrated hydrochloric acid and 75 ml of water in a glass mortar, and transfer the suspension to a 500-ml round-bottomed flask which is provided with a mechanical stirrer. Cool the contents of the flask in an ice bath to 0–5 °C, and add a solution of 13.0 g (0.19 mol) of sodium nitrite in 175 ml of water from a dropping funnel during about 20 minutes. Keep the diazonium solution below 5 °C and, if it is not clear, filter it by suction through a chilled Buchner funnel immediately before use.

Surround the reducing solution in the 1-litre beaker (which is equipped with a mechanical stirrer) with a bath of crushed ice so that the temperature of the solution is about 10 °C. Attach, by means of a short length of rubber tubing, to the stem of a dropping funnel a glass tube which dips well below the surface of the solution and is bent upwards at the end and constricted so that the opening is about 2 mm (this arrangement ensures that the diazonium solution reacts with the ammoniacal solution in the beaker and prevents the latter rising in the stem of the funnel). Place about 45 ml of the cold diazonium solution in the funnel and add it at the rate of about 10 ml per minute while the mixture is stirred. Add the remainder of the diazonium solution at the same rate; continue the stirring for 5 minutes after the addition is complete. Heat the solution rapidly to boiling and carefully acidify with 125 ml of concentrated hydrochloric acid; the diphenic acid precipitates as pale brown crystals. Allow to stand overnight and filter with suction; wash the crude diphenic acid with about 25 ml of cold water. Suspend the crude acid in 100 ml of water and add 20 g of solid sodium hydrogen carbonate. Filter the resulting solution by gravity, and then boil with about 0.5 g of decolourising carbon; filter and acidify the filtrate while still hot with excess of dilute hydrochloric acid (1:1). Collect the precipitated diphenic acid on a Buchner funnel, wash it with 20 ml of cold water and dry at 100 °C. The yield of diphenic acid is 18 g (82%); it melts at 227–228 °C and usually possesses a light cream colour.

Experiment 6.10 1,1′-BI-2-NAPHTHOL

\[
\begin{align*}
2 \text{OH} & \quad + 2\text{FeCl}_3 \quad \rightarrow \quad \text{HO} \quad + 2\text{FeCl}_2 \quad + 2\text{HCl}
\end{align*}
\]
In a 1-litre three-necked flask, provided with a dropping funnel, a sealed stirrer and a reflux condenser, place 14.4 g (0.1 mol) of 2-naphthol and 600 ml of water, and heat to the boiling point. To the boiling liquid containing liquid 2-naphthol in suspension, add slowly through the dropping funnel and with vigorous stirring a solution of 28 g (0.1 mol) of crystallised iron(III) chloride in 60 ml of water. The oily drops of 2-naphthol will disappear and the bis-2-naphthol separates out in flakes. Boil for 5-10 minutes, filter the hot suspension at the pump through a previously warmed Buchner funnel, wash with boiling water and dry in the air upon filter paper. The crude product weighs 9 g. Recrystallise from toluene (about 150 ml); almost colourless crystals (7.5 g, 52%), m.p. 218 °C, are obtained.

### 6.1.4 CONDENSED POLYCYCLIC SYSTEMS

Dehydrogenation (the conversion of alicyclic or hydroaromatic compounds into their aromatic counterparts by removal of hydrogen – and also, in some cases, of other atoms or groups) has found wide application in the determination of structure of natural products containing complex hydroaromatic systems. Dehydrogenation is employed also for the synthesis of polycyclic hydrocarbons and their derivatives from readily accessible synthetic hydroaromatic compounds. The general process is illustrated by the conversion of tetralin into naphthalene.

\[
\text{tetralin} \rightarrow \text{naphthalene}
\]

The principal dehydrogenation agents are (i) sulphur, (ii) selenium and (iii) catalytic metals. With sulphur, the general method is to heat the compound at 200–260 °C with the theoretical amount of sulphur required to convert it into an aromatic system. In the case of selenium, the substance is heated with a large excess of selenium at 280–350 °C for 36–48 hours. Better yields (and less side reactions) are usually obtained than with sulphur, but, owing to the higher temperature, rearrangements are more likely. Oxygen-containing groups are particularly prone to elimination. Palladium and platinum catalysts are generally employed with a charcoal carrier. The dehydrogenation can be conducted in the vapour phase by distilling the compound through a tube containing the catalyst heated to 300–350 °C, but the liquid phase method is generally more convenient. Charcoal is employed containing 10–30 per cent of the metal. It has been established that the best results are obtained by conducting the process in an actively boiling medium (e.g. mesitylene, b.p. 165 °C; p-cymene, b.p. 177 °C; naphthalene, b.p. 218 °C; and 1-methylnaphthalene, b.p. 242 °C) and to provide for the removal of the hydrogen as it is formed (e.g. by sweeping the system with a stream of carbon dioxide).

Examples of dehydrogenation processes are to be found in the synthetic sequences described in Expts 6.11 and 6.12. In the former instance, 1-methylnaphthalene is synthesised from α-tetralone by first introducing a 1-methyl substituent by reaction with methylmagnesium iodide. The resulting tertiary alcohol undergoes dehydration and dehydrogenation on heating with a palladium-on-charcoal catalyst. The preparation of the ketonic starting material from benzene is described in Expt 6.123 (see also Section 6.11.1, p. 1006); the
conversion of \( \alpha \)-tetralone into 1-methylnaphthalene completes the reaction sequence known as the *Haworth procedure* for the synthesis of polycyclic aromatic hydrocarbons.

Intramolecular cyclisation of a 4-arylbutanoic acid system is also an important step in a convenient synthesis of the polycyclic system, chrysene, which is formulated and described in Expt 6.12. Here, methyl cinnamate is first subjected to reductive dimerisation to give methyl meso-\( \beta,\gamma \)-diphenyladipate, which is accompanied by some of the (\( \pm \))-form. The *meso* isomer (16) is the most easily isolable and cyclisation occurs smoothly in sulphuric acid to yield the diketone 2,11-dioxo-1,2,9,10,11,18-hexahydrochrysene, which is obtained as the *trans* form (17) as shown in the following formulation. Clemmensen reduction of this ketone followed by dehydrogenation (in this case using selenium) completes the synthesis of chrysene.

\[
\text{OMe} \quad \text{O=C} \quad \text{C=O} \quad -2\text{MeOH}
\]

(16)

\[
\begin{align*}
\text{OMe} & \quad \text{O} \\
\text{C=O} & \quad \text{H} \\
\text{H} & \quad \text{OMe}
\end{align*}
\]

(17)

The synthesis of a tetraphenyl derivative (rubrene, Expt 6.13) of the linearly fused tetracyclic aromatic hydrocarbon naphthacene involves an interesting intermolecular cyclisation process between two molecules of 1-chloro-1,3,3-triphenylpropa-1,2-diene. This substituted allene is formed *in situ* from 1,1,3-triphenylprop-2-yn-1-ol (Expt 5.41) when the latter is allowed to react with thionyl chloride and the resulting chlorosulphite ester heated with a little quinoline; cyclisation occurs spontaneously under these reaction conditions to give rubrene which has an intense red colour.

\[
\begin{align*}
\text{Ph}\cdot\text{C} \equiv \text{C} \quad & \quad \text{Ph} \quad \text{Ph} \quad \text{OH} \quad \text{SOCl}_2 \\
& \quad \text{Cl} \quad \text{S} \\
& \quad \text{O} \quad \text{O}
\end{align*}
\]

840
The synthesis of 9-phenylphenanthrene (Expt 6.14) illustrates the formation of the phenanthrene system by the cyclisation of a 1,2-diphenylethylene (stilbene). The process involves an allowed photochemical cyclisation which gives initially a dihydrophenanthrene. This is readily dehydrogenated in situ by molecular oxygen in the presence of iodine.

The required stilbene is usually readily prepared by dehydration of the appropriate alcohol obtained by a Grignard reaction, e.g.

The method has been applied to the synthesis of a range of substituted phenanthrenes and has the merit that it involves fewer steps than, for example, the Haworth synthesis. Good results are not always obtained, however, when some electron-withdrawing substituents (e.g. NO₂, Me·CO) are present.

**Experiment 6.11 1-METHYLNAPHTHALENE**

![Chemical structures](image)

---

841
1-Hydroxy-1-methyl-1,2,3,4-tetrahydronaphthalene. Prepare an ethereal solution of methylmagnesium iodide (cf. Expt 5.39) from 1.8 g (0.075 mol) of magnesium, 10.6 g (4.7 ml, 0.075 mol) of methyl iodide (CAUTION) and 30 ml of ether in a 100-ml two-necked flask fitted with a dropping funnel and a reflux condenser protected by a calcium chloride guard-tube. Slowly add a solution of 7.3 g (0.05 mol) of \( \alpha \)-tetralone (Expt 6.123) in 10 ml of ether, swirling the contents of the flask from time to time, and finally heat under reflux on a steam bath for 1 hour to complete the reaction. Cool in ice, and decompose the reaction mixture with a cold saturated aqueous solution of ammonium chloride. Separate the ether layer, and extract the aqueous phase with 10 ml of ether. Wash the combined ethereal solutions with aqueous ammonium chloride solution, dry over anhydrous sodium sulphate and evaporate off the ether. A solid residue of 1-hydroxy-1-methyl-1,2,3,4-tetrahydronaphthalene of sufficient purity for use in the next stage is obtained; the yield is 7.5 g (92%), m.p. 77–79 °C. Recrystallise a sample from light petroleum (b.p. 60–80 °C); the purified material has m.p. 86–87 °C.

![Fig. 6.1](image-url)

1-Methylnaphthalene. This preparation illustrates the general procedure for catalytic dehydrogenation. The apparatus used is shown in Fig. 6.1. Heat a mixture of 3.2 g (0.02 mol) of the above hydroaromatic compound with 0.3 g of palladised charcoal (Section 4.2.54, p. 452) at 250–270 °C in a slow current of dry carbon dioxide in a Silicone oil or fusible metal bath for 3 hours (1). Cool, dissolve the residue in ether and filter off the catalyst. Wash the extract with dilute aqueous sodium hydroxide and dry it over anhydrous sodium sulphate. Remove the ether and distil the residual oil under reduced pressure; use a small-scale distillation apparatus (cf. Fig. 2.111). Collect the 1-methylnaphthalene, b.p. 121–123 °C/20 mmHg. The yield is 2.5 g (89%).

**Note.** (1) If it is desired to follow the progress of the dehydrogenation, attach the side-tube through a U-tube packed with self-indicating soda-lime to a nitrometer filled with potassium hydroxide solution: almost the theoretical quantity of hydrogen will be collected.
**Experiment 6.12 CHRYSENE**

![Chemical Reaction Diagram]

*meso-Dimethyl 3,4-diphenyladipate.* Prepare aluminium amalgam from 75 g of the foil (Section 4.2.3, p. 415) and cover with 1 litre of moist ether (1) in a 2-litre flask fitted with a large double surface reflux condenser. Immediately add a solution of 48.5 g (0.3 mol) of recrystallised methyl cinnamate (Expt 6.163) in 100 ml of ether and shake the flask to mix the contents thoroughly. Evolution of hydrogen ceases and after an induction period of up to 1 hour the ether boils; moderate the reaction if necessary by cooling the flask. Towards the end of the reaction, which should be complete in 6 hours, warm the flask to maintain gentle reflux of the ether. Cool, filter off the aluminium hydroxide sludge (do not discard this residue) and dry the ethereal solution over anhydrous sodium sulphate. Remove ether on a rotary evaporator and cool the residual oil thoroughly in an ice bath (or overnight in a refrigerator). Filter the resulting crystalline mass and wash the crystals with a little cold ether; about 4 g of the crude *meso*-adipate, m.p. 170 °C, are obtained (2). Much of the product adheres to the aluminium hydroxide residue, however. Cover this residue with 1 litre of water and add 1 litre of concentrated hydrochloric acid slowly with stirring to dissolve most of the aluminium hydroxide. Extract with three 150 ml portions of chloroform, dry the extract over anhydrous sodium sulphate and remove the chloroform on a rotary evaporator; a further 7 g of the crude *meso*-adipate is obtained. Recrystallise the combined crops of crude material from rectified spirit (about 250 ml). Pure *meso*-dimethyl 3,4-diphenyladipate, m.p. 175 °C, is obtained; the yield is about 9 g (18%).

*trans-2,11-Dioxo-1,2,9,10,11,18-hexahydrochrysene.* Add 8.2 g (0.025 mol) of *meso*-dimethyl 3,4-diphenyladipate to a stirred mixture of 100 ml of concentrated sulphuric acid previously added to 33 ml of water and heat on a water bath for 3 hours. Cool the mixture and pour it carefully with stirring into 1 litre of water. Filter off the resulting precipitate and digest it on the steam bath with hot sodium carbonate solution. Filter again, wash the product with water and dry in an oven. The dioxohexahydrochrysene is obtained as a pale buff powder, m.p. 293–300 °C, yield 5.5 g (85%). Crystallise a small specimen from butan-1-ol; colourless plates, m.p. 303 °C (sealed tube), are obtained.
trans-1,2,9,10,11,18-Hexahydrochrysene. Prepare amalgamated zinc from 35 g of zinc wool (Section 4.2.80, p. 467) and cover it with 25 ml of concentrated hydrochloric acid. Add 5.2 g (0.02 mol) of the dioxyhexahydrochrysene and boil the mixture under reflux for 8 hours. Add 20 ml more of concentrated hydrochloric acid and reflux for a further 8 hours. Cool the mixture, when the oily product solidifies. Extract the product, together with any solid material which has formed in the reflux condenser, with two 50 ml portions of hot benzene. Cool, separate the benzene layer and dry over anhydrous sodium sulphate. Remove the benzene with a rotary evaporator, transfer the residue to a small-scale distillation unit (Fig. 2.111) and distil under reduced pressure. Collect the hexahydrochrysene which distils at 230°C/14 mmHg as a colourless oil which readily crystallises, m.p. 113°C, yield 3.5 g (75%).

Chrysene. Since selenium and selenium compounds are toxic this dehydrogenation and the associated work-up procedure must be carried out in an efficient fume cupboard. Mix 3.5 g (0.015 mol) of hexahydrochrysene with 16 g (0.2 mol) of selenium in a boiling tube and heat in a fusible metal bath at 300°C for 20 hours (fume cupboard). From time to time, melt the crystalline sublimate which gradually forms so that it runs back into the reaction mixture. Remove the cooled product and grind it in a mortar to a fine powder. [CAUTION: (3).] Extract by boiling under reflux for 30 minutes with 200 ml of benzene, filter and reflux the filtered extract over a little clean sodium wire (or thin narrow slices of sodium metal); this treatment removes traces of selenium. Evaporate the benzene solution using a rotary evaporator and crystallise the residue from toluene (about 20 ml per 1 g) (4). Colourless plates with a bluish fluorescence, m.p. 254°C, are obtained. The yield of chrysene is about 2 g (59%).

Notes. (1) The ether should be saturated by shaking it with a little water in a separatory funnel.
(2) If the filtrate is distilled under reduced pressure, 30 g of methyl 3-phenylpropionate, b.p. 111–130°C/15 mmHg, are obtained. When the distillation residue is dissolved in the minimum of hot ether and cooled, a further 1 g of the meso-adipate is obtained. The ether filtrate from this contains racemic dimethyl 3,4-diphenyladipate; the latter may be recovered by evaporating the ether and crystallising the residue from the minimum of methanol; m.p. 70–71°C.
(3) Do not inhale any of the finely divided material; it is advisable to wear a face mask or alternatively to grind the material in an enclosed (i.e. glove) box.
(4) The crude product may also be purified by sublimation under reduced pressure (c. 0.1 mmHg) from an oil bath maintained at 200°C.

Experiment 6.13 5,6,11,12-TETRAPHENYLNAPHTHACENE (Rubrene)

\[ 2\text{Ph} \cdot \text{C} = \text{C} \cdot \text{C(Ph)}_2 \text{OH} \quad \text{SOCl}_2 \quad \rightarrow \quad 2\text{Ph} \cdot \text{C} = \text{C(Ph)}_2 \quad \text{Cl} \]

\[
\begin{align*}
\text{Ph} & \quad \text{Ph} \\
\text{Ph} & \quad \text{Ph} \\
\text{Ph} & \quad \text{Ph}
\end{align*}
\]
Add 28.5 g (0.1 mol) of 1,1,3-triphenylprop-2-yn-1-ol (Expt 5.41) in small portions with shaking to 24 g (14.5 ml, 0.2 mol) of redistilled thionyl chloride cooled to −10 °C in an ice–salt bath. Set the resulting solution aside at room temperature for 1 hour and then remove excess chloride by warming under reduced pressure (water pump); the residue solidifies (1). Add 0.5 ml of redistilled quinoline and heat the mixture in an oil bath at 120 °C under reduced pressure (water pump) for 2 hours. Wash the dark red residue with ether and then with boiling acetone and dissolve it in benzene. Filter off any insoluble impurity, dilute with light petroleum (b.p. 100–120 °C) and remove most of the benzene carefully by evaporation under reduced pressure. Cool and filter off the bright red crystals of rubrene; the yield is 7 g (26%), m.p. 320 °C. Store the product in a specimen tube protected from the light by a covering of black paper.

Note. (1) If the product does not solidify it must be purified by distillation under reduced pressure using an efficient oil-immersion pump; b.p. 190 °C/0.05 mmHg.

Experiment 6.14 9-PHENYLPHENANTHRENE

**Triphenylethylene.** Equip a 2-litre, three-necked round-bottomed flask with a sealed stirrer unit, a 250-ml dropping funnel and a double surface condenser. All the apparatus should be rigorously dried and the dropping funnel and reflux condenser protected by calcium chloride guard-tubes. Place in the flask 12.2 g (0.50 mol) of magnesium turnings and about 250 ml of ether previously dried over anhydrous calcium chloride. In the funnel place a solution of 57.5 ml (63.3 g, 0.50 mol) of freshly distilled benzyl chloride in about 100 ml of dry ether. Without stirring the contents of the flask run in about 20 ml of the benzyl chloride solution and then add a large crystal of iodine and allow the mixture to stand undisturbed. Reaction commences after about 5 minutes and the magnesium begins to dissolve. Add the benzyl chloride solution dropwise at such a rate as to maintain a steady reflux of the ether solvent. When the reaction is well established, start the stirrer motor and stir the reaction mixture at a moderate rate. When all the benzyl chloride solution has been added (about half an hour), heat the flask in an electric heating mantle and with continued stirring maintain a vigorous rate of reflux for a further half an hour. Turn off the heating mantle but continue stirring fairly rapidly, and add from the dropping funnel a solution of 91.1 g (0.50 mol) of benzophenone in about 250 ml of dry ether. The rate of addition should be sufficient to maintain rapid reflux. On completion of the addition (about 15
minutes) heat under reflux with stirring for a further half an hour before allowing the reaction mixture to stand at room temperature for at least 2 hours or preferably overnight. Cool the reaction mixture in an ice-water bath, add 400 g of crushed ice to the flask contents, followed by 250 ml of cold 2.5 M sulphuric acid. Transfer the reaction mixture to a 3-litre separating funnel, run off the aqueous layer and extract with two 150 ml portions of ether. Combine the ether layer and extracts, dry over calcium sulphate and evaporate the ether on a rotary evaporator. To the syrupy residue add 100 ml of 2.5 M sulphuric acid and boil vigorously under reflux for 2 hours. Cool the mixture to room temperature, add 50 ml of ether and shake vigorously. Transfer the resulting emulsion to a 1-litre separatory funnel, wash the flask thoroughly with a mixture of 50 ml of water and 50 ml of ether and add this to the separatory funnel. After a few minutes the emulsion separates into two layers and the aqueous fraction can be run off and extracted with two 50 ml portions of ether. Combine the ether layer and extracts (1), and evaporate the ether using a rotary evaporator. Distil the residue under reduced pressure collecting the main fraction (93 g, 73%) at 196–200 °C/2.5 mmHg. Dissolve the greenish-yellow syrupy distillate in 450 ml of hot 95 per cent aqueous ethanol and allow to cool slowly. Trituration is usually required to induce crystallisation. Complete the crystallisation process by cooling in ice-water and filter under suction to obtain 85 g (66%) of colourless crystals having m.p. 68–69 °C. Further recrystallisations from ethanol or acetic acid gives pure triphenylethylene, m.p. 72–73 °C.

9-Phenylphenanthrene. The photochemical reactor should be completely screened with metal foil to avoid hazards from stray radiation (see Section 2.17.5, p. 113). Dissolve 2.56 g (0.01 mol) of triphenylethylene and 0.127 g (0.0005 mol) of iodine in 1 litre of redistilled cyclohexane contained in a photochemical reactor vessel of 1-litre capacity and fitted with a 100-W medium-pressure mercury arc lamp in a water-cooled quartz immersion well (Section 2.17.5, p. 110, Fig. 2.67(f)). Place the apparatus on a magnetic stirrer unit, insert a magnetic follower and with both the side-necks of the vessel open to the atmosphere irradiate the stirred solution until all the triphenylethylene has reacted (2); this should take approximately 21–22 hours. There is no observable change in the colour of the cyclohexane solution during the irradiation. Remove the reaction mixture and evaporate to dryness under reduced pressure on a rotary evaporator to obtain the crude phenylphenanthrene as a pale fawn solid. Purify by column chromatography as follows. Dissolve the solid in 60 ml of warm cyclohexane, allow to cool and pour on to a short (c. 2 cm x 7 cm) column of neutral alumina (c. 16–17 g, Activity I, prepared as a slurry in cyclohexane). Collect the eluate, and when most of the solution has passed down the column rinse the flask which contained the solid with two 10 ml portions of cyclohexane and add to the column. When this has also been adsorbed, elute with a further 100–120 ml of cyclohexane or until no more phenylphenanthrene is obtained in the eluate. It is best to monitor the elution of the product by collecting and evaporating 40 ml fractions; a band of yellow material should remain near the top of the column and elution of this must be avoided. Crystallise the solid so obtained from 60 ml of ethanol and collect the crystals which separate by suction filtration; a second crop may be obtained by concentrating the filtrate to c. 20 ml and
cooling in ice. The yield of 9-phenylphenanthrene (white needles), m.p. 104.5–
105.5 °C, is 2.16 g (85%) (3).

Notes. (1) Do not wash the ethereal fraction with water or with aqueous sodium
hydrogen carbonate solution, since the presence of a trace of sulphuric acid during the
final distillation is necessary to complete the dehydration.
(2) The irradiation time for complete reaction will depend on the power of the
mercury arc used; in particular the light output of a lamp will vary with its age and use
of a higher wattage lamp will, of course, shorten the reaction time required. The extent
of the reaction may be most conveniently followed by g.l.c. of 0.5 µl samples of the
reaction solution on a 1.5-m column of Methyl Silicone Gum S.E.30 on Chromosorb W
held at 240 °C and with a nitrogen flow rate of 40 ml/minute. Triphenylethylene and 9-
phenylphenanthrene have \( t_R \) 2.3 minutes and 5.2 minutes respectively, cyclohexane
has \( t_R \) 0.5 minutes. Alternatively the reaction may be followed by evaporating 5–10 ml
portions of the solution and recording the infrared spectrum of the residue as a mull in
Nujol. Bands at 887(m), 750(m) and 738(s) cm\(^{-1}\) characteristic of 9-phenylphen-
anthrene gradually appear and increase in intensity relative to bands due to the
stilbene at 872(w) and 757(s) cm\(^{-1}\) which gradually disappear. Other regions of the
spectrum of the individual compounds are very similar and it is advisable to use the
scale expansion adjustment of the instrument to enable the bands in the low
wavenumber region to be readily identified.
(3) For the preparation of larger amounts of the phenanthrene the reaction should be
repeated; photolysis of more concentrated solutions is to be avoided in order to
minimise the possibility of photodimerisation to give a cyclobutane derivative.

6.1.5 SOME NON-BENZENOID SYSTEMS

Two examples, namely ferrocene and azulene, are selected to illustrate this
group of aromatic compounds.

The former is prepared (Expt 6.15) by the reaction of cyclopentadiene with
iron(II) chloride in the presence of diethylamine. Iron(II) chloride is prepared \( \text{in situ} \) from iron(III) chloride in tetrahydrofuran by reduction with iron metal. This
preparation is one of the simplest for ferrocene, although not of general
application for substituted ferrocenes. The acetylation of ferrocene in a Friedel–
Crafts manner to yield the monoacetyl derivative is described in Expt 6.122.

The aromatic character of ferrocene originates in the anionic cyclopentadienide system (18), which has six \( \pi \)-electrons delocalised over a symmetrical
cyclic five-carbon system. Coordination of two such ring systems with a metal
ion (iron in the case of ferrocene) in a sandwich-like structure (20) gives rise to a
remarkably stable compound.

\[
\begin{align*}
(18) & \quad (19) & \quad (20) \\
& \quad (21)
\end{align*}
\]

It is possible that the cyclopentadienide system also contributes to the
structure of the undoubtedly aromatic azulene molecule (21) which may be
regarded as a condensed bicyclic system comprised of the anion (18) in combination with the cycloheptatrienylium ion (19) – the latter also has an aromatic sextet of six \( \pi \)-electrons, disposed in this case over a seven-membered ring. Alternatively azulene may be viewed as a conjugated cyclodecapentaene with an additional transannular \( C-C \) single bond; such a structure is predicted to be aromatic by the Huckel \((4n + 2)\) rule, having ten \( \pi \)-electrons in a cyclic system.

The preparation of azulene (Expt 6.16) provides an interesting series of rearrangements. The key step in the synthesis is the intramolecular insertion reaction, carried out under conditions of high dilution, of the ketocarbene (22) into the 1,2-position of the benzene ring. The unstable norcaradiene (23) which is formed then ring-opens to the bicyclic trienone (24), which isomerises to the more stable cross-conjugated trienone (25) during isolation. Dehydration of the trienone with a mixture of phosphorus pentoxide and methanesulphonic acid yields azulene.

\[ \text{O} \quad \text{CH} \quad \rightarrow \quad \text{O} \quad \text{H} \quad \rightarrow \quad \text{O} \quad \text{H} \quad \rightarrow \quad \text{O} \quad \text{H} \]

\( (22) \quad (23) \quad (24) \quad (25) \)

The ketocarbene is formed from 3-phenylpropanoyl chloride (dihydrocinnamic acid chloride) and diazomethane; ring substituted dihydrocinnamic acids provide a route to substituted azulenes. Alternatively the keto group in (25) may be treated with a Grignard reagent for the introduction of alkyl substituents into the five-membered ring.

**Experiment 6.15 FERROCENE**

\[ 2\text{FeCl}_3 + \text{Fe} \rightarrow 3\text{FeCl}_2 \]
\[ 2\text{C}_5\text{H}_6 + \text{FeCl}_2 \xrightarrow{\text{Et}_2\text{NH}} \text{Fe}^{2+}, \left(\text{C}_5\text{H}_3\right)_2 \]

Equip a 250-ml, three-necked round-bottomed flask with a stirrer, a reflux condenser with a nitrogen inlet (cf. Fig. 2.60), and a stopper in the third neck. Flush the flask with nitrogen and charge it with dry tetrahydrofuran (100 ml) (Section 4.1.19, p. 406). Add with stirring anhydrous iron(III) chloride (27.1 g, 0.166 mol) followed by iron powder (4.7 g, 0.84 g-atom) which should preferably be 300 mesh. Heat under reflux with stirring and under nitrogen for 4.5 hours. The reaction mixture should then consist of a grey powder and a brown supernatant liquid. Remove the tetrahydrofuran under reduced pressure by setting the condenser for downward distillation, and attaching a vacuum take-off receiver adapter and receiver flask; stir until the residue is

* The editors are indebted to Dr R. Thomas, Thames Polytechnic, for these experimental details; this experiment, and the preparation of acetylferrocene (Expt 6.122), are very suitable as undergraduate exercises.
almost dry. Cool the flask in an ice bath, re-assemble the apparatus as before but with a pressure-equalising funnel in the third neck. Add dropwise with stirring and cooling under nitrogen, first cyclopentadiene (42 ml, 0.5 mol, Expt 7.24) and then diethylamine (100 ml). Stir the mixture at room temperature for 6–8 hours or overnight. Remove the excess amine under reduced pressure. Extract the residue repeatedly with light petroleum (b.p. 60–80 °C) under reflux, filter the hot extracts and evaporate the solvent to leave crude ferrocene. Recrystallise the crude product from cyclohexane to give pure ferrocene (34 g, 73%). m.p. 173–174 °C. The p.m.r. spectrum (CDCl₃, TMS) exhibits a single absorption at δ 4.09.

Experiment 6.16 AZULENE⁹

3-Phenylpropanoyl chloride. A mixture of 15 g (0.1 mol) of 3-phenylpropanoic acid and 18.0 ml (0.25 mol) of thionyl chloride, protected from the atmosphere by a drying tube, is heated under reflux for 2 hours. Excess thionyl chloride is removed under reduced pressure and the residue is vacuum distilled giving 16.3 g (97%) of 3-phenylpropanoyl chloride as a colourless liquid, b.p. 43–48 °C/0.04 mmHg; i.r. (neat) 1812 cm⁻¹ (C=O); δ (CCl₄, TMS) 7.04 (s, 5H), 2.93 (m, 4H).

1-Diazo-4-phenylbutan-2-one. CAUTION: All operations involving diazomethane are hazardous and must be conducted in an efficient fume cupboard and using adequate screens, Section 4.2.25, p. 430. A solution of diazomethane (c. 100 mmol) in 300 ml of anhydrous ether is prepared in the standard way from 30 g N-methyl-N-nitrosotoluene-p-sulphonamide (Section 4.2.25, p. 431). To this solution, cooled in an ice–salt bath under a drying tube, is added an additional 35 ml of anhydrous ether containing 4.94 ml (33 mmol) of 3-phenylpropanoyl chloride dropwise during 1 hour with magnetic stirring. At the end of the addition the reaction mixture is stirred 1 hour more in the cold bath and then 1 hour more while being warmed to room temperature. Concentration of the reaction mixture under reduced pressure gives 5.8 g (100%) of the diazoketone as a yellow oil, i.r. (neat) 2083 and 1631 cm⁻¹; δ (CCl₄, TMS) 7.07 (s, 5H), 5.07 (s, 1H), 3.00–2.29 (m, 4H).

3,4-Dihydro-1(2H)-azulenone (25). A suspension of 0.8 g of anhydrous copper(II) chloride, in 3 litres of bromobenzene freshly distilled from calcium hydride, is heated to 80 °C under nitrogen in an oven-dried, 5-litre, three-necked round-bottomed flask fitted with a mechanical stirrer, a constant addition funnel and a reflux condenser. To this vigorously stirred suspension is added 1 litre of bromobenzene containing 20.4 g (0.117 mol) of the foregoing diazoketone dropwise over 7 hours. Heating and stirring are
continued for an additional 1 hour; the pale yellow reaction mixture is cooled and filtered through 30 g of alumina to remove copper salts and to isomerise the unconjugated triene (24) to the more stable isomer (25). The alumina is washed with 500 ml of ethyl acetate, and the combined filtrates are concentrated at 40 °C under reduced pressure, first at 20 mm to remove the more volatile solvent, and then at 0.5 mm to remove the bromobenzene; there is left finally a brown oil. Chromatography on 200 g of silica gel using 15 per cent ethyl acetate-light petroleum as the eluant gives 8.9 g (52%) of (25) as a light brown oil; i.r. (neat) 1690 (C==O) and 1620 cm⁻¹ (C=C); u.v. (EtOH) 232 (ε 15 200) and 265 nm (ε 4800); δ (CDCl₃, TMS) 6.68 (d, 1H, J = 10 Hz, C₈—H), 6.48 (d of d, 1H, J = 10 and 6 Hz, C₇—H), 6.09 (d of d, 1H, J = 6 and 9 Hz, C₆—H), 5.39 (d of t, J = 9 and 6 Hz, C₅—H), 2.83 (d, 2H, J = 6 Hz, C₄ (CH₂)), and 2.58 (sym. m, 4H, —CH₂—CH₂—).

Azulene. A mixture of 5 g (35 mmol) of phosphorus pentoxide (weighed under nitrogen) and 34 ml of redistilled methanesulphonic acid (CAUTION) is heated under nitrogen to 60 °C with mechanical stirring. When the mixture is homogeneous, 0.48 g (3.3 mmol) of (25) is added neat, dropwise during 7 minutes. The solution rapidly darkens to orange-brown. Progress of the reaction is followed by removing one-drop aliquot portions and quenching them into water-hexane. The u.v. spectrum of the hexane layer shows a gradual decrease in the absorption at 226 nm due to (25) and the corresponding growth of the characteristic three-line pattern due to azulene around 274 nm. When the 226 nm absorption is no longer discernible (about 6 hours), the reaction mixture is poured into 500 ml of ice-cold water and extracted twice with pentane. The dark-blue pentane layers are combined and washed with water until neutral, washed with saturated sodium chloride solution, dried over magnesium sulphate and concentrated under reduced pressure. The oily blue residue is purified by preparative layer chromatography on silica gel (1) using pentane as the eluant to give 130–210 mg (30–50%) of azulene as beautiful dark-blue crystals, m.p. 98–98.5 °C.

Note. (1) Silica gel PF 254-366 (Brinkmann) is used for the preparative layer chromatography. The editors suggest that the use of flash chromatography (Section 2.31) could be explored in this case.

6.2 AROMATIC NITRO COMPOUNDS

The importance of aromatic nitro compounds arises in particular from the ready conversion of the nitro group into other functional groups, principally by routes involving initial reduction to the amino group. The following procedures, of which the first is by far the most important, are available for the synthesis of aromatic nitro compounds.

1. Direct nitration (Expts 6.17 to 6.21).
2. The oxidation of amines (Expt 6.22).
3. The replacement of a diazo group by a nitro group (see Expt 6.78).
SUMMARY OF RETROSYNTHETIC STRATEGIES

Functional group interconversion (FGI) (method 2), e.g.

\[
\text{NO}_2 \quad \text{(TM)} \quad \Rightarrow \quad \text{NH}_2
\]

C—N Disconnection (methods 1 and 3), e.g.

\[
\text{HNO}_3/\text{H}_2\text{SO}_4 + \text{PhH} \quad \rightarrow \quad \text{Ph}^+\text{N}_2 + \text{NaNO}_2/\text{Cu}
\]

SPECTROSCOPIC FEATURES

The presence of a nitro group in a compound is readily recognised from its strong characteristic i.r. absorption frequencies (Fig. 3.38). The aromatic substitution pattern is less easily assigned by inspection of the longer wavelength region (p. 310). However, this may be frequently assessed by examination of the p.m.r. spectrum (Fig. 3.64, m-dinitrobenzene). Further examples are given in descriptive style in the preparative examples. The fragmentation pattern observed in the m.s. of a nitro compound is discussed on p. 855 and further illustrated in some of the preparations described below. The nitro group exerts a bathochromic shift on the aromatic absorption frequencies in the u.v.—visible spectrum (p. 392).

6.2.1 DIRECT NITRATION

Aromatic hydrocarbons may be nitrated, i.e. the hydrogen atoms replaced by nitro (NO\(_2\)) groups, with concentrated nitric acid in the presence of concentrated sulphuric acid (‘mixed acid reagent’).

\[
\text{ArH} + \text{HNO}_3/\text{H}_2\text{SO}_4 \quad \rightarrow \quad \text{ArNO}_2
\]

The function of the sulphuric acid is to convert the nitric acid into the highly reactive, electrophilic, nitronium ion, NO\(_2^+\), which is the effective nitrating agent.

\[
\text{HONO}_2 + \text{H}_2\text{SO}_4 \quad \rightarrow \quad \text{NO}_2^- + \text{H}_3\text{O}^+ + 2\text{HSO}_4^-
\]

The mechanism of aromatic nitration, which is illustrated below in the case of benzene, is a two-step process involving electrophilic attack of the nitronium ion on the benzene molecule to form the intermediate mesomeric ion (1), followed by removal of a proton by the hydrogen sulphate ion, which is the most basic species in the reaction mixture.
Nitrations of aromatic hydrocarbons is usually carried out with the above mixed acid reagent at comparatively low temperatures (e.g. about 50 °C, as used in the preparation of nitrobenzene and 1-nitronaphthalene, Expt 6.17). Unnecessarily high temperatures should be avoided since polynitrations is then more likely and oxidative breakdown of the aromatic ring system may occur.

The nitrations of substituted aromatic compounds (e.g. Ar·Z) presents a range of practical and theoretical problems which need to be briefly surveyed. These include: (a) the severity of the reaction conditions; (b) the sensitivity of the group Z to the oxidising conditions of the nitrating agents; (c) the regioselectivity of the reaction (i.e. the orienting influence of the group Z to either the meta or to the ortho/para positions); (d) the sequence of reactions (i.e. either to nitrate Ar·Z, or to introduce the substituent Z into the nitro compound Ar·NO₂); (e) the use of a substituted compound Z·C₆H₄·Y, wherein the orientating influence of Y predominates, and thus directs the nitro group to the desired position, but is then removed in a subsequent reaction step.

Thus the nitrations of aromatic compounds containing an electron-withdrawing group (e.g. —NO₂, —SO₃H, —CHO, —CO·R, —CO₂H, —CO₂R) does not occur readily under the above conditions, in which case forcing conditions which require the use of fuming nitric acid and concentrated sulphuric acid need to be employed. Nitrobenzene, for example, is converted by a mixture of fuming nitric acid and concentrated sulphuric acid into about 90 per cent of m-dinitrobenzene (Expt 6.18) and small amounts of the o- and p-isomers; the latter are eliminated in the process of recrystallisation. p-Nitrotoluene is similarly converted largely into 2,4-dinitrotoluene (Expt 6.18). A further example is the nitration of benzaldehyde to give m-nitrobenzaldehyde (Expt 6.19) in reasonable yield in spite of the fact that the reaction conditions are strongly oxidising. The nitro group is thus seen to be meta-directing in common with the other deactivating groups specified above.

The deactivating effect of the nitro group is largely the result of its mesomeric interaction (—M effect) with the π-electron system of the benzene ring which is supplemented by the inductive (—I) effect (2).

The overall electron withdrawal from the ring system results in the rate of attack of the nitronium ion being substantially retarded compared to benzene. Moreover, the representations of the canonical forms of nitrobenzene formulated above show that the ortho and para positions are subject to the greatest reduction in electron density. In addition the reaction intermediate resulting
from attack at a position \textit{para} to the nitro group would be represented by the following hybrid species (similar formulations being possible as a result of \textit{ortho} attack).

It follows that since (3(b)) is energetically unfavourable the mesomeric stabilisation of this intermediate is less than that of the corresponding intermediate resulting from attack in the \textit{meta} position (4).

The nitration of aromatic compounds containing electron-releasing groups (e.g. \(-\text{R}, \quad \text{—OH}, \quad \text{—NH}_2, \quad \text{—NHCO-Me}\)) needs to be conducted under conditions which are milder than those specified for benzene, since in these cases the aromatic nucleus is activated towards attack by the electrophilic species, and furthermore the ring system is more likely to be oxidatively cleaved. An example is provided by the nitration of acetonilide (Expt 6.68) to yield a mixture of \textit{o}- and \textit{p}-nitroacetanilides (see also Section 6.6.2, p. 916); the overall nitration of phenol to a mixture of \textit{o}- and \textit{p}-nitrophenols (Expt 6.102) is anomalous in that the reagent is dilute nitric acid alone; the mechanism is outlined in Section 6.9.2, p. 975. These activating groups are therefore seen to be \textit{ortho} and \textit{para} directing. By contrast to the effect of electron-withdrawing groups, activating and \textit{ortho/para} directing groups will stabilise by electron release the reaction intermediate formed as a result of attack at any of the three possible positions, but particularly so when attack is at the \textit{ortho} and \textit{para} positions.

An interesting case is provided by the nitration of aryl halides where the effect of the halogen is to deactivate the aromatic nucleus (by the \(-I\) effect) but to direct the incoming nitronium ion to the \textit{ortho} and \textit{para} positions as a result of the mesomeric interaction of the halogen lone electron pair with the charge developed in the corresponding intermediates [e.g. (5), in the formation of \textit{p}-bromonitrobenzene from bromobenzene, Expt 6.20].
Experimental details for the nitration of benzyl cyanide are also included (Expt 6.21). The product is largely $p$-nitrobenzyl cyanide (some of the ortho isomer is also formed); the cyanomethyl substituent (as a substituted alkyl group) is thus an ortho/para directing and weakly activating group.

The electronic effect of groups in aromatic electrophilic substitution processes is fully discussed in all standard organic chemistry textbooks.

**Experiment 6.17 NITROBENZENE**

\[
\text{PhH} + \text{HNO}_3 \xrightarrow{\text{H}_2\text{SO}_4} \text{Ph} \cdot \text{NO}_2
\]

**CAUTION:** This preparation should be conducted in an efficient fume cupboard.

Place 50 g (35 ml, c. 0.5 mol) of concentrated nitric acid in a 500-ml round-bottomed flask, and add, in portions with shaking, 74 g (40 ml) of concentrated sulphuric acid. Keep the mixture cool during the addition by immersing the flask in cold water. Place a thermometer (110 °C range) in the acid mixture. Introduce 26 g (30 ml, 0.33 mol) of benzene (CAUTION) in portions of 2–3 ml; shake the flask well, to ensure thorough mixing, after each addition of the benzene. Do not allow the temperature of the mixture to rise above 55 °C; immerse the flask, if necessary, in cold water or in ice-water. When all the benzene has been added, fit a reflux condenser to the flask and heat it in a water bath maintained at 60 °C (but not appreciably higher) for 40–45 minutes; remove the flask from time to time from the bath and shake it vigorously to ensure good mixing of the immiscible layers. Pour the contents of the flask into about 500 ml of cold water in a beaker, stir the mixture well in order to wash out as much acid as possible from the nitrobenzene and allow to stand. When the nitrobenzene has settled to the bottom, pour off the acid liquor as completely as possible, and transfer the residual liquid to a separatory funnel. Run off the lower layer of nitrobenzene and reject the upper aqueous layer; return the nitrobenzene to the separatory funnel and shake it vigorously with about 50 ml of water. Separate the nitrobenzene as completely as possible and run it into a small conical flask containing about 5 g of anhydrous calcium chloride. If the nitrobenzene does not become clear on shaking because of the presence of emulsified water, warm the mixture, with shaking, for a short period on a water bath; the cloudiness will soon disappear. Filter the cold product through a small fluted filter paper into a small (50- or 100-ml) distilling flask and attach a still-head and air condenser.

Heat the flask on a ceramic-centred wire gauze or preferably in an air bath, and collect the fraction which boils at 206–211 °C (1). Do not distil quite to dryness nor allow the temperature to rise above 214 °C, for there may be a residue of $m$-dinitrobenzene and higher nitro compounds and an explosion may result. The yield of nitrobenzene is 35 g (85%). Pure nitrobenzene is a clear, pale yellow liquid, b.p. 210 °C.
The i.r. spectrum of nitrobenzene is reproduced on p. 313. The p.m.r. spectrum (CCl₄, TMS) shows signals at δ 7.3–7.8 (m, 3H, C₃,₄,₅—H) and a lower field signal at δ 8.0–8.3 (m, 2H, C₂,₆—H). The m.s. reveals significant fragment ions at m/z 123 (M), 93 (M – NO), 77 (M – NO₂; base peak), and 65 (93 – CO).

**Note.** (1) Nitrobenzene (and many other liquid organic compounds containing nitrogen) is appreciably toxic and its vapour should not be allowed to escape into the atmosphere of the laboratory. Site the distillation apparatus in a fume cupboard, use the receiver assembly illustrated in Fig. 2.98, and attach to the outlet of the receiver adapter a piece of rubber tubing leading to the extraction system. The liquid is also a skin poison; if it is accidentally spilled on the skin, it should be removed by washing with a little methylated spirit, followed by soap and warm water.

**Cognate preparation. 1-Nitronaphthalene.** Use 40 ml of concentrated nitric acid and 40 ml of concentrated sulphuric acid with 50 g (0.39 mol) of finely powdered naphthalene as detailed for nitrobenzene. The subsequent heating at 60 °C should be for 30–40 minutes or until the smell of naphthalene has disappeared. Pour the reaction mixture into 500 ml of water; decant the washings from the product and then boil the solid with 200 ml of water for 20 minutes. Decant the water and subject the oil to steam distillation (Fig. 2.102) to remove unreacted naphthalene. Pour the warm residue into a large volume of water with vigorous stirring. Filter and recrystallise from dilute alcohol to give pure 1-nitronaphthalene (60 g, 89%), m.p. 61 °C.

**Experiment 6.18 m-DINITROBENZENE**

\[
\text{Ph} \cdot \text{NO}_2 + \text{HNO}_3 \xrightarrow{\text{conc. H}_2\text{SO}_4} \text{m-C}_6\text{H}_4(\text{NO}_2)_2
\]

Place 37.5 g (21 ml) of concentrated sulphuric acid and 22.5 g (15 ml) of fuming nitric acid, d 1.5, in a 250- or 500-ml round-bottomed flask; add a few fragments of unglazed porcelain. Attach a reflux condenser and place the apparatus in a fume cupboard. Add slowly, in portions of about 3 ml, 15 g (12.5 ml, 0.122 mol) of nitrobenzene; after each addition, shake the flask to ensure thorough mixing. Heat the mixture, with frequent shaking, on a boiling water bath for 30 minutes. Allow the mixture to cool somewhat and pour it cautiously with vigorous stirring into about 500 ml of cold water; the dinitrobenzene soon solidifies. Filter with suction, wash thoroughly with cold water and allow to drain as completely as possible.

Transfer the crude dinitrobenzene to a 250-ml flask fitted with a reflux condenser, add 80–100 ml of industrial (or rectified) spirit and heat on a water bath until all the crystalline solid dissolves. If the resulting solution is not quite clear, filter it through a fluted filter paper on a large funnel which has previously been warmed or through a warm Buchner funnel. Colourless crystals of m-dinitrobenzene (15 g, 73%) are deposited on cooling. If the m.p. is below 89–90 °C, recrystallisation is necessary.

The i.r. absorption bands of the nitro group (KBr disc) should be noted at c. 1525 and 1340 cm⁻¹ (see Fig. 3.38). The p.m.r. is noted on p. 349 (cf. ortho and para isomers, both being noted on p. 942). The ¹³C-n.m.r. spectrum shows signals at δ 118.6, 128.8, 130.8 and 148.1. The m.s. shows significant fragment ions at m/z 168 (M), 122 (M – NO₂), 76 (M – 2NO₂), 92 (M – [NO₂ + NO]), 64 (92 – CO), and 30 (NO₂, base peak).
Cognate preparation. **2,4-Dinitrotoluene.** Use 18 g (12 ml, c. 0.36 mol) of fuming nitric acid, d 1.5, and 30 g (16.5 ml) of concentrated sulphuric acid in a two-necked flask (reflux condenser, stopper side-arm). Add, in small portions, 14 g (0.1 mol) of p-nitrotoluene through the side-arm keeping the temperature below 50°C. Heat the reaction mixture and isolate the product as described above. Recrystallise from methanol. The yield of pure 2,4-dinitrotoluene, m.p. 71°C, is 12.5 g (69%). The stretching vibrations of the nitro groups are clearly visible in the i.r. spectrum (KBr disc) at c. 1520 and 1340 cm⁻¹. The p.m.r. spectrum (CDCl₃, TMS) may be interpreted by first-order analysis: δ 2.75 (s, 3H, Me), 7.68 (d, 1H, C₆—H), 8.38 (d of d, 1H, C₅—H), and 8.74 (d, 1H, C₃—H).

**Experiment 6.19 m-NITROBENZALDEHYDE**

\[
\text{PhCHO} + \text{fuming HNO}_3 \xrightarrow{\text{conc. H}_2\text{SO}_4} m\text{-O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{CHO}
\]

Place 250 ml of concentrated sulphuric acid and 21.5 ml of fuming nitric acid, d 1.5, in a 500-ml two-necked flask fitted with a mechanical stirrer (unsealed) and a dropping funnel. Stir and cool to 0°C in a bath of ice and salt. Add 62.5 g (60 ml, 0.59 mol) of benzaldehyde (see Expt 6.133) dropwise from the dropping funnel; do not allow the temperature to rise above 5°C. Then warm the mixture gradually to 40°C, cool to room temperature and pour in a thin stream with vigorous stirring on to finely crushed ice. Filter through a sintered glass funnel, wash with a little water, press out the oil with a wide glass stopper and dry the solid in the air upon absorbent paper. The resulting crude m-nitrobenzaldehyde weighs 55 g and melts at 48–50°C. Melt the crude solid under excess of 10 per cent sodium carbonate solution, stir, cool, filter and dry in the air; the product has m.p. 51–52°C. Dissolve the solid in 120 ml of hot toluene (water bath; fume cupboard), decant from any solid present and add light petroleum, b.p. 40–60°C, until a slight turbidity results and cool. Collect the pure m-nitrobenzaldehyde and dry in the air; the yield is 45 g (50%), m.p. 58°C.

Note the i.r. absorptions at c. 3100 cm⁻¹ (C=Ar—H), c. 2800 cm⁻¹ (H—CO), and at c. 1700 cm⁻¹ (C=O), together with well-observed aromatic ring vibrations (at 1600, 1590, 1500 and 1450 cm⁻¹) and the absorptions arising from the vibrations of the nitro group. The p.m.r. spectrum (CDCl₃, TMS) shows δ 7.85 (distorted t, 1H, C₄—H), 8.2–8.9 (broad m, 3H, C₂,₅,₆—H), and 10.19 (s, 1H, H—CO).

**Experiment 6.20 p-BROMONITROBENZENE**

\[
\text{PhBr} + \text{HNO}_3 \xrightarrow{\text{H}_2\text{SO}_4} p\text{-Br} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2
\]

Prepare a mixture of 28.5 g (20 ml) of concentrated nitric acid and 37 g (20 ml) of concentrated sulphuric acid in a 250-ml round-bottomed flask (see Expt 6.17) and cool it to the laboratory temperature. Attach a reflux condenser to the flask. Add 16 g (10.5 ml, 0.1 mol) of bromobenzene (Expt 6.23) in portions of 2–3 ml during about 15 minutes; shake the flask vigorously during the whole process and do not allow the temperature to rise above 50–60°C by cooling in running water, if necessary. When the temperature no longer tends to rise owing to the heat of reaction, heat the flask on a boiling water bath for
30 minutes. Allow to cool to room temperature and pour the reaction mixture with stirring into 200 ml of cold water. Filter the bromonitrobenzene at the pump, wash well with cold water and finally drain as far as possible. Recrystallise from 100 to 125 ml of industrial spirit (flask, reflux condenser and water bath; see Expt 6.18). When cold, filter the almost pure \( p \)-bromonitrobenzene, m.p. 125 °C. The yield is 14 g (70%). The mother-liquor contains the \( o \)-bromonitrobenzene, contaminated with some of the \( p \)-isomeride.

The \( para \)-substitution pattern is clearly revealed by the p.m.r. spectrum (CDCl₃, TMS), which shows the characteristic pair of two-proton doublets, \( \delta 7.26 \) (d, 2H, \( ortho \)-H’s to Br), and 8.03 (d, 2H, \( ortho \)-H’s to NO₂).

**Experiment 6.21 \( p \)-NITROBENZYL CYANIDE**

\[
\text{Ph} \cdot \text{CH}_2 \cdot \text{CN} + \text{HNO}_3 \xrightarrow{\text{H}_2\text{SO}_4} \text{p-O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{CN}
\]

Place a mixture of 275 ml of concentrated nitric acid with an equal volume of concentrated sulphuric acid in a 2-litre three-necked flask, fitted with a thermometer, a mechanical stirrer and a dropping funnel and assembled in the fume cupboard. Cool the mixture to 10 °C in an ice bath, and run in 100 g (98 ml, 0.85 mol) of benzyl cyanide (Expt 5.157) at such a rate (about 1 hour) that the temperature remains at about 10 °C and does not rise above 20 °C. Remove the ice bath, stir the mixture for 1 hour and pour it on to 1200 g of crushed ice. A pasty mass slowly separates; more than half of this is \( p \)-nitrobenzyl cyanide, the other components being the \( ortho \) isomeride and a variable amount of an oil. Filter the mass on a sintered glass funnel, press well to remove as much oil as possible and then dissolve in 500 ml of boiling rectified spirit. The \( p \)-nitrobenzyl cyanide crystallises on cooling. Filter this off at the pump and recrystallise from 80 per cent ethanol. The yield of \( p \)-nitrobenzyl cyanide, m.p. 115–116 °C, is 75 g (54%). Another recrystallisation raises the m.p. to 116–117 °C.

The i.r. spectrum (KBr disc) shows absorptions at c. 3050 (C=\( \text{AR} \)–H str.), c. 2950 (C=\( \text{AI} \)–H str.), 2250 (C=\( \text{N} \) str.), 1500 and 1380 cm⁻¹ (NO₂ str.). The \( para \) substitution is confirmed by the p.m.r. spectrum (CDCl₃, TMS), \( \delta 3.89 \) (s, 2H, CH₂), 7.48 (d, 2H, C₂,₆–H), and 8.18 (d, 2H, C₃,₅–H).

**6.2.2 THE OXIDATION OF AMINES**

Various reagents are available for the oxidation of an aromatic amine to the corresponding nitro compound. For example, peroxymonosulphuric acid (Caro’s acid) and other peroxyacids have been quite widely used in the past, although the yields of nitro compounds are rather variable owing to the concomitant formation of azoxycompounds. Pertrifluoroacetic acid is the reagent of choice since it generally gives improved yields of purer products; its use is illustrated by the conversion of \( p \)-toluidine into \( p \)-nitrotoluene (Expt 6.22). Further examples are the formation of \( o \)-chloronitrobenzene and 2,6-dichloronitrobenzene from the corresponding primary amines. The method is not, however, generally suitable for amines having ring systems which are highly activated as the result, for example, of the presence of an alkoxy substituent.

\[
\text{ArNH}_2 + \text{CF}_2\cdot\text{CO}_2\text{H} \rightarrow \text{ArNO}_2
\]
6.2.3 THE REPLACEMENT OF A DIAZO GROUP BY A NITRO GROUP

This replacement is achieved by the decomposition of the aryldiazonium fluoroborate with aqueous sodium nitrite in the presence of copper powder and is described in Expt 6.78. This procedure gives better yields and thus replaces the former method of reacting an acidic aryldiazonium salt solution with nitrous acid in the presence of copper(II) oxide.

Experiment 6.22 p-NITROTOLUENE

\[(\text{CF}_3\cdot\text{CO})_2\text{O} + \text{H}_2\text{O}_2 \rightarrow \text{CF}_3\cdot\text{CO}_2\text{H} + \text{CF}_3\cdot\text{CO}_2\text{H}\]

\[p\text{-MeC}_6\text{H}_4\cdot\text{NH}_2 + \text{CF}_3\cdot\text{CO}_2\text{H} \rightarrow p\text{-MeC}_6\text{H}_4\cdot\text{NO}_2\]

CAUTION: This reaction should be carried out in a fume cupboard behind a safety screen. Adequate precautions should be observed in handling the hydrogen peroxide solution (Expt 5.190, Note (1)).

Prepare a solution of perfluorooctanoic acid in dichloromethane as follows. Place 50 ml of dichloromethane in a two-necked, 250-ml round-bottomed flask fitted with a reflux condenser and a dropping funnel. Insert a plastic-covered magnetic stirrer follower bar, and cool the flask in an ice bath sited on the stirrer unit. To the cooled and stirred solution add 3.5 ml (0.12 mol) of 85 per cent hydrogen peroxide and then 22.7 ml (33.9 g, 0.14 mol) of trifluoroacetic anhydride. Stir for 5 minutes after the addition is completed and then allow the solution to warm to room temperature. To this stirred solution add over 15 minutes a solution of 3.2 g (0.03 mol) of p-toluidine in 10 ml of dichloromethane. The reaction is exothermic but no cooling is necessary in this case. When the addition is complete heat the solution under reflux on the water bath for 1 hour. Cool, wash the dichloromethane solution with two 100 ml portions of water, dry (MgSO4) and remove the solvent on a rotary evaporator to obtain p-nitrotoluene, 2.9 g (71%), having m.p. c. 49 °C. Recrystallisation from a small volume of ethanol gives a purer product, m.p. 51–52 °C.

In the i.r. spectrum (KBr disc) note absorptions at c. 1555 and 1355 cm\(^{-1}\) (NO2 str.). The para substitution is confirmed by the p.m.r. spectrum (CDCl3, TMS) which shows δ 2.45 (s, 3H, Me), 7.30 (d, 2H, C2,6—H), and 8.10 (d, 2H, C3,5—H). The m.s. reveals principal fragment ions at m/z 137 (M), 107 (M − NO), 91 (M − NO2, base peak), 79 (107 − CO), and 77 (79 − H2).

6.3 AROMATIC HALOGEN COMPOUNDS

The compounds described and discussed below are those in which the halogen is directly attached to the aromatic nucleus (e.g. C6H5Cl, or PhCl, chlorobenzene) and those in which the halogen is substituted into an alkyl side chain (e.g. C6H5−CH3Cl, or Ph·CH2Cl, benzyl chloride).

The following procedures are available for the preparation of aromatic halogen compounds.

1. Direct halogenation by (a) substitution in the nucleus, and (b) substitution in the side chain (Expts 6.23 to 6.28).
2. Chloromethylation (Expt 6.29).
3. The replacement of a diazo group by a halogen (see Expts 6.70 to 6.72).
4. The replacement of a hydroxyl group by a halogen (Expt 6.30).
5. Methods leading to polyvalent iodine compounds (Expts 6.31 to 6.36).

SUMMARY OF RETROSYNTHETIC STRATEGIES

C—X Disconnection into an aryl anionic site (methods 1(a) and 2), e.g.

\[
\text{(TM)} \quad \begin{array}{c}
\text{X} \\
\text{Cl}
\end{array} \quad \xrightarrow{(1a)} \quad \begin{array}{c}
\text{X}^\ominus \\
\text{PhH} + \text{X}_2
\end{array} \\
\text{(TM)}
\]

C—X Disconnection into an aryl cationic site (methods 3 and 4), e.g.

\[
\text{(TM)} \quad \begin{array}{c}
\text{X} \\
\text{X}
\end{array} \quad \xrightarrow{(3)} \quad \begin{array}{c}
\text{X}^\ominus \\
\text{Ph} \cdot \text{N}_2^\ominus \cdot \text{Cu}^+ \cdot \text{X}
\end{array} \\
\text{(TM)}
\]

\[
\text{(TM)} \quad \begin{array}{c}
\text{X} \\
\text{X}
\end{array} \quad \xrightarrow{(4)} \quad \begin{array}{c}
\text{X}^\ominus \\
\text{Ph} \cdot \text{O} \cdot \text{PPh}_3 \cdot \text{X}^\ominus
\end{array} \\
\text{(TM)}
\]

C—X Disconnection in the side-chain (method 1(b)), e.g.

\[
\text{(TM)} \quad \begin{array}{c}
\text{X} \\
\cdot \text{CH}_2
\end{array} \quad \xrightarrow{(1b)} \quad \begin{array}{c}
\cdot \text{CH}_2 \\
\text{Ph} \cdot \text{Me} + \text{X}_2(\text{hv})
\end{array} \\
\text{(TM)}
\]

SPECTROSCOPIC FEATURES

The *i.r.* spectrum of an aromatic halogen compound shows the expected absorptions due to the aromatic nucleus and strong absorption in the longer wavelength region due to the stretching of the C—X bond (p. 316). The *p.m.r.* spectrum and the *m.s.* are more useful for definitive structural characterisation. The former may frequently enable the substitution pattern to be assigned; examples are to be found in the preparative accounts below. By virtue of the
natural isotope ratios of bromine and chlorine (p. 366) the m.s. often enables the various possible combinations in mono- and poly-halogenated compounds to be assessed (see for example bromobenzene and p-dibromobenzene, Expt 6.23; p-bromochlorobenzene, Expt 6.30; 2,4,6-tribromoaniline Expt 6.59). The u.v.-visible spectrum is not sufficiently informative to be of value in structural assignments.

6.3.1 DIRECT HALOGENATION

NUCLEAR SUBSTITUTION

Benzene does not react appreciably with chlorine and bromine in the cold, but in the presence of catalysts, such as aluminium amalgam, pyridine or iron, reaction takes place readily, affording in the first instance the mono-halogenated derivative as the main product. Di-substituted products (largely the para isomer) are obtained if the proportion of the halogen is increased. A typical procedure is given in the preparation of bromobenzene (Expt 6.23). The function of the catalyst is to increase the electrophilic activity of the halogen and the mechanism of the bromination of benzene with pyridine as the catalyst can be represented by the following scheme (cf. the nitration of benzene, Section 6.2.1, p. 851).

\[
\begin{align*}
\text{Br—Br} & \rightleftharpoons \text{Br}^- + \text{Br}^+ \\
\text{Br}^- \text{N} & \rightleftharpoons \left[ \text{H}^- \text{Br} \right] + \text{C}_5\text{H}_5\text{N} \\
\text{H}^+ + \text{C}_5\text{H}_5\text{N} & \rightarrow \text{HBr} + \text{C}_5\text{H}_5\text{NH} \\
\text{Br}^- + \text{C}_5\text{H}_5\text{NH} & \rightarrow \text{HBr} + \text{C}_5\text{H}_5\text{N}
\end{align*}
\]

Since iodine is the least reactive of the halogens, iodination does not occur unless the reaction is carried out in the presence of an oxidising agent. When using fuming nitric acid, the nature of the electrophile which functions as the I\(^{\ominus}\) donor is thought to be [O—N(I)OH]\(\ominus\).\(^\text{10}\) More recently a procedure has been reported using copper(II) chloride as the source of oxidant in the presence of aluminium chloride.\(^\text{11}\) Both methods give good yields of iodosobenzene (Expt 6.24), but the latter method is more suitable for the iodination of alkylbenzenes (e.g. p-xylene, which gives a good yield of 2-iodo-1,4-dimethylbenzene). Benzene derivatives with electron-withdrawing groups are not iodinated under these conditions.

Condensed aromatic hydrocarbons are more reactive towards electrophilic reagents, and naphthalene, for example, may be brominated quite readily in solution in carbon tetrachloride without the need for a catalyst; electrophilic attack takes place at the more reactive \(\alpha\)-position to yield 1-bromonaphthalene (Expt 6.25).

The effects of substituents in electrophilic aromatic substitution processes,
which are outlined in Section 6.2.1, p. 852, are further illustrated here with reference to the bromination of nitrobenzene, where a substantially higher reaction temperature is required (the nitro group is deactivating) and the product is predominantly m-bromonitrobenzene (Expt 6.26). Nitration of an aryl halide gives a mixture of o- and p-halonitrobenzenes (Expt 6.20).

SIDE-CHAIN HALOGENATION

In the absence of catalysts, treatment of toluene with chlorine (or bromine) at the boiling point, preferably with exposure to sunlight or other bright light source, results in halogenation in the side chain. The introduction of the first chlorine atom, for example, proceeds at a much faster rate than the introduction of the second chlorine atom so that in practice the major portion of the toluene is converted into benzyl chloride (1) before appreciable chlorination of benzyl chloride occurs to give benzylidene chloride (2) and benzo-trichloride (3).

\[
\text{Ph} \cdot \text{Me} + \text{Cl}_2 \xrightarrow{\text{heat}, \text{hv}} \text{Ph} \cdot \text{CH}_2\text{Cl} \xrightarrow{} \text{Ph} \cdot \text{CHCl}_2 \xrightarrow{} \text{Ph} \cdot \text{CCl}_3
\]

The reaction proceeds by the radical mechanism shown; the first step is facilitated by the mesomeric stabilisation of the benzylic radical.

\[
\text{Cl}_2 \xleftrightarrow{} 2\text{Cl}\cdot
\]

\[
\text{Ph} \cdot \text{Me} + \text{Cl} \cdot \xrightarrow{\text{HCl}} \text{Ph} \cdot \text{CH}_2 \xrightarrow{\text{Cl}_2} \text{Ph} \cdot \text{CH}_2\text{Cl} + \text{Cl} \cdot \text{etc.}
\]

Rapid side-chain chlorination of toluene proceeds in the dark with sulphuryl chloride in the presence of benzoyl peroxide (0.001–0.005 mol per mol of \(\text{SO}_2\text{Cl}_2\)) as catalyst (Expt 6.27). With an excess of sulphuryl chloride, benzylidene chloride is formed, but in this case chlorination does not proceed beyond this stage.

Side-chain halogenation is illustrated also by the bromination of p-nitrotoluene (Expt 6.28). The radical mechanism with molecular bromine is similar to that of chlorination above; N-bromosuccinimide has also found use as a side-chain brominating reagent and its application is described in Expts 6.119 and 6.152.

**Experiment 6.23 BROMOBENZENE**

\[
\text{PhH} + \text{Br}_2 \xrightarrow{\text{pyridine}} \text{C}_6\text{H}_5\text{Br}
\]

*This preparation should be conducted in an efficient fume cupboard.*

Place 50 g (57 ml, 0.64 mol) of dry benzene (CAUTION) and 0.5 ml of dry pyridine (1) (dried over potassium hydroxide pellets) in a 500-ml round-bottomed flask. Attach a reflux condenser to the flask and fit a device for absorbing the hydrogen bromide gas subsequently evolved (Fig. 2.61(a)). Partially immerse the flask in a bath of cold water, supported upon a tripod and gauze. Carefully pour 125 g (40 ml) of bromine (for precautions to be taken with bromine, see Section 4.2.9, p. 422) through the condenser and immediately insert the absorption device into the upper end of the condenser. A vigorous reaction soon occurs and hydrogen bromide is evolved which is absorbed by the water in the beaker; when the reaction slackens, warm the bath to 25–30°C for 1 hour. Finally raise the temperature of the bath to 65–
70 °C for a further 45 minutes or until all the bromine has disappeared (no red vapours visible) and the evolution of hydrogen bromide has almost ceased. Transfer the dark-coloured reaction product to a separatory funnel and shake successively with water, with sufficient 5–10 per cent sodium hydroxide solution to ensure that the washings are alkaline to litmus, and finally with water. Dry with magnesium sulphate or anhydrous calcium chloride. Filter through a fluted filter paper into a small distilling flask and distill slowly. Collect the crude bromobenzene at 150–170 °C; pour the residue while still hot into a small porcelain basin. Redistil the liquid of b.p. 150–170 °C (2) and collect the bromobenzene at 154–157 °C; the yield is about 60 g (60%).

In the i.r. spectrum (thin film) note absorptions at c. 3050 cm⁻¹ (C=H, stretching), and at 1600, 1590, 1500 and 1450 cm⁻¹ (ring-breathing vibrations). The p.m.r. spectrum (CCI₄, TMS) shows two complex signals at δ 7.13 (m, 3H, C₃,4,5—H) and at 7.41 (m, 2H, C₂,6—H). The presence of bromine is clearly revealed in the m.s. which shows principal fragment ions at 158 (M, ⁸¹Br) and 156 (M, ⁷⁹Br) of nearly equal intensity, and at 77 (M – Br, base peak) and 51 (77 – C₂H₂).

Isolate the pure p-dibromobenzene from the residue in the basin by recrystallisation from hot ethanol with the addition of 1–2 g of decolourising charcoal; use about 4 ml of ethanol (industrial spirit) for each gram of material. Filter the hot solution through a fluted filter paper, cool in ice and filter the crystals at the pump. The yield of p-dibromobenzene, m.p. 89 °C, is about 12 g.

The p.m.r. spectrum (CDCl₃, TMS) shows a sharp signal at δ 7.29 (s, 4H, C₉—H) characteristic of an A₄ aromatic substitution pattern. The m.s. shows the typical molecular ion cluster due to the presence of two bromine atoms (p. 366), namely, m/z 238 (RA 48.8%), 236 (RA 100%) and 234 (RA 51.4%); the other ions are observable at m/z 157 (C₆H₄ ⁸¹Br), 155 (C₆H₄ ⁷⁹Br), 75 (157 – H ⁸¹Br, and 155 – H ⁷⁹Br), 76 (157 – ⁸¹Br and 155 – ⁷⁹Br) and 50 (76 – C₂H₂).

Notes. (1) Other halogen carriers may be used, e.g. 1–2 g of iron filings, or 1 g of aluminium amalgam. The bromine must then be added slowly from a dropping funnel to the benzene warmed on a water bath; a suitable two- or three-necked flask should be used. After all the bromine has been introduced, the mixture is heated on a water bath until no red vapours are visible above the liquid. The subsequent procedure is as above.
(2) The best results are obtained by distillation from a small flask through a short fractionating column: a Hempel column filled with glass rings (Fig. 2.105(c)) and lagged with several thicknesses of linen cloth is quite satisfactory.

### Experiment 6.24 IODOBENZENE

\[2\text{PhH} + I₂ \xrightarrow{\text{HNO}_₃} 2\text{PhI} + \text{H}_₂\text{O}\]

**This preparation should be conducted in an efficient fume cupboard.**

Equip a 500-ml three-necked flask with a reflux condenser, a sealed mechanical stirrer and separatory funnel, and support it on a water bath. Attach an absorption device (Fig. 2.61) to the top of the condenser. Place 134 g (152 ml, 1.72 mol) of benzene (CAUTION) and 127 g (0.5 mol) of iodine in the flask, and heat the water bath to about 50 °C; add 92 ml of fuming nitric acid, d 1.50, slowly from the separatory funnel during 30 minutes (1). Oxides
of nitrogen are evolved in quantity. The temperature rises slowly without the application of heat until the mixture boils gently. When all the nitric acid has been introduced, reflux the mixture gently for 15 minutes. If iodine is still present, add more nitric acid to the warm solution until the purple colour (due to iodine) changes to brownish-red.

Separate the lower oily layer, mix with it an equal volume of 10 per cent sodium hydroxide solution and steam distil from a 1-litre flask until no more oil passes over. A yellow solid, consisting of nitro compounds, may collect towards the end of the distillation; remove this by mechanical stirring of the oil for about 3 hours with 7 ml of concentrated hydrochloric acid, 100 ml of water and 70 g of iron filings in a 1-litre three-necked flask connected with a reflux condenser. Allow the mixture to cool and filter. Render the filtrate distinctly acid to Congo red with hydrochloric acid and again steam distil. Separate the oil, dry it with anhydrous calcium chloride or magnesium sulphate, distil through a suitably lagged fractionating column and collect the fraction of b.p. 180–190 °C. Upon redistillation, pure iodobenzene, b.p. 184–186 °C, is obtained. The yield is 180 g (87%).

**Note.** (1) In an alternative procedure, iodine (3.8 g, 15 mmol) is dissolved in benzene (50 ml), to this solution is added a mixture of anhydrous aluminium chloride (4.0 g, 30 mmol) and copper(II) chloride (4.0 g, 30 mmol) previously dried at 120 °C/3 mmHg for more than 3 hours. The mixture is stirred at 40 °C for 2 hours, and then poured into water. The organic layer is washed with aqueous sodium hydrogen sulphite, dried and fractionally distilled. The yield of iodobenzene is 79 per cent.

**Experiment 6.25 1-BROMONAPHTHALENE**

\[ C_{10}H_8 + Br_2 \xrightarrow{CCl_4} C_{10}H_7Br + HBr \]

Use a 500-ml three-necked flask equipped as in Expt 6.26 but mounted on a water bath. Place 128 g (1 mol) of naphthalene and 45 ml of dry carbon tetrachloride in the flask, and 177 g (55 ml, 1.11 mol) of bromine (CAUTION) in the separatory funnel. Heat the mixture to gentle boiling and run in the bromine at such a rate that little, if any, of it is carried over with the hydrogen bromide into the trap; this requires about 3 hours. Warm gently, with stirring, for a further 2 hours or until the evolution of hydrogen bromide ceases. Replace the reflux condenser by a condenser set for downward distillation, stir and distil off the carbon tetrachloride as completely as possible. Mix the residue with 8 g of sodium hydroxide pellets and stir at 90–100 °C for 3 hours; this treatment will remove impurities which gradually evolve hydrogen bromide. Distil the product under diminished pressure and collect the following fractions: (i) up to 131 °C/12 mmHg (or 144 °C/20 mmHg); (ii) 132–135 °C/12 mmHg (or 145–148 °C/20 mmHg); and (iii) above 135 °C/12 mmHg (or 148 °C/20 mmHg). Fraction (ii) is almost pure 1-bromonaphthalene. Fraction (i) contains unchanged naphthalene, while (iii) contains dibromonaphthalene. Cool fraction (i) in ice when most of the naphthalene will crystallise out; filter this off on a sintered glass funnel, combine the filtrate with fraction (iii), redistil and collect the 1-bromonaphthalene fraction separately. The total yield of colourless product is 150 g (72.5%).
Experiment 6.26  

$m$-BROMONITROBENZENE  

\[ \text{Ph} \cdot \text{NO}_2 + \text{Br}_2 \xrightarrow{\text{Fe}} \text{m-Br} \cdot \text{C}_6 \text{H}_4 \cdot \text{NO}_2 + \text{HBr} \]

Equip a 1-litre three-necked flask with a separatory funnel, a sealed mechanical stirrer (1) and a double surface reflux condenser carrying an outlet tube connected to a gas trap (Fig. 2.62). Support the flask in an oil bath. Place 90 g (75 ml, 0.73 mol) of dry, freshly distilled nitrobenzene in the flask. Weigh out 10 g of pure iron powder (95%) 'reduced by hydrogen'. Heat the oil bath to 135–145 °C and introduce 3 g of the iron powder by temporarily removing the separatory funnel. Into the latter place 62.5 g (20 ml, 1.17 mol) of dry bromine (CAUTION) (Section 4.2.9, p. 422) and run it into the flask at such a rate that bromine vapours do not rise appreciably in the condenser (c. 20 minutes). Continue stirring and heating for 1 hour before adding a further 3 g of iron powder and 20 ml of dry bromine in a similar manner. Stir for a further hour, add another 3 g of iron powder and 20 ml of bromine. When there is no more bromine vapour in the condenser, make a final addition of 1 g of iron powder and heat for 1 hour longer.

Pour the resulting dark reddish-brown liquid into 500 ml of water to which 17 ml of saturated sodium metabisulphite solution has been added (the latter to remove the excess of bromine). Steam distil the resulting mixture (Fig. 2.102); collect the first portion of the distillate, which contains a little unchanged nitrobenzene, separately. Collect about 4 litres of distillate. Filter the yellow crystalline solid at the pump, and press well to remove the adhering liquid. The resulting crude $m$-bromonitrobenzene, m.p. 51–52 °C, weighs 110 g (74%). If required pure, distil under reduced pressure (Section 2.27) and collect the fraction of b.p. 117–118 °C/9 mmHg; it then melts at 56 °C and the recovery is about 85 per cent.

Note. (1) Mechanical stirring, although not essential and replaceable by occasional shaking by hand, is advantageous.

Experiment 6.27  

BENZYL CHLORIDE  

\[ \text{Ph} \cdot \text{Me} + \text{SO}_2\text{Cl}_2 \xrightarrow{\text{peroxide}} \text{Ph} \cdot \text{CH}_2\text{Cl} + \text{SO}_2 + \text{HCl} \]

In an efficient fume cupboard attach a double surface condenser to a 500-ml round-bottomed flask containing 92 g (106 ml, 1 mol) of toluene, 68 g (41 ml, 0.5 mol) of redistilled sulphuryl chloride and 1 g of benzoyl peroxide (Section 4.2.6, p. 417). Reflux gently and remove the heat source if necessary to moderate the vigorous reaction which takes place. The reaction is complete in 30 minutes. Distil the reaction mixture using a fractionating column, first under atmospheric pressure until the temperature reaches 135–140 °C, and continue the distillation under diminished pressure collecting the benzyl chloride at 64–69 °C/12 mmHg (1). The latter on redistillation boils at 63–65 °C/12 mmHg. The yield of benzyl chloride is 50 g (79%).

Note. (1) The benzyl chloride may also be isolated by distillation under atmospheric pressure. The material boiling between 165 and 185 °C is collected and redistilled; the final product is collected at 178–182 °C (pure benzyl chloride has b.p. 179 °C). The resulting benzyl chloride is, however, of lower purity unless an efficient fractionating column is used.
Experiment 6.28 p-NITROBENZYL BROMIDE

\[ p-O_2N\cdot C_6H_4\cdot Me \quad Br_2 \rightarrow p-O_2N\cdot C_6H_4\cdot CH_2Br \]

Place 150 g (1.1 mol) of p-nitrotoluene, m.p. 51–52°C, in a 500-ml three-necked flask, fitted with a reflux condenser, a sealed mechanical stirrer and a separatory funnel with stem reaching nearly to the bottom of the flask. Attach a gas absorption trap (Fig. 2.62) to the top of the condenser; the whole assembly should be sited in a fume cupboard. Heat the flask in an oil bath at 145–150°C and add 184 g (59 ml, 1.15 mol) of bromine during 2 hours (1). Continue the stirring for an additional 10 minutes after all the bromine has been added. Pour the contents of the flask while still liquid (CAUTION) (2) into a 2.5-litre round-bottomed flask containing 2 litres of hot light petroleum, b.p. 80–100°C, and 8 g of decolourising carbon. Attach a reflux condenser to the flask, heat it with the aid of a heating mantle until the material dissolves, boil for 10 minutes and filter rapidly through a pre-heated Buchner funnel. Cool the filtrate to 20°C, filter the crystals with suction, press well and wash with two 25 ml portions of cold light petroleum. The crude p-nitrobenzyl bromide, m.p. 95–97°C (150 g), is sufficiently pure for many purposes. Purify by dissolving in 1500–1700 ml of light petroleum, b.p. 80–100°C, boil with 8 g of decolourising carbon, and filter through a preheated Buchner or sintered glass funnel. Cool the filtrate in ice, filter at the pump, drain well and wash with two 15 ml portions of cold light petroleum. The yield of pure p-nitrobenzyl bromide (pale yellow crystals, m.p. 98–99°C) is 135 g (57%).

Structural characterisation is confirmed by the p.m.r. spectrum (CDCl₃, TMS) which shows signals at δ 4.51 (s, 2H, CH₂), 7.57 (d, 2H, ortho-H's to CH₂Br) and 8.18 (d, 2H, ortho-H's to NO₂). In the i.r. spectrum the absorption due to the nitro group (c. 1340 and 1550 cm⁻¹) is clearly visible.

Notes. (1) Improved yields may be obtained by exposing the flask to the light of two 300-watt tungsten lamps during the bromination.
(2) Care must be taken in manipulating the lachrymatory solutions of p-nitrobenzyl bromide. If the substance should come into contact with the skin, bathe the affected part with alcohol.

6.3.2 CHLOROMETHYLATION

This is the replacement of a hydrogen atom in an aromatic compound by a chloromethyl (CH₂Cl) group in a single operation. The original classical reaction consists essentially of the interaction of formaldehyde and hydrogen chloride in the presence of a catalyst such as zinc chloride or aluminium chloride with an aromatic system (Blanc chloromethylation reaction). The reaction is similar in some respects to that of Friedel and Crafts (see Sections 6.1.1, p. 828, and 6.11.1, p. 1006) and involves the hydroxymethyl cation as the electrophilic species. This reacts with the aromatic ring to give the benzylic alcohol which is then converted into the chloromethyl derivative by hydrogen chloride.

\[ H_2C=O + HCl \quad \rightleftharpoons \quad \text{Cl}^+ + [H_2C=\overset{\text{\textregistered}}{\text{\textbar}}\text{OH} \quad \rightleftharpoons \quad H_2C-OH] \]

\[ \text{ArH} + \overset{\text{\textregistered}}{\text{CH}_2\text{OH}} \quad \rightarrow \quad \text{Ar} \cdot \text{CH}_2\text{OH} + \text{H}^+ \]

\[ \text{Ar} \cdot \text{CH}_2\text{OH} + \text{HCl} \quad \rightarrow \quad \text{Ar} \cdot \text{CH}_2\text{Cl} + \text{H}_2\text{O} \]
However, it has been found that a by-product arising from the interaction of formaldehyde and hydrogen chloride is bis(chloromethyl)ether (BCME), which is a potent carcinogen. For this reason the classical chloromethylation route to side-chain halogenated products should not be regarded as a desirable synthetic procedure, and in general should only be used if the required compound cannot be readily prepared by other methods. When used, effective precautions should be taken during the reaction and in the disposal of the reaction residues.\(^{12,13}\)

Recently two alternative procedures have been described. In one case\(^{14}\) methoxyacetyl chloride (MeO-CH\(_2\)-COCl) in the presence of anhydrous aluminium chloride is thought to provide the source of the cation (4), which substitutes in the aromatic nucleus to give the benzyl methyl ether (5), which is subsequently converted into the chloromethylated product (6).

\[
\begin{align*}
\text{MeO-CH}_2\text{-COCl} & \xrightarrow{\text{AlCl}_3} \text{MeO-CH}_2\bigcirc\leftrightarrow\text{C}=\text{O}\bigcirc\text{AlCl}_4 \xrightarrow{\text{CO}} \text{MeO-CH}_2\bigcirc\text{AlCl}_4 \\
\text{ArH} + \text{MeO}=\text{CH}_2 & \rightarrow \text{Ar-CH}_2\bigcirc\text{O-CH}_2 \rightarrow \text{Ar-CH}_2\text{Cl}
\end{align*}
\]

A wide range of substituted aromatic systems have been chloromethylated by this procedure, the only disadvantage being the expense of the methoxyacetyl chloride.

In the second alternative method a two-step procedure has been described.\(^{15}\) The first step involves amidomethylation of the aromatic nucleus by reaction with paraformaldehyde and acetamide in the presence of concentrated sulphuric acid. The isolated intermediate is then treated with phosphorus oxychloride in dimethylformamide and xylene and converted into the chloromethylated product [e.g. see 2-(chloromethyl)-4-nitrotoluene, Expt 6.29, for formulation]. The mechanisms of these reactions are currently only speculative.

**Experiment 6.29 2-(CHLOROMETHYL)-4-NITROTOLUENE\(^{15}\)**

\[
\begin{align*}
\text{Me} & \quad + \quad \text{CH}_2\text{O} + \text{Me-CONH}_2 \rightarrow \\
\text{NO}_2 & \quad \text{Me} \quad \text{CH}_2\text{-NH-.CO-Me} \quad \xrightarrow{\text{POCl}_3} \quad \text{Me} \quad \text{CH}_2\text{Cl} \\
\text{NO}_2 & \quad \text{Me} \quad \text{CH}_2\text{-NH-.CO-Me} \quad \xrightarrow{\text{POCl}_3} \quad \text{Me} \quad \text{CH}_2\text{Cl}
\end{align*}
\]

**N-(2-Methyl-5-nitrobenzyl)acetamide.** To a solution of 6.85 (0.05 mol) of p-nitrotoluene and 1.5 g (0.05 mol) of paraformaldehyde in 60 ml of concentrated sulphuric acid is added 8.85 g (0.15 mol) of acetamide in portions. The solution is heated at 55 °C for 8 hours and poured over ice and water. The resulting solid is collected and heated in 10–12 parts of butyl acetate at 90 °C and filtered. Cooling the filtrate gives 7.8 g (75\%) of the acetamide as a
colourless solid, m.p. 141–143 °C; i.r. 3275, 1640 and 1660 (sh) cm⁻¹; m/z 208 (M); p.m.r. (CDCl₃, TMS) δ 2.02 (s, 3H, CO·Me), 2.37 (s, 3H, Ar·Me), 4.39 (d, 2H, CH₂), 6.32 (broad s, 1H, NH), 7.18 (d, 1H, J = 8 Hz, C₃—H), and 7.86 (d, 2H, J = 10 Hz, C₄—H and C₆—H). Material insoluble in butyl acetate is recrystallised from chloroform–methanol to give bis(2-methyl-5-nitropheny) methane, m.p. 153 °C.

2-(Chloromethyl)-4-nitrotoluene. A solution of 6.24 g (0.03 mol) of the foregoing acetamide, 9.67 g (0.063 mol) of phosphorus oxychloride and 2.19 g (0.03 mol) of dimethylformamide in 50 ml of xylene is refluxed for 1 hour. The cooled solution is washed with water and evaporated to give 4.73 g (85%) of product [CAUTION (1)] which after recrystallation from hexane has m.p. 61–62 °C.

Note. (1) This compound is lachrymatory and may be a skin irritant.

6.3.3 THE REPLACEMENT OF A DIAZO GROUP BY A HALOGEN

The most generally applicable route to nuclear substituted aromatic halogen compounds involves decomposition of a diazonium salt under suitable conditions. These reactions are discussed in Section 6.7.1, p. 922.

6.3.4 THE REPLACEMENT OF A HYDROXYL GROUP BY A HALOGEN

Replacement of the hydroxyl group in a phenol by halogen cannot be accomplished by reaction with the hydrogen halides as in the case of alcohols, and reaction with phosphorus halides gives only low yields of halogenobenzenes (except in the case of nitrophenols), the main product being a phosphite or phosphate ester.

ArOH + PCl₃ → (ArO)₃P + 3HCl

However, if the phenol is first treated with the complex formed from triphenylphosphine and a halogen in acetonitrile solution, an aryloxytriphenylphosphonium halide is formed which on thermal decomposition yields the aryl halide in good yield (e.g. the preparation of p-bromochlorobenzene, Expt 6.30).

Ph₃P + X₂ → Ph₃PX₂[ArOH] → Ph₃P(OAr)+X- → Ph₃PO → ArX

Experiment 6.30 p-BROMOCHLOROBENZENE

p-Cl·C₆H₄OH + Ph₃PBr[Br] → p-Cl·C₆H₄Br + HBr + Ph₃PO

CAUTION: This preparation should be carried out in the fume cupboard.

Equip a 250-ml three-necked round-bottomed flask with a reflux condenser and a dropping funnel (both protected by calcium chloride guard-tubes), and a sealed stirrer unit. In the flask place 29 g (0.11 mol) of finely powdered triphenylphosphine and 100 ml of dry acetonitrile (Section 4.1.27, p. 410). Cool the flask in an ice-water bath and add with stirring over a period of 20 minutes 17.3 g (5.5 ml, 0.108 mol) of bromine. After the addition is complete remove the cooling bath, set the condenser for downward distillation and
replace the dropping funnel with a stopper. Remove the acetonitrile under reduced pressure using a water pump; warm the flask to 40 °C on a water bath and use an oil pump to remove last traces of solvent. Add 10g (0.078 mol) of redistilled, powdered p-chlorophenol to the solid residue, replace the condenser (together with its guard-tube) in the reflux position and site the flask on a sand bath. Raise the temperature of the sand bath to between 250 and 280 °C and slowly stir the contents of the flask which soon melt; hydrogen bromide is evolved over a period of 3 hours. When evolution of gas ceases, cool the residue, add water and steam distil. Collect the solid p-bromochlorobenzene by filtration of the distillate; it has m.p. 63–65 °C. Recrystallise from ethanol to obtain the pure product, m.p. 65–66 °C; the yield is 12.5 g (83%).

The p.m.r. spectrum (CCl₄, TMS) shows a pair of doublets characteristic of para substitution at δ 7.13 (d, 2H, ortho-H's to Cl) and at 7.37 (d, 2H, ortho-H's to Br). The m.s. provides an excellent illustration of the isotope combinations of chlorine and bromine (p. 366); principal fragment ions are at m/z 194 (M, ⁸¹Br³⁷Cl, RA 23.6%), 192 (M, ⁸¹Br³⁵Cl and ⁷⁹Br³⁷Cl, RA 100%), 190 (M, ⁷⁹Br³⁵Cl, RA 76.1%), 113 (194 – ⁸¹Br, 192 – ⁷⁹Br), 111 (192 – ⁸¹Br, 190 – ⁷⁹Br) and 75 (113 – H³⁷Cl, 111 – H³⁵Cl).

### 6.3.5 METHODS LEADING TO POLYVALENT IODINE COMPOUNDS

Aryl iodides are exceptional among the aromatic halogen compounds in that they form a series of derivatives in which the iodine exhibits a covalency greater than one. Some typical interconversions for which experimental conditions are given (Expts 6.31 to 6.36) are summarised below.

\[
\begin{align*}
\text{ArI} & \xrightarrow{\text{Cl}_2/\text{CHCl}_3} \text{ArCl}_2 \xrightarrow{\text{OH}} \text{ArI(O-CO-CH}_3\text{)}_2 \quad \text{ArI(O-CO-CH}_3\text{)}_2 \xrightarrow{\text{IO}_2} \text{ArI}_2\text{IO}_3 \xrightarrow{\text{OH}} \text{ArI}_2\text{I}^+ \text{I}^- \\
\text{heat} & \quad \text{H}_2\text{O} \\
\text{ArCl}_2 & \quad \text{ArI}_2\text{I}^+ \text{I}^- \\
\text{ArI} & \quad \text{ArIO} \\
\text{CH}_3\text{CO}_2\text{H} & \quad \text{ArI}_2\text{I}^+ \text{I}^- \\
\text{ArI} & \quad \text{ArIO}_2 \\
\end{align*}
\]

Two polyvalent iodine compounds arising from o-iodobenzoic acid have been found to be useful synthetic reagents. Thus oxidation of the iodo acid (7) with potassium persulphate, followed by the addition of benzene and treatment with potassium iodide gives the iodonium iodide (8) which is converted into diphenyliodonium-2-carboxylate [DPIC (9)] with aqueous alkali (Expt 6.35).
AROMATIC COMPOUNDS

DIPC has been used as a benzyne precursor$^{17}$ into which it decomposes at 160–220 °C. At lower temperatures (80–100 °C) and in the presence of copper(II) acetate, it reacts with amino and phenolic nucleophiles to give ortho-substituted benzoic acids.$^{16}$

The periodinane (10) may also be prepared from o-iodobenzoic acid by oxidation with potassium bromate and then treatment with acetic anhydride$^{18a}$ (see Expt 6.36 for detailed formulation). It should be noted that the organic derivatives of pentacoordinate iodine(v) are termed periodinanes.$^{18b}$ This compound (the systematic name is 1,1,1-triacetoxy-2,1-benzoxiodol-3(3H)-one) has found use as an oxidant of primary alcohols to aldehydes and alicyclic ketones to secondary alcohols; it is claimed to have advantages over the chromium-based oxidation reagents.

**Experiment 6.31 (DICHLOROIOIDO)BENZENE (Iodobenzene dichloride)**

\[
\text{PhI} + \text{Cl}_2 \rightarrow \text{PhICl}_2
\]

Equip a 500-ml three-necked flask with a mechanical stirrer, an adjustable inlet tube at least 10 mm in diameter for the introduction of chlorine (see Section 4.2.15, p. 424) and an outlet tube carrying a calcium chloride guard-tube. Charge the flask with 75 ml of chloroform (dried with anhydrous calcium chloride: see Section 4.1.6, p. 399) (CAUTION) and 51 g (0.25 mol) of iodobenzene (Expt 6.24); adjust the inlet tube so that it terminates about 5 mm above the surface of the liquid. Set up the apparatus in the fume cupboard and protect it from the light. Cool the flask in an ice–salt mixture and pass in dry chlorine as rapidly as the solution will absorb it until an excess is present (1.5–2 hours). Filter the yellow, crystalline iodobenzene dichloride at the pump, wash it sparingly with chloroform and dry it in the air upon filter paper. The yield is 65 g (93.5%). The substance decomposes slowly upon standing; it may be kept unchanged for a short period in a well-fitting, ground glass stoppered bottle.

**Experiment 6.32 IODOSYLBENZENE (Iodosobenzene) AND IODOBENZENE DIACETATE [(Diacetoxyiodo)benzene]**

\[
\text{PhICl}_2 \xrightarrow{2\text{NaOH}} \text{PhIO} \xrightarrow{2\text{Me}\cdot\text{CO}_2\text{H}} \text{PhI(O\cdot\text{CO}\cdot\text{Me})}_2
\]
Cool a large glass mortar in ice and then place in it 50 g of anhydrous sodium carbonate, 55 g (0.2 mol) of iodobenzene dichloride (Expt 6.31) and 100 g of finely crushed ice. Grind the mixture thoroughly until all the ice has melted and a thick paste results. Add 140 ml of 5 M sodium hydroxide in 20 ml portions and triturate vigorously after each addition; finally add 120 ml of water and allow to stand overnight. Filter with suction, press well with a large flat glass stopper on the filter, transfer to a beaker and stir with 300 ml of water (1). Filter again at the pump, transfer again to a beaker containing 300 ml of water, filter and wash with about 200 ml of water on the filter. Dry in the air upon filter papers, stir with a little chloroform (to dissolve a little iodobenzene which is present), filter with suction and dry on filter paper in the air. The yield is 27 g (61%).

Iodosylbenzene explodes violently at about 220 °C, so that determinations of the melting point should not be attempted. It may, however, be converted into *iodobenzene diacetate* in the following manner. Dissolve 2 g of iodosylbenzene in 6 ml of glacial acetic acid; boiling is usually necessary. Cool. The resulting diacetate is readily soluble in acetic acid but is insoluble in ether. Add about 50 ml of ether in order to precipitate the iodobenzene diacetate. Filter and wash with ether. The yield is 2 g, m.p. 157 °C. It may be recrystallised from benzene, and will keep indefinitely (unlike the iodobenzene dichloride).

**Note. (1)** The filtrate contains some diphenyliodonium salts; these may be recovered as the sparingly soluble diphenyliodonium iodide (about 8 g) (Expt 6.34) by the addition of potassium iodide.

**Experiment 6.33 IODYLBENZENE (Iodoxybenzene)**

\[2\text{PhIO} \xrightarrow{\text{heat}} \text{PhIO}_2 + \text{PhI} \]

Fit up a 1-litre round-bottomed flask for steam distillation (Fig. 2.102) and place in it 22 g (0.1 mol) of iodosylbenzene (Expt 6.32) made into a thin paste with water (1). Steam distil until almost all the iodosylbenzene has been removed (about 9 g); cool the residue in the flask at once, filter the white solid with suction and dry in the air. Wash it with a little chloroform, filter with suction and dry in the air upon filter paper. The yield is 10.5 g (89%). It may be recrystallised from 800–900 ml of water. Iodylbenzene melts with explosive decomposition at 237 °C.

**Note. (1)** Iodosylbenzene when heated directly may decompose with explosive violence, particularly when dry.

**Experiment 6.34 DIPHENYLIODONIUM IODIDE**

\[\text{PhIO} + \text{PhIO}_2 \rightarrow [\text{Ph}_2\text{I]}\text{O}_3 \xrightarrow{\text{KI}} [\text{Ph}_2\text{I}]\text{I}^- \]

Grind together 12 g (0.05 mol) of iodylbenzene (Expt 6.33), and 11 g (0.05 mol) of iodosylbenzene (Expt 6.32) with 25 ml of water, add 100 ml of 1 M sodium hydroxide solution and stir for 24 hours in a 1-litre vessel. Dilute with 500 ml of cold water, stir thoroughly, allow to settle and decant the supernatant solution of diphenyliodonium iodate, through a fluted filter paper. Extract the solid residue with two 250 ml portions of water, and decant the extract.
through a fluted filter paper: a small tarry residue remains. To the combined filtrates add an aqueous solution containing 10 g of potassium iodide. Allow the bulky white precipitate of diphenyliodonium iodide to stand for 1.5 hours with occasional shaking, and then filter it with suction. Dry on a porous tile. The yield is 15 g (74%). The product melts at 173–175 °C with vigorous decomposition.

Experiment 6.35 DIPHENYLIODONIUM-2-CARBOXYLATE

Potassium persulphate (42.0 g, 0.156 mol) is added at 10 °C over 40 minutes to a solution of o-iodobenzoic acid (20.0 g, 0.0807 mol) in 80 ml of concentrated sulphuric acid, and the mixture is kept at this temperature for an additional 20 minutes. Benzene (75 ml) (CAUTION) is added, and the mixture is stirred for 3 hours at 25 °C and then poured on to ice. A small amount of 2-carboxydiphenyliodonium bisulphate is collected. The addition of 40 g of potassium iodide in a minimum of water precipitates the iodonium iodide. The salts are combined and stirred with 200 ml of 5 M sodium hydroxide, and the product (DPIC) is collected and washed with water. Recrystallisation from c. 350 ml of water gives 20.1 g (77%) of DPIC as coarse prisms (not hydrated), m.p. 223–225 °C.

Experiment 6.36 1,1,1-TRIACETOXY-2,1-BENZOXIODOL-3(H)-ONE (A periodinane)

2-Iodoxybenzoic acid. Potassium bromate (76.0 g, 0.45 mol) is added over a half-an-hour period to a vigorously stirred mixture of o-iodobenzoic acid (85.2 g, 0.34 mol) and 730 ml of 0.73 M sulphuric acid. During the addition the reaction mixture is kept below 55 °C. The mixture is warmed to 65 °C and stirred for 3.6 hours. Cooling to 0 °C, filtering, and washing with 1000 ml of water and two 50-ml portions of ethanol give the product (89.1 g, 93%).

The periodinane. A stirred slurry of the foregoing compound (25.0 g, 0.089 mol) in acetic anhydride (84.0 g, 0.83 mol) and acetic acid (70 ml) is heated to 100 °C. After 40 minutes the solid will dissolve. The solvent is removed under vacuum at room temperature until a thick slurry remains.
Filtering the slurry in an inert atmosphere and washing with 180 ml of ether gives the product (35.1 g), 93 per cent in overall yield from o-iodobenzoic acid. This compound has an indefinite shelf-life when stored in a sealed container.

### 6.4 AROMATIC SULPHONIC ACIDS AND THEIR DERIVATIVES

The following structures indicate the range of aromatic sulphonic acids (1), sulphinic acids (2), sulphonyl chlorides (3), sulphonamides (4) and sulphonate esters (5) to be discussed below.

```
 (1) SO₂·OH  (2) SO·OH  (3) SO₂Cl  (4) SO₂·NH₂  (5) SO₂·OR
```

The reaction processes described in this section are as follows.

1. The preparation of arylsulphonic acids by direct sulphonation (Expts 6.37 to 6.40).
2. The preparation of arylsulphonyl chlorides (Expt 6.41).
3. The preparation of arylsulphonamides from arylsulphonyl chlorides (Expts 6.42 to 6.45).
4. The preparation of arylsulphonate esters from arylsulphonyl chlorides (Expt 6.46).
5. Reduction products from arylsulphonyl chlorides (Expt 6.47).

### SUMMARY OF RETROSYNTHETIC STRATEGIES

**C—S Disconnection at the aryl nucleus (methods 1 and 2), e.g.**

```
  SO₃H
  →
  PhH + SO₃/H₂SO₄
```

**S—N and S—O Disconnections within the functional group (methods 3 and 4), e.g.**

```
  O₂S·OR
  →
  O₂S·Cl
  →
  O₂S·NH₂
```

872
Functional group interconversion (FGI) (method 5), e.g.

\[ \text{SH} \quad \xrightarrow{(5)} \quad \text{SO}_2\text{H} \quad \xrightarrow{(5)} \quad \text{SO}_2\text{Cl} \]

SPECTROSCOPIC FEATURES
The strong characteristic i.r. absorption of the SO\(_2\) (or SO) group exhibited by all these compounds is clearly apparent in the spectrum of toluene-\(p\)-sulphonamide (Fig. 3.40). In addition, the absorption arising from the presence of the OH, Cl, NH\(_2\) or OR groups is usually easily assigned. The confirmation of aromatic substitution patterns by inspection of the p.m.r. spectra is described in the preparative examples below, wherein the fragmentation patterns observable in the m.s. are also discussed.

6.4.1 DIRECT SULPHONATION
Aromatic hydrocarbons may be monosulphonated by heating with a slight excess of concentrated sulphuric acid; for benzene, oleum (7–8% SO\(_3\)) gives somewhat better results. The reaction is usually complete when all the hydrocarbon has dissolved.

\[ \text{ArH} + \text{H}_2\text{SO}_4 \rightleftharpoons \text{Ar-SO}_3\text{H} + \text{H}_2\text{O} \]

The mechanism of aromatic sulphonation is broadly analogous to that previously described for aromatic nitration and halogenation and may be represented in the following way, the neutral sulphur trioxide molecule functioning as the electrophilic species. Sulphonation differs from nitration and halogenation, however, in that the overall reaction is reversible.

\[ 2\text{H}_2\text{SO}_4 \rightleftharpoons \text{SO}_3 + \text{H}_3\text{O}^+ + \text{HSO}_4^- \]

Because of their high solubility in water the sulphonic acids are not usually isolated from aqueous solution in the free state, but are converted into and isolated as their sodium salts. The simplest procedure is to partially neutralise the reaction mixture (say, with sodium hydrogen carbonate) and then to pour it into water and add an excess of sodium chloride, when the following equilibrium is established.

\[ \text{Ar-SO}_3\text{H} + \text{NaCl} \rightleftharpoons \text{Ar-SO}_3\text{Na} + \text{HCl} \]

The high sodium ion concentration results in crystallisation of the sodium salt. This process of salting out with common salt may be used for recrystallisation, but, for example, sodium benzenesulphonate (and salts of other acids of comparable molecular weight) is so very soluble in water that the solution
must be almost saturated with sodium chloride, and consequently the product is likely to be contaminated with it. In such a case a pure product may be obtained by crystallisation from, or Soxhlet extraction with, absolute ethanol; the inorganic salts are almost insoluble, but the sulphonate salt is slightly soluble and may be recovered by evaporation of the ethanol. Very small amounts of sulphones are formed as by-products, but since these are insoluble in water, they separate when the reaction mixture is poured into water.

\[ \text{Ar} \cdot \text{SO}_3 \text{H} + \text{ArH} \rightarrow \text{Ar} \cdot \text{SO}_2 \cdot \text{Ar} + \text{H}_2\text{O} \]

The sulphonation of toluene (Expt 6.37) with concentrated sulphuric acid at 100–120 °C results in the formation of toluene-\(p\)-sulphonic acid as the chief product, accompanied by small amounts of the ortho and meta isomers; these are easily removed by crystallisation of the sodium salt of the para isomer in the presence of sodium chloride. Sulphonation of naphthalene at about 160 °C yields largely the 2-sulphonic acid (the product of thermodynamic control) (Expt 6.38); at lower temperatures (0–60 °C) the 1-sulphonic acid (the product of kinetic control) is produced almost exclusively. In both cases the product is isolated as its sodium salt. In anthraquinone the carbonyl groups deactivate the aromatic nucleus towards electrophilic attack and vigorous conditions of sulphonation are required, i.e. oleum at about 160 °C. The product is largely sodium anthraquinone-2-sulphonate (Expt 6.39).

The free sulphinic acids [e.g. toluene-\(p\)-sulphonic acid, for preparation see, Expt 6.37, Note (1)], as opposed to their sodium salts, may sometimes be obtained directly if the sulphonation reaction is carried out with continuous removal of the water formed in the reaction, conveniently by using a Dean and Stark water separator. \(p\)-Xylene-2-sulphonic acid (Expt 6.40) is an example of a sulphinic acid whose solubility in water is such that it crystallises directly from the reaction medium and hence it may readily be isolated.

Examples of the sulphonation of functionally substituted aromatic compounds are given in Expt 6.37, cognate preparation of sodium \(p\)-bromobenzenesulphonate; Expt 6.63, sulphanilic acid; and Expt 6.104, as an intermediate in the preparation of 2-nitroresorcinol.

### Experiment 6.37 SODIUM TOLUENE-\(p\)-SULPHONATE AND TOLUENE-\(p\)-SULPHONIC ACID

\[ \text{Ph} \cdot \text{Me} + \text{H}_2\text{SO}_4 \rightarrow \text{p-Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H} \xrightarrow{\text{NaCl}} \text{p-Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{Na}^+ \]

Into a 500-ml three-necked flask, provided with a sealed mechanical stirrer and a reflux condenser, place 60 g (69 ml, 0.65 mol) of pure toluene (Section 4.1.3, p. 398) and 60 g (33 ml) of concentrated sulphuric acid. Heat the mixture, with stirring, in an oil bath maintained at 110–120 °C. When the toluene layer has disappeared (c. 1 hour), allow the reaction mixture to cool to room temperature. Pour it with stirring into 250 ml of cold water; filter from any solid substance which may separate. Partly neutralise the acid solution by adding cautiously and in small portions 30 g of sodium hydrogen carbonate. Heat the solution to boiling and saturate it with sodium chloride (about 100 g of salt are required), filter hot through a hot water funnel, or through a Buchner funnel previously warmed to about 100 °C. Transfer the hot filtrate to a beaker and cool the solution, with stirring, in ice. Filter the
crystals at the pump (rinse any residual crystals out of the beaker with a little
of the filtered mother-liquor), press well with a large glass stopper and wash
with 30 ml of saturated salt solution. To recrystallise the crude sodium
toluene-p-sulphonate, dissolve it in 200–250 ml of water, heat to boiling,
saturate with salt, allow to cool somewhat, stir with 2–3 g of decolourising
charcoal (if the solution is coloured) and filter the hot solution with suction
through a previously warmed Buchner funnel. Transfer the warm filtrate to a
beaker and cool in ice: collect the sulphonate with suction on a Buchner
funnel, wash it with 20 ml of saturated sodium chloride solution, press well
and finally wash with a little alcohol. Dry the hydrated crystals in air upon
filter papers, powder in a mortar and then dry in an oven or in an air oven at
100–110 °C. The yield of anhydrous sodium toluene-p-sulphonate is 50 g
(40%). It still contains traces of sodium chloride and other salts; these can be
removed by recrystallisation from rectified spirit (1 g of solid to about 40 ml
of alcohol) or by extraction with boiling alcohol in a Soxhlet apparatus (Figs
2.96 and 2.97).

Note. (1) Toluene-p-sulphonic acid may be prepared by gently boiling a mixture of
87 g (100 ml, 0.95 mol) of pure toluene and 37 g (20 ml) of concentrated sulphuric acid
(92% H₂SO₄ by weight) in a 250-ml bolt-head flask fitted with a Dean and Stark tube
(Fig. 2.31(a)), which should be filled such that a further 9 ml of water may be collected
(4–5 hours). After this period of heating add 6.3 ml of water to the cold contents of the
flask, and when crystallisation is complete, filter on a sintered-glass funnel. Dissolve
the solid (47 g) in 22 ml of water, saturate with hydrogen chloride gas and allow the
solution to stand for several hours. Filter the product of toluene-p-sulphonic acid and
dry in a desiccator (KOH and CaCl₂ as absorbents). The yield is 35 g (22%), m.p. 105–
106 °C (sealed tube). Note the i.r. absorption (KBr disc) at c. 3350 (OH), 3050 (C₅H₅—
H), 2900 cm⁻¹ (C₅H₅—H), multiple bands around 1250–1160 and 1080–1000 cm⁻¹ (SO₂
asym. and sym. stretching respectively), and at c. 685 cm⁻¹ (S–O stretching). The
SO₂ stretching vibration is observed at lower frequencies in sulphonamic acids compared
to sulphonamides due, it is thought, to hydrogen bonding.

Cognate preparation. Sodium p-bromobenzencesulphonate. Equip a 500-ml
three-necked flask with a separatory funnel, an unsealed stirrer guide fitted
with a mechanical stirrer and a thermometer. Place 75 g (40 ml) of fuming
sulphuric acid, d 1.88 (7–8% SO₃), in the flask and 40 g (27 ml, 0.25 mol) of
bromobenzene (Expt 6.23) in the separatory funnel. Add the bromobenzene
in small portions so that the temperature does not rise above 100 °C. If any
bromobenzene remains unattacked, warm the mixture on a water bath until
all of it has passed into solution. Allow to cool, and pour the reaction mixture
in a thin stream with stirring into 140 ml of cold water. If a precipitate
separates (dibromodiphenylsulphone, a by-product), filter the warm solution
at the pump. Add 55 g of sodium chloride to the filtrate and heat (with
stirring) until the salt dissolves. Cool the solution rapidly with stirring, filter
the separated crude sulphonate at the pump and press the crystals as dry as
possible. Upon drying in the air, the yield is 47 g. To purify the crude sodium
p-bromobenzencesulphonate, powder the crystals in a mortar, transfer to a
beaker, add 75 ml of a filtered, saturated solution of sodium chloride, stir,
heat on a water bath for 30 minutes, allow to cool, filter and press the crystals
as dry as possible; finally wash with a little alcohol. Dry in the air by
spreading upon filter papers. The yield of purified sodium p-bromobenzene-
sulphonate is 45 g (68%). The product, although pure enough for most
practical purposes, contains traces of sodium chloride and other salts: these can be removed either by recrystallisation from hot rectified spirit (1 g of salt requires c. 25 ml of alcohol) or, more economically, by extraction with alcohol in a Soxhlet apparatus (Figs 2.96 and 2.97).

**Experiment 6.38 SODIUM NAPHTHALENE-2-SULPHONATE**

\[ \text{C}_{10}\text{H}_8 + \text{H}_2\text{SO}_4 \rightarrow 2\text{-C}_{10}\text{H}_7\cdot\text{SO}_3\text{H} \xrightarrow{\text{NaCl, HCl}} 2\text{-C}_{10}\text{H}_7\cdot\text{SO}_3\text{Na} \]

Equip a 500-ml three-necked flask with a separatory funnel, a thermometer with its bulb about 2 cm from the bottom and a mechanical stirrer; the bearing for the stirrer consists of a glass tube lubricated with a little glycerine. Place 100 g (0.78 mol) of naphthalene in the flask and heat it either in an air bath or by means of a free flame. When the naphthalene melts, start the stirrer and adjust the heating so that the temperature is 160 ± 5°C. Run in 166 g (90 mL) of concentrated sulphuric acid from the funnel during 5–6 minutes: take care to maintain the temperature at 160°C and remove the flame if necessary. Stir for 5 minutes and pour the solution into 750 mL of cold water. If the sulphonation has been properly conducted, there will be no precipitate of naphthalene but about 4 g of insoluble di-2-naphthyl sulphone may separate. Boil with 3–4 g of decolourising carbon and filter with suction through a Buchner funnel. Partly neutralise the clear solution by carefully adding 40 g of sodium hydrogen carbonate in small portions. Heat the solution to the boiling point, saturate with sodium chloride (about 70 g are required) and then set aside to crystallise. Filter the crude sodium naphthalene-2-sulphonate at the pump and recrystallise from hot 10 per cent sodium chloride solution; dry by heating on a water bath or in an oven. The yield is 140 g (78%).

**Experiment 6.39 SODIUM ANTHRAQUINONE-2-SULPHONATE**

\[
\begin{array}{c}
\text{O} \\
\text{C} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O}
\end{array} 
\xrightarrow{(i) \text{oilum, 160°C, (ii) NaOH}} 
\begin{array}{c}
\text{O} \\
\text{C} \\
\text{O} \\
\text{SO}_3\text{Na}
\end{array}
\]

Place 50 g of fuming sulphuric acid (40–50% SO₃, Section 4.2.75, p. 465) in a 250- or 500-ml two-necked flask equipped with a thermometer with the bulb within 2 cm of the bottom and add 50 g (0.24 mol) of dry, finely powdered anthraquinone (Expt 6.128). Fit an air condenser to the flask and heat the mixture slowly in an oil bath, with occasional shaking, so that at the end of 1 hour the temperature has reached 160°C. Allow to cool and pour the warm mixture carefully into a 2-litre beaker containing 500 g of crushed ice. Boil for about 15 minutes and filter off the unchanged anthraquinone at the pump. Neutralise the filtrate by carefully adding concentrated (50% w/w) aqueous sodium hydroxide and allow to cool, when the greater part of the sodium anthraquinone-2-sulphonate separates as silvery glistening plates ('silver salt'). Filter these with suction and dry upon filter paper or upon a porous plate. The yield is 40–45 g (54–60%).
Experiment 6.40 2,5-DIMETHYLBENZENESULPHONIC ACID
(p-Xylene-2-sulphonic acid)

\[ p-\text{MeC}_6\text{H}_4\cdot\text{Me} \rightarrow 2,5-(\text{Me})_2\text{C}_6\text{H}_3\cdot\text{SO}_3\text{H} \]

Place 5.2 g (6.0 ml, 0.05 mol) of p-xylene in a 25- or 50-ml round-bottomed flask and add, with gentle swirling agitation, 10 ml of concentrated sulphuric acid. Heat the mixture on a water bath for 10–15 minutes; remove the flask from the bath and mix the contents with a circular motion every two minutes. The reaction is complete when the xylene layer on the surface of the acid has disappeared. Cool to room temperature, add 5.0 ml of water cautiously with gentle swirling. Pour the warm reaction mixture into a 100-ml beaker and cool in ice. Filter off the crystalline solid with suction on a sintered glass funnel and press the crystals down with a glass stopper. Recrystallise the crude product from 5 ml of water and dry on filter paper. The yield of pure 2,5-dimethylbenzenesulphonic acid, m.p. 82 °C, is 8.2 g (90%).

After drying the crystals over phosphorus pentoxide, record the i.r. spectrum (KBr disc) and assign the principal absorptions. Record the p.m.r. spectrum in deuterium oxide using DSS as reference; note the solvent signal (HOD) at \( \delta 5.45 \) and signals at \( \delta 2.31 \) (s, 3H, C5—Me), 2.69 (s, 3H, C2—Me), 7.20 (sharp m, 2H, C3,4—H), and 7.82 (broad s, 1H, C6—H).

6.4.2 THE PREPARATION OF ARYLSULPHONYL CHLORIDES

Arylsulphonic acids, either free or in the form of their sodium salts, are converted into the acid chloride by reaction with phosphorus pentachloride (or phosphorus oxychloride).

\[ 3\text{Ar} \cdot \text{SO}_3\text{Na} + 5\text{PCl}_5 \rightarrow 3\text{Ar} \cdot \text{SO}_2\text{Cl} + \text{NaPO}_3 + 2\text{NaCl} \]

The arylsulphonyl chlorides may be obtained more conveniently from the aromatic hydrocarbon by reaction with an excess of chlorosulphonic acid (chlorosulphonation)

\[ \text{ArH} + 2\text{Cl} \cdot \text{SO}_3\text{H} \rightarrow \text{Ar} \cdot \text{SO}_2\text{Cl} + \text{H}_2\text{SO}_4 + \text{HCl} \]

The latter general procedure is illustrated by the chlorosulphonation of toluene which yields a mixture of toluene-\( \alpha \)- and \( p \)-sulphonyl chlorides which may be separated by cooling to −10 to −20 °C when most of the \( p \)-isomer, which is a solid, m.p. 69 °C, separates out (Expt 6.41).

Experiment 6.41 TOLUENE-\( \alpha \) AND \( p \)-SULPHONYL CHLORIDES

\[ \text{Ph} \cdot \text{Me} \rightarrow \alpha- \text{ and } p-\text{MeC}_6\text{H}_4 \cdot \text{SO}_2\text{Cl} + \text{H}_2\text{SO}_4 + \text{HCl} \]

In a 750-ml three-necked flask equipped as in Fig. 6.2 place 400 g (228 ml, 3.44 mol) of chlorosulphonic acid (CAUTION: see Section 4.2.16, p. 424) and cool to 0 °C in a freezing mixture of ice and salt. Introduce 100 g (115 ml, 1.09 mol) of pure dry toluene from the dropping funnel dropwise at such a rate that the temperature of the well-stirred mixture does not rise above 5 °C. When all the toluene has been added (about 3 hours), stir the reaction mixture for 4 hours, and then allow to stand overnight in a refrigerator. Pour
To gas adsorption trap

Fig. 6.2

the liquid on to 1 kg of crushed ice, separate the aqueous solution from the oily layer (mixture of toluene-<i>o</i>- and -<i>p</i>-sulphonyl chlorides) and wash the latter several times by decantation with cold water. To separate the <i>ortho</i> and <i>para</i> isomers, cool the oil at −10 to −20 °C (e.g. with ice and calcium chloride) for several hours; the almost pure toluene-<i>p</i>-sulphonyl chloride will crystallise out. Filter at the pump upon a sintered glass funnel. The toluene-<i>p</i>-sulphonyl chloride (30 g, 14%) may be purified by recrystallisation from light petroleum (b.p. 40–60 °C) and then melts at 69 °C. The filtrate consists largely of toluene-<i>o</i>-sulphonyl chloride: it may be obtained pure by dissolving it in carbon tetrachloride, removing the solvent and fractionating under reduced pressure; it is an oil, b.p. 126 °C/10 mmHg. The yield is about 120 g (58%).

The i.r. spectra of these two isomers may be recorded as a KBr disc (<i>para</i>) and as a thin film (<i>ortho</i>); both spectra exhibit strong absorption at c. 1380 and 1170 cm<sup>−1</sup> arising from the stretching of the sulphur–oxygen double bonds. The p.m.r. spectrum (CDCl<sub>3</sub>, TMS) of the <i>para</i> isomer confirms the aromatic substitution pattern, having signals at δ 2.49 (s, 3H, Me), 7.41 (d, 2H, ortho-H’s to Me) and 7.90 (d, 2H, ortho-H’s to SO<sub>2</sub>Cl). The <i>ortho</i> isomer has δ 2.79 (s, 3H, Me), 7.21–7.73 (m, 3H, C<sub>4,5,6</sub>—H), and 8.0 (m, 1H, C<sub>3</sub>—H). The m.s. of the <i>ortho</i> isomer has principal fragment ions at m/z 192 (M, <sup>37</sup>Cl), 190 (M, <sup>35</sup>Cl), 155 (M − <sup>37</sup>Cl or <sup>35</sup>Cl), 91 (M − SO<sub>2</sub>Cl, base peak), and 65 (91 − C<sub>2</sub>H<sub>2</sub>).

Cognate preparation. 2,4,6-Triisopropylbenzenesulphonyl chloride.<sup>19</sup> To a mixture of triisopropylbenzene (100 ml) in chloroform (500 ml), magnetically stirred at 0 °C, is added chlorosulphonic acid (120 ml) within 15 minutes under cooling and exclusion of moisture (CAUTION). The stirring is continued for 45 minutes at room temperature and the mixture poured on to crushed ice. The product is extracted with chloroform (500 ml) (CAUTION), dried over anhydrous sodium sulphate and freed from solvent in vacuo at 30 °C. The white residue is dissolved in warm pentane, and the solution is filtered and concentrated to about 200 ml. Triisopropylbenzenesulphonyl
chloride crystallises slowly on standing and is washed with pre-chilled (−30°C) pentane; after drying in vacuo over phosphorus pentoxide the yield is 75.1 g, m.p. 96–97°C. Further concentration of the mother-liquor gives a second crop, 31.4 g, m.p. 94–96°C. Total yield 106.5 g (86%). The product is recrystallised from pentane and dried over phosphorus pentoxide in vacuo.

6.4.3 THE PREPARATION OF ARYSULPHONAMIDES

Arylsulphonyl chlorides may be readily converted into the corresponding arylsulphonamides (e.g. by treatment with solid ammonium carbonate or with concentrated ammonia solution) or into a substituted arylsulphonamide (by reaction with the appropriate amino compound). Arylsulphonylhydrazides (for use in the preparation of aliphatic nitriles, Section 5.13.2, p. 712) may be prepared by a similar reaction using anhydrous hydrazine.20

\[
\text{Ar-}&\text{SO}_2&\text{Cl} + \text{NH}_3 \rightarrow \text{Ar-}&\text{SO}_2&\text{NH}_2 + \text{HCl}
\]

\[
\text{Ar-}&\text{SO}_2&\text{Cl} + \text{RNH}_2 \rightarrow \text{Ar-}&\text{SO}_2&\text{NHR} + \text{HCl}
\]

\[
\text{Ar-}&\text{SO}_2&\text{Cl} + \text{N}_2\text{H}_4 \rightarrow \text{Ar-}&\text{SO}_2&\text{NH}.\text{NH}_2 + \text{HCl}
\]

These sulphonamides are highly crystalline, and in particular the derivatives from benzenesulphonyl chloride and toluene-p-sulphonyl chloride are used in the separation and identification of aromatic amines (Sections 9.6.21, p. 1273 and 9.7.1, p. 1287).

Toluene-o-sulphonamide is an intermediate in the synthesis of saccharin (Expt 6.42). Upon oxidising toluene-o-sulphonamide with potassium permanganate in alkaline solution, the sodium salt of o-sulphonamidobenzoic acid is formed, which on acidification with concentrated hydrochloric acid passes spontaneously into the cyclic imide of o-sulphobenzoic acid or saccharin. Saccharin itself is sparingly soluble in cold water, but the imino hydrogen is acidic and the compound forms a water-soluble sodium salt. The latter is about 500 times as sweet as cane sugar.

When toluene-p-sulphonamide is dissolved in excess calcium hypochlorite solution and then acidified with acetic acid, the \(N,N\)-dichloro derivative [(6) dichloramine-T] separates rapidly. When this is heated with sodium hydroxide solution the sodium salt of the \(N\)-monochloro derivative [(7) chloramine-T)] is formed and crystallises out on cooling at a suitable concentration (Expt 6.43).

\[
\text{Ar-}&\text{SO}_2&\text{NH}_2 + \overset{\circ}{\text{OCl}} \rightarrow \text{Ar-}&\overset{\circ}{\text{SO}}_2&\text{NCl} + \text{H}_2\text{O}
\]

\[
\text{Ar-}&\overset{\circ}{\text{SO}}_2&\text{NCl} + \overset{\circ}{\text{OCl}} + 2\text{H}^+ \rightarrow \text{Ar-}&\overset{\circ}{\text{SO}}_2&\text{NCl}_2 + \text{H}_2\text{O}
\]

\[
(6)
\]

\[
\text{Ar-}&\overset{\circ}{\text{SO}}_2&\text{NCl}_2 + 2\text{NaOH} \rightarrow \text{Ar-}&\overset{\circ}{\text{SO}}_2&\text{NCl}_2\text{Na} + \text{NaOCl} + \text{H}_2\text{O}
\]

\[
(7)
\]

Both chloramine-T and dichloramine-T slowly liberate hypochlorous acid in contact with water and are therefore employed as antiseptics; the former is employed in the form of a dilute (e.g. 0.2%) aqueous solution, and the latter (which is insoluble in water) as a solution in an organic solvent, such as a chloroalkane.
The chlorosulphonation of acetanilide with excess chlorosulphonic acid affords mainly p-acetamidobenzenesulphonyl chloride (Expt 6.44). This is the essential intermediate in the synthesis of a range of sulphanilamide drugs. The simplest example, p-aminobenzenesulphonamide (sulphanilamide), is obtained by converting p-acetamidobenzenesulphonyl chloride into the amide with aqueous ammonia, and then selectively removing the protecting acetyl grouping with boiling aqueous hydrochloric acid. 2-(p-Aminobenzenesulphonamido)-pyridine (sulphapyridine, M and B 693, Expt 6.45) is prepared by reacting p-acetamidobenzenesulphonyl chloride with 2-aminopyridine and then removing the acetyl group as before. The synthesis of the required 2-aminopyridine is of interest in that it represents an example of a nucleophilic aromatic substitution by the amide ion at the 2-position in a pyridine ring system, under the influence of the powerful electron-withdrawing influence of the heteroatom.

![Chemical structure](image)

**Experiment 6.42 TOLUENE-o-SULPHONAMIDE AND SACCHARIN**

Place 20 g (0.105 mol) of toluene-o-sulphonyl chloride (Expt 6.41) in a large evaporating dish mounted on a water bath. Add powdered ammonium carbonate cautiously with stirring until the mass is quite hard and solid and the unpleasant odour of the sulphonyl chloride has disappeared. Allow to cool, and extract with cold water to remove the excess of ammonium carbonate. Recrystallise the crude toluene-o-sulphonamide first from hot water (add a little decolourising carbon if it is dark in colour) and then from ethanol. The yield of pure product, m.p. 154 °C, is 16 g (89%).

Record the i.r. spectrum and compare it with that of the para isomer shown on p. 317. The p.m.r. spectrum (DMSO-\(d_6\) at 60 °C, TMS) shows signals at \(\delta 2.65\) (s, 3H, Me), 7.21 (broad s, 2H, NH\(_2\)), 7.25-7.50 (m, 3H, C\(_4\),\(_5\),\(_6\) — H) and 7.91 (m, 1H, C\(_3\) — H); this spectrum should be contrasted with that of the para isomer detailed below. The m.s. shows principal
fragment ions at $m/z$ 171 (M), 155 (M – NH$_2$), 91 (M – SO$_2$NH$_2$ or 155 – SO$_2$), and 90 [M – (SO$_2$ + NH$_3$), base peak].

**Oxidation of toluene-o-sulphonamide to saccharin.** In a 600-ml beaker, mounted on an electric hot plate and provided with a mechanical stirrer, place 12 g (0.07 mol) of toluene-o-sulphonamide, 200 ml of water and 3 g of pure sodium hydroxide. Stir the mixture and warm to 34–40 °C until nearly all has passed into solution (about 30 minutes). Introduce 19 g (0.12 mol) of finely powdered potassium permanganate in small portions at intervals of 10–15 minutes into the well-stirred liquid. At first the permanganate is rapidly reduced, but towards the end of the reaction complete reduction of the permanganate is not attained. The addition occupies 4 hours. Continue the stirring for a further 2–3 hours, and then allow the mixture to stand overnight. Filter off the precipitated manganese dioxide at the pump and decolourise the filtrate by the addition of a little sodium metabisulphite solution. Exactly neutralise the solution with dilute hydrochloric acid (use methyl orange or methyl red as external indicator). Filter off any o-sulphonamidobenzoic acid (and/or toluene-o-sulphonamide) which separates at this point. Treat the filtrate with concentrated hydrochloric acid until the precipitation of the saccharin is complete. Cool, filter at the pump and wash with a little cold water. Recrystallise from hot water. The yield of pure saccharin, m.p. 228 °C, is 7.5 g (58%).

**Conversion of saccharin into pseudosaccharin chloride.** Mix intimately in a glass mortar 35 g (0.19 mol) of saccharin and 70 g (0.336 mol) of phosphorus pentachloride (CAUTION), transfer to a 250-ml round-bottomed flask connected by a ground glass joint to a reflux condenser; attach the latter through a calcium chloride guard-tube to a gas absorption trap. Heat the mixture in an oil bath at 175–180 °C for 90 minutes; at the end of this period the vigorous evolution of hydrogen chloride will have subsided. Replace the reflux condenser by a fractionating column, distil off the phosphorus oxychloride and pour the warm residue upon finely crushed ice. Extract the crude solid pseudosaccharin chloride with chloroform, dry the chloroform solution with anhydrous magnesium sulphate and distil off the solvent. Recrystallise the residue from chloroform or from dry benzene. The yield of pure pseudosaccharin chloride, m.p. 143–145 °C (decomp.), is 26 g (67.5%). It is best kept in a sealed glass tube or in a glass-stoppered bottle.

**Cognate preparation.** 2,4,6-Trisopropylbenzenesulphonyl hydrazide.$^{20}$ A magnetically stirred solution of 2,4,6-trisopropylsulphonyl chloride (30.3 g, 0.1 mol) (Expt 6.41), in tetrahydrofuran (60 ml), is cooled to −10 °C in an ice-salt freezing mixture and anhydrous hydrazine hydrate (10.2 g, 0.22 mol, 100%) (CAUTION) is added dropwise over a period of 15 minutes. The temperature rises to 0 °C, and after stirring at 0 °C for 3 hours, water (c. 2 ml) is added dropwise to dissolve the precipitated solids. The product is then transferred to a separatory funnel and the lower aqueous layer discarded. The organic layer is washed with ice-cold brine (3 × 20 ml), dried (anhydrous sodium sulphate) for 3 hours, filtered through hyflosupercel and then concentrated under reduced pressure below room temperature. Light petroleum (100 ml, b.p. 30–40 °C) is added to the crystalline mass so obtained. The material is collected by filtration, washed several times with light
petroleum (b.p. 30–40°C) and any remaining solvent removed by evaporation under reduced pressure at room temperature. The product is triturated with ice-cold water (3 × 100 ml), and finally dried in vacuo over phosphorus pentoxide at room temperature for 24 hours to give 2,4,6-trisopropylbenzenesulphonyl hydrazide (TBSH) as a colourless solid, m.p. 118–120°C (decomp.); yield 28.9 g (96%) (1), \( R_F \) 0.7 (chloroform–methanol, 9:1).

Note. (1) TBSH should be stored in a dark bottle preferably at 4°C. Under these conditions decomposition occurs to only a small extent (5% in 9 months). The purity of TBSH may be assessed by t.l.c. analysis (CHCl₃–MeOH, 9:1 v/v). Impure TBSH may be purified as follows: TBSH (60 g) is dissolved in ether (600 ml) and the solution washed first with aqueous sodium hydroxide solution (3 × 50 ml, 0.75 M), and then with water (25 ml). Light petroleum (1 litre, b.p. 30–40°C) is added to the dried (magnesium sulphate) organic layer. The precipitated TBSH (50 g) is collected by filtration and dried in vacuo over phosphorus pentoxide for 24 hours at room temperature.

Experiment 6.43 TOLUENE-\( p \)-SULPHONAMIDE, DICHLORAMINE-T AND CHLORAMINE-T

\[
p-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2\text{Cl} \rightarrow \text{NH}_2 \rightarrow p-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2 \cdot \text{NH}_2 \rightarrow \text{OCl} \rightarrow \text{Me} \cdot \text{CO}_2\text{H} \\
p-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2 \cdot \text{NCl}_2 \rightarrow \text{NaOH} \rightarrow p-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2 \cdot \text{NCl} \cdot \text{Na}^+ \\
\]

Toluene-\( p \)-sulphonamide. Grind together 10 g (0.0525 mol) of toluene-\( p \)-sulphonyl chloride (Expt 6.41) and 20 g of ammonium carbonate in a mortar until a fine uniform powder is obtained. Heat the mixture in an evaporating dish on a water bath for 1–2 hours and stir the mixture frequently with a glass rod. Allow to cool and extract with a little cold water to remove the excess of ammonium salts. Recrystallise the crude toluene-\( p \)-sulphonamide from boiling water (200–250 ml), and dry the colourless crystals at 100°C. The yield of pure product, m.p. 138°C, is 7.9 g (88%).

The i.r. spectrum is given on p. 317. The para-substitution pattern is clearly shown by the p.m.r. spectrum (TFA, TMS) having signals at \( \delta \) 2.46 (s, 3H, Me), c. 4.05 (broad low signal, 2H, NH₂), 7.37 (d, 2H, ortho-H’s to Me), and 7.84 (d, 2H, ortho-H’s to SO₂NH₂). The m.s. is similar to that of the ortho isomer noted above with some variation of relative abundance of individual fragment ions.

Alternatively, grind 10 g of toluene-\( p \)-sulphonyl chloride to a fine powder and add it to 30 ml of concentrated ammonia solution (d 0.88). Heat the mixture to boiling (fume cupboard) and cool. Filter and recrystallise the toluene-\( p \)-sulphonamide from boiling water (add 1 g of decolourising carbon, if necessary). The yield of pure product, m.p. 138°C, is almost theoretical.

Dichloramine-T(\( N,N \)-dichlorotoluene-\( p \)-sulphonamide). Prepare about 200 ml of a saturated solution of calcium hypochlorite by grinding a fresh sample of bleaching powder with water and filtering with slight suction. Dissolve 5 g (0.029 mol) of toluene-\( p \)-sulphonamide in as small a volume of the calcium hypochlorite solution as possible (about 150 ml) and filter the solution if necessary. Cool in ice, and add about 50 ml of a mixture of equal volumes of glacial acetic acid and water slowly and with stirring until precipitation is complete. The dichloramine-T separates out first as a fine emulsion, which
rapidly forms colourless crystals. Filter the latter at the pump, wash with a little cold water, drain and dry immediately either between pads of filter paper or upon a porous tile. The yield is 5.3 g (76%), m.p. 81 °C. Upon recrystallisation from light petroleum (b.p. 60–80 °C) or from chloroform-light petroleum, pure dichloramine-T, m.p. 83 °C, is obtained with negligible loss.

Chloramine-T (sodium N-chlorotoluene-p-sulphonamide). For this preparation use dichloramine-T which has been prepared as above and thoroughly dried but not necessarily dried. Heat 45 ml of 10 per cent aqueous sodium hydroxide solution in a beaker to a temperature of about 80 °C, add 3.5 g (0.015 mol) of dichloramine-T in small quantities, stirring the mixture gently after each addition until a clear solution is obtained. When the addition is complete, filter the hot solution if turbid, and then allow it to cool spontaneously. Filter the crystals with suction, wash with a little saturated sodium chloride solution and dry upon filter paper or in a desiccator over anhydrous calcium chloride. The resulting chloramine-T weighs 3 g (75%) and is almost pure. It may be recrystallised, if desired, from twice its weight of hot water.

Chloramine-T is a salt and has no definite m.p.: upon heating it loses water of crystallisation and decomposes violently at 175–180 °C.

Experiment 6.44  

**p-AMINOBENZENESULPHONAMIDE (Sulphanilamide)**

\[ p-\text{MeCO\cdot NH\cdot C}_6\text{H}_5 \xrightarrow{\text{Cl\cdot SO}_2\text{H}} p-\text{MeCO\cdot NH\cdot C}_6\text{H}_4\cdot \text{SO}_2\text{Cl} \xrightarrow{\text{NH}_3} p-\text{MeCO\cdot NH\cdot C}_6\text{H}_4\cdot \text{SO}_2\text{NH}_2 \]

\[ p-\text{MeCO\cdot NH\cdot C}_6\text{H}_4\cdot \text{SO}_2\text{NH}_2 \xrightarrow{\text{H}_2\text{O}} p-\text{NH}_2\cdot \text{C}_6\text{H}_4\cdot \text{SO}_2\text{NH}_2 \]

**p-Azetidobenzenesulphonyl chloride.** Equip a 500-ml two-necked flask with a dropping funnel and a reflux condenser: attach the top of the latter to a device for the absorption of hydrogen chloride (e.g. Fig. 2.61). Place 20 g (0.148 mol) of dry acetanilide in the flask and 50 ml (90 g, 0.77 mol) of a good grade of chlorosulphonic acid (CAUTION: see Section 4.2.16, p. 424) in the dropping funnel and insert a calcium chloride guard-tube into the latter. Add the chlorosulphonic acid in small portions and shake the flask from time to time to ensure thorough mixing (1). When the addition has been made, heat the reaction mixture on a water bath for 1 hour in order to complete the reaction. Allow to cool and pour the oily mixture in a thin stream with stirring into 300 g of crushed ice (or ice-water) contained in a 1-litre beaker. Carry out this operation carefully in the fume cupboard since the excess of chlorosulphonic acid reacts vigorously with the water. Rinse the flask with a little ice-water and add the rinsings to the contents of the beaker. Break up any lumps of solid material and stir the mixture for several minutes in order to obtain an even suspension of the granular white solid. Filter off the p-azetidobenzenesulphonyl chloride at the pump and wash it with a little cold water; press and drain well. Use the crude product (2) immediately in the next stage.

**p-Azetidobenzenesulphonylamide.** Transfer the crude p-azetidobenzenesulphonyl chloride to the rinsed reaction flask, and add a mixture of 70 ml of concentrated ammonia solution (d 0.88) and 70 ml of water. Mix the
contents of the flask thoroughly, and heat the mixture with occasional swirling \((fume\ cupboard)\) to just below the boiling point for about 15 minutes. The sulphonyl chloride will be converted into a pasty suspension of the corresponding sulphonamide. Cool the suspension in ice, and then add dilute sulphuric acid until the mixture is just acid to Congo red paper. Collect the product on a Buchner funnel, wash with a little cold water and drain as completely as possible. It is desirable, but not essential, to dry the crude \(p\)-acetamidobenzencesulphonamide at \(100\,^\circ\text{C}\): the yield is about 18 g. The material is sufficiently pure (3) for the next stage.

\textbf{\(p\)-Aminobenzencesulphonamide.} Transfer the crude \(p\)-acetamidobenzencesulphonamide to a 500-ml flask, add 10 ml of concentrated hydrochloric acid and 30 ml of water. Boil the mixture gently under reflux for 30–45 minutes. The solution, when cooled to room temperature, should deposit no solid amide; if a solid separates, heat for a further short period. Treat the cooled solution with 2 g of decolourising carbon, heat the mixture to boiling and filter with suction through a hardened filter paper. Place the filtrate (a solution of sulphanilamide hydrochloride) in a litre beaker and cautiously add 16 g of solid sodium hydrogen carbonate in portions with stirring. After the evolution of gas has subsided, test the suspension with litmus paper and if it is still acid, add more sodium hydrogen carbonate until neutral. Cool in ice, filter off the sulphanilamide with suction and dry. The yield is 15 g (59\% overall yield), m.p. 161–163 \(^\circ\text{C}\). A pure product, m.p. 163–164 \(^\circ\text{C}\), may be obtained by recrystallisation from water or from alcohol.

\textbf{Notes.} (1) The reaction may be more easily controlled and the chlorosulphonic acid added all at once if the acetonilide is employed in the form of a hard cake. The latter is prepared by melting the acetanilide in the flask over a free flame and causing the compound to solidify over the lower part of the flask by swirling the liquid. If the reaction becomes too vigorous under these conditions, cool the flask momentarily by immersion in an ice bath.

(2) The crude sulphonyl chloride, even if dry, cannot be kept without considerable decomposition. It may be purified by triturating with dried acetone, filtering any undissolved \(p\)-acetamidosulphonic acid and evaporating the filtrate. The pure chloride has m.p. 149 \(^\circ\text{C}\).

(3) A small portion may be recrystallised from water, with the addition of a little decolourising carbon if necessary. The pure compound has m.p. 218 \(^\circ\text{C}\).

\textbf{Experiment 6.45 \(2-(p\)-AMINO\-BENZENESULPHONAMIDO\)PYRIDINE (Sulphapyridine)}

\[

884
CAUTION: This preparation should be conducted in an efficient fume cupboard and great care exercised in the handling of pyridine.

2-Aminopyridine. In a 1-litre four-necked flange flask, equipped with a sealed mechanical stirrer, reflux condenser, thermometer and inlet tube for nitrogen, place 300 ml of dry toluene (1) and 75 g (1.92 mol) of fine granular sodamide (2); bubble a steady stream of nitrogen through the toluene. Stir the mixture vigorously and heat the flask in an oil bath until the internal temperature is 110°C (the bath temperature required is approximately 130°C). Add 100 g (1.26 mol) of pure dry pyridine (CAUTION: Section 4.1.29, p. 410) dropwise through the condenser fitted with a pressure-equalising funnel over a period of 4 hours: maintain the very efficient stirring and the stream of nitrogen. After 1 hour the reaction mixture becomes black in colour, and after 3 hours becomes viscous, and bubbling and slight frothing occurs, due to liberation of hydrogen. When all the pyridine has been introduced, continue the heating for a further 5 hours while maintaining the internal temperature at 110°C. Towards the end of the reaction, stirring may become difficult owing to the separation of a solid or viscous cake. Allow the reaction mixture to cool (without the stream of nitrogen and without stirring); then introduce 175 ml of water very slowly through the condenser over a period of 2 hours while continuing the passage of the stream of nitrogen. During the addition the temperature rises to about 50°C; resume the stirring as soon as possible. Transfer the contents of the flask to a separatory funnel, separate the lower aqueous solution and extract it with two 150 ml portions of toluene. Dry the combined main toluene layer and toluene extracts over anhydrous potassium carbonate for 2 hours; filter and remove the toluene by distillation. Distil the syrupy residue from an oil bath under diminished pressure through an air condenser: adjust the bath temperature to 120–130°C. Collect the 2-aminopyridine at 95°C/10 mmHg; this solidifies on cooling to a colourless solid, m.p. 55°C (3). The yield is about 80 g (67%).

Sulphapyridine. Dissolve 4.7 g (0.05 mol) of 2-aminopyridine in a mixture of 40 ml of anhydrous acetone and 6 ml of dry pyridine (CAUTION) in a 250-ml flask, and add 11.7 g (0.05 mol) of pure p-acetamidobenzenesulphonyl chloride (4). The reaction mixture is set aside overnight and 5.5 g of the almost pure 2-(p-acetamidobenzenesulphonamido)pyridine (≡ acetylsulphapyridine) is filtered off; by diluting the filtrate with water a further crop (4 g) is obtained. The total product is recrystallised from acetone to give white needles of pure product, m.p. 224°C. The yield is 8 g (55%).

The acetylsulphapyridine (7.3 g) is hydrolysed by heating it under reflux with 75 ml of ethanol containing 15 ml of concentrated hydrochloric acid for 20 min. The cooled solution is diluted with water and made just alkaline with concentrated ammonia solution (d 0.880). The sulphapyridine is isolated by filtration and recrystallised from ethanol; yield 4.9 g (75%), m.p. 190–191°C.

Notes. (1) Technically pure toluene can be conveniently dried by distilling 350 ml from a litre flask and rejecting the first 50 ml.
(2) It is important to use recently prepared pure sodamide, which must be of fine granular form. Old material of irregular lumpy form, even if ground gives poor results, and should not be employed. The sodamide may be prepared as detailed in Section 4.2.67, p. 462. A satisfactory grade is marketed by May and Baker Ltd.
(3) The residue in the flask is said to contain 4-amino- and 2,6-diaminopyridine, 4,4'-bipyridyl and di(2-pyridyl) amine in varying amounts.

(4) The p-acetamidobenzencesulphonyl chloride (Expt 6.44) must be pure; under no circumstances should it contain more than 1–2 per cent of the corresponding sulphonic acid. This may be ensured by lixiviating the sulphonyl chloride with pure anhydrous acetone and filtering the solution from the acid.

### 6.4.4 THE PREPARATION OF ARYLSULPHONATE ESTERS

These are prepared by the interaction of the arylsulphonyl chloride and an alcohol or phenol in the presence of sodium hydroxide solution or of pyridine (Expt 6.46).

$$\text{ROH} + \text{Ar} \cdot \text{SO}_2 \text{Cl} \xrightarrow{\text{NaOH}} \text{RO} \cdot \text{SO}_2 \text{Ar} + \text{HCl}$$

These sulphonate esters cannot be made by direct esterification of the sulphonic acids since further reaction of the ester with the alcohol gives rise to an ether by means of an alkyl-oxygen fission process.

$$\text{ROH} \underset{\text{H}^+}{\overset{\text{H}^+}{\xrightarrow{\text{R} \cdot \text{O} \cdot \text{Ar}}} \text{R} \cdot \text{O} + \text{HO} \cdot \text{SO}_2 \text{Ar}}$$

For this reason the arylsulphonate esters find use as alkylating agents (cf. dimethyl sulphate and dialkyl sulphates, Section 4.2.24, p. 430).

#### Experiment 6.46 BUTYL TOLUENE-p-SULPHONATE

$$p\cdot\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2 \text{Cl} + \text{BuOH} \xrightarrow{\text{NaOH} \text{ or pyridine}} p\cdot\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_2 \cdot \text{OBu}$$

Equip a 1-litre three-necked flask with a separatory funnel, a mechanical stirrer and a thermometer, the bulb of which reaches within 2 cm from the bottom. Place 74 g (89 ml, 1 mol) of butan-1-ol and 105 g (0.55 mol) of toluene-p-sulphonyl chloride (Expt 6.41) in the flask and 160 ml of 20 per cent sodium hydroxide solution in the separatory funnel; immerse the flask in a bath of cold water. Run in the sodium hydroxide solution, with stirring, at such a rate that the temperature does not rise above 15 °C (3–4 hours). Now add another portion of 105 g (0.55 mol) of toluene-p-sulphonyl chloride, and introduce 160 ml of 20 per cent sodium hydroxide solution slowly, keeping the temperature below 15 °C. Continue the stirring for 4 hours longer. Separate the oily layer and treat it with enough light petroleum (b.p. 60–80 °C) to cause it to float on water; then wash it well with 25 ml of 10 per cent sodium hydroxide solution, and dry by allowing it to stand over 10 g of anhydrous potassium carbonate. Filter and distil off the solvent using a 250-ml flask (rotary evaporator). Distil the residual ester under reduced pressure (1) (oil pump) and collect the butyl toluene-p-sulphonate at 132–133 °C/3 mmHg. The yield is 130 g (57%).

Record the i.r. spectrum (thin film) and note the strong absorptions at c. 1325 and 1165 cm$^{-1}$ arising from the SO$_2$-group. The p.m.r. spectrum (CCl$_4$, TMS) shows signals at $\delta$ 0.88 (distorted t, 3H, $-\text{CH}_2\cdot\text{Me}$), 1.08–2.70 (m, 4H, $-\text{CH}_2\cdot\text{CH}_2\cdot$), 2.42 (s, 3H, $\text{C}_{\text{Ar}}\cdot\text{Me}$), 3.94 (t, 2H, $-\text{OCH}_2\cdot$), 7.27 (d, 2H, ortho-$\text{H}$'s to Me), and 7.71 (d, 2H, ortho-$\text{H}$'s to SO$_2$).
Note. (1) It is best to distil under greatly reduced pressure; slight decomposition occurs even at 10 mm pressure (b.p. 170–171 °C/10 mmHg).

Cognate preparation. Dodecyl toluene-p-sulphonate (pyridine method) (fume cupboard). In a 500-ml three-necked flask, equipped with a stirrer and thermometer, place 46.5 g (0.25 mol) of dodecan-1-ol (lauryl alcohol), m.p. 22–23 °C, and 79 g (81 ml, 1 mol) of dry pyridine (CAUTION). Surrounded the flask by a bath sufficiently cold to lower the temperature of the mixture to 10 °C. Add 52.5 g of toluene-p-sulphonyl chloride in portions during 20 minutes, or at such a rate that the temperature does not rise above 20 °C. Stir the mixture for 3 hours at a temperature below 20 °C, then dilute with 150 ml of concentrated hydrochloric acid in 500 ml of ice-water. Collect the ester on a chilled Buchner funnel and suck as dry as possible. Transfer the solid to a 400-ml beaker, add 150 of methanol and warm the mixture on a steam bath until the ester melts. Cool in a freezing mixture while stirring vigorously; the ester separates in a finely divided state. Collect it on a chilled funnel and allow to dry in the air, preferably below 20 °C. The yield of ester, m.p. 24–25 °C, is 78 g (92%). Recrystallise by dissolving in 100 ml of light petroleum, b.p. 40–60 °C, drying the solution over magnesium sulphate to remove traces of water, and cool to 0 °C. Collect the pure dodecyl toluene-p-sulphonate, m.p. 29–30 °C, in a chilled funnel (Section 2.20).

The pyridine procedure may be applied to the preparation of other esters; they are isolated by ether extraction. The yields are generally better than by the sodium hydroxide method.

Decyl toluene-p-sulphonate (pyridine–chloroform method). Decan-1-ol (1.58 g, 10 mmol) is dissolved in chloroform (10 ml) and cooled in an ice bath (0 °C). Pyridine (1.62 ml, 20 mmol; CAUTION) is then added, followed by the addition of toluene-p-sulphonyl chloride (2.85 g, 15 mmol) in small portions with constant stirring. The reaction is completed in 2.5 hours (t.l.c. monitoring). Ether (30 ml) and water (7 ml) are added, and the organic layer is washed successively with hydrochloric acid (2 M), 5 per cent sodium hydrogen carbonate and water, and dried (magnesium sulphate). The solvent is removed under reduced pressure and the crude tosylate is chromatographed on silica gel (eluants, 2 % ether–light petroleum) to yield the product as an oil, 3.06 g (98%); p.m.r. spectrum (CDCl3, TMS) δ 0.87 (t, 3H, Me), 1.22 (broad s, 14H, alkane), 1.59 (m, 2H, –CH2CH2O), 2.44 (s, 3H, Me), 4.02 (t, 2H, CH2O), 7.56 (AA’BB’, 4H, ArH); C-n.m.r. spectrum (CDCl3) δ 144.46, 133.12, 129.65, 127.64 (Ar carbons) 70.53 (CH2O), 31.70, 29.29, 29.24, 29.10, 28.75, 28.64, 25.17, 22.49, 21.38 and 13.94 (alkane).

6.4.5 REDUCTION PRODUCTS FROM ARYLSULPHONYL CHLORIDES

Reduction of an arylsulphonyl chloride with zinc dust and water affords the zinc salt of the sulphinic acid, converted by sodium carbonate to the sodium salt, in which form it is conveniently isolated (e.g. sodium toluene-p-sulphonate, Expt 6.47) and thence by hydrochloric acid into the somewhat unstable sulphinic acid.

\[
\text{Ar} \cdot \text{SO}_2\text{Cl} \xrightarrow{\text{Zn/H}_2\text{O}} \text{Ar} \cdot \text{SO}_2\text{H}
\]

\[
\text{(i) Zn/H}_2\text{O} \quad \text{(ii) Na}_2\text{CO}_3 \quad \text{(iii) HCl}
\]
Excessive drying of the free sulphinic acid must be avoided since it leads to partial conversion into the sulphonic acid and the thiolsulphinic ester.

\[ 3\text{ArSO}_2\text{H} \xrightarrow{\text{H}_2\text{O}} \text{ArSO}_3\text{H} + \text{ArSO}_2\text{Ar} \]

An alternative synthesis of benzenesulphinic acid by way of the diazonium salt is given in Expt 6.75.

More vigorous reduction of arylsulphonyl chlorides (or of sulphinic acids), for example with zinc and dilute sulphuric acid, gives rise to thiophenols, which are conveniently isolated by steam distillation.

\[ \text{ArSO}_2\text{Cl} + \text{Zn}, \text{HCl} \rightarrow \text{ArSH} \]

The thiophenols have an extremely unpleasant and repulsive odour and their preparation in the undergraduate laboratory is not recommended. In those cases where preparative details are required, reference to reliable procedures is advised.  

**Experiment 6.47 SODIUM TOLUENE-\(p\)-SULPHINATE**

\[ p-\text{MeC}_6\text{H}_4\text{SO}_2\text{Cl} \xrightarrow{(1) \text{Zn/H}_2\text{O}} (i) \text{Na}_2\text{CO}_3 \rightarrow p-\text{MeC}_6\text{H}_4\text{SO}_2\text{Na} \xrightarrow{\text{HCl}} p-\text{MeC}_6\text{H}_4\text{SO}_2\text{H} \]

In a 2-litre bolt-necked flask place 300 ml of water and insert a mechanical stirrer. Warm on a boiling water bath until the temperature reaches 70 °C and add 40 g (0.61 mol) of zinc powder (90–100% pure). Stir the mixture and add 50 g (0.26 mol) of finely powdered toluene-\(p\)-sulphonyl chloride in portions during about 10 minutes; the temperature rises to about 80 °C. Stir for a further 10 minutes and then heat the mixture further until the temperature is 90 °C. Add 25 ml of 12 m sodium hydroxide solution, followed by finely powdered sodium carbonate in 5 g portions until the mixture is strongly alkaline. Considerable frothing occurs. Filter at the pump and extract the residue by heating on a steam bath with 75 ml of water until excessive frothing occurs; continue stirring for a further 10 minutes. Filter with suction and add the filtrate to the main solution, concentrate to a volume of about 100 ml with a rotary evaporator and cool in ice-water. Filter at the pump and dry the crystals upon filter or drying paper until efflorescence just commences, then place in a tightly stoppered bottle. The yield of sodium toluene-\(p\)-sulphinate dihydrate is 35 g (63%).

The free sulphinic acid may be precipitated from a solution of the sodium salt in cold water by cautious acidification with hydrochloric acid. The toluene-\(p\)-sulphinic acid is filtered and sucked as dry as possible at the pump and dried rapidly between sheets of filter paper, m.p. 85 °C.

**6.5 AROMATIC AMINES**

Aromatic amines may be divided into three classes:

(a) **Primary amines**: where the amino group is directly attached to the aromatic ring, e.g. aniline Ph-\(\text{NH}_2\). Amines with the amino group in the side chain, e.g. benzylamine Ph-\(\text{CH}_2\text{NH}_2\), possess properties similar to those of simple aliphatic amines (Section 5.16).
(b) Secondary amines: (i) purely aromatic amines, e.g. diphenylamine Ph₂NH, and (ii) aromatic–aliphatic amines, e.g. N-methylaniline, Ph-NH·Me.

(c) Tertiary amines: (i) purely aromatic amines, e.g. triphenylamine Ph₃N, and (ii) aromatic–aliphatic amines, e.g. N,N-dimethylaniline, Ph-NMe₂.

Primary aromatic amines are prepared by the following procedures.
1. The reduction of nitro compounds (Expts 6.48 to 6.52).
3. The replacement of a halogen by an amino group (see Expt 6.93).
4. The replacement of a phenolic hydroxyl group by an amino group (Expt 6.55).

Secondary and tertiary amines are prepared by:
5. (a) Alkylation and (b) reductive alkylation procedures (Expts 6.56 to 6.58).

Methods for the protection of the amino and imino groups are discussed in Section 6.5.6.

SUMMARY OF RETROSYNTHETIC STRATEGIES

Functional group interconversion (FGI) (method 1)

\[
\begin{align*}
\text{NH}_2 & \quad \xrightarrow{(1)} \quad \text{NO}_2 \\
\text{TM} & \quad & \text{TM}
\end{align*}
\]

C—N Disconnection (methods 3 and 5(a)), e.g.

\[
\begin{align*}
\text{NH}_2 & \quad \xrightarrow{-\text{H}^\circ} \quad \text{NH}_2 \\
\text{TM} & \quad & \text{TM}
\end{align*}
\]

\[
\begin{align*}
\text{Y} & \quad \xrightarrow{(3)} \quad \text{Y} \quad \text{NH}_2 \equiv \text{Y} \cdot \text{C}_6\text{H}_4 \cdot \text{X} + \text{NH}_3
\end{align*}
\]

\[Y = \text{electron-withdrawing group}\]

\[
\begin{align*}
\text{HN}^\circ\text{ı} & \quad \xrightarrow{(5\text{a})} \quad \text{HN}^\circ \\
\text{TM} & \quad & \text{TM}
\end{align*}
\]

\[
\begin{align*}
\text{R}^\circ & \equiv \text{Ph} \cdot \text{NH}_2 + \text{RX}
\end{align*}
\]
FGI followed by C—N disconnection (method 5(b)), e.g.

\[
\begin{align*}
\text{HN}^R \xrightarrow{	ext{FGI}} \text{N}^R \xrightarrow{(5b)} \text{NH}_2 + R\cdot\text{CHO}
\end{align*}
\]

Rearrangement (method 2), e.g.

\[
\begin{align*}
\text{NH}_2 \xrightarrow{(2)} \text{H}_2\text{N}^\circlearrowleft \text{O}
\end{align*}
\]

SPECTROSCOPIC FEATURES
The characteristic i.r. absorption of the stretching vibrations of the NH\(_2\) and NH groups of primary and secondary amines are clearly visible in the 3300 cm\(^{-1}\) region (p. 290), as in the spectrum of N-methylaniline (Fig. 3.27). The substitution pattern may often be assigned from inspection of the longer wavelength region (p. 280). The provisional assignment may be supported by consideration of the p.m.r. spectrum; descriptive illustrations are given in the preparative examples below. The frequently observed broad signals observed in the p.m.r. spectra of the nitrogen-bound protons, and also their ready exchange with, for example, deuterium oxide have been discussed on pp. 350 and 348. Some typical fragmentation patterns in the m.s. are descriptively analysed in the appropriate preparative sections. The u.v.-visible absorption of the aromatic system is slightly affected by the presence of an amino or imino group (bathochromic shift), but the additional presence of electron-withdrawing groups (e.g. NO\(_2\)) in the ortho or para positions can cause a marked shift into the longer wavelength (visible) region of the spectrum.

6.5.1 THE REDUCTION OF NITRO COMPOUNDS
Primary arylamines are generally prepared by the reduction of nitro compounds. When only small quantities are to be reduced and cost is a secondary consideration, tin and hydrochloric acid may be employed.

\[
\text{Ar-NO}_2 + 6[H] \rightarrow \text{Ar-NH}_2 + \text{H}_2\text{O}
\]

Theoretically 1.5 mol of tin are needed for the reduction of the nitro group, the metal being oxidised to the tin(iv) state.

\[
2\text{Ar-NO}_2 + 3\text{Sn} + 12\text{H}^\oplus \rightarrow 2\text{Ar-NH}_2 + 3\text{Sn}^{4\oplus} + 4\text{H}_2\text{O}
\]

When reduction is complete, a complex amine chlorostannate may separate from which the amine is liberated by basification, using enough alkali to dissolve the tin hydroxides formed (e.g. the preparation of aniline, Expt 6.48).

\[
[\text{Ar-NH}_3]^\ominus[\text{SnCl}_6]^{2\ominus} + 8\ominus\text{OH} \rightarrow \text{Ar-NH}_2 + \text{SnO}_3^{2\ominus} + 6\text{Cl}^\ominus
\]
Alternatively decomposition of the complex is achieved by precipitation of the tin as its sulphide by passing hydrogen sulphide into the mixture at the end of the reaction (e.g. m-phenylenediamine, cognate preparation in Expt 6.48).

Other metal–acid reducing systems may be used; reduction with iron and hydrochloric acid is employed on the technical scale for the manufacture of aniline.

\[
\text{Ph\textbullet }\text{NO}_2 + 2\text{Fe} + 6\text{H}^\oplus \rightarrow \text{Ph\textbullet }\text{NH}_2 + 2\text{Fe}^{2\oplus} + 2\text{H}_2\text{O}
\]

\[
\text{Ph\textbullet }\text{NO}_2 + 3\text{Fe} + 6\text{H}^\oplus \rightarrow \text{Ph\textbullet }\text{NH}_2 + 3\text{Fe}^{2\oplus} + 2\text{H}_2\text{O}
\]

In practice, however, the amount of hydrochloric acid used is less than 5 per cent of the amounts indicated by either of the above equations. Various explanations have been advanced to account for this; one is that the following reaction is catalysed by acid or by hydroxonium ions.

\[
\text{Ph\textbullet }\text{NO}_2 + 2\text{Fe} + 4\text{H}_2\text{O} \xrightarrow{\text{H}^\oplus} \text{Ph\textbullet }\text{NH}_2 + 2\text{Fe(OH)}_3
\]

The use of iron and a little hydrochloric acid (or alternatively of iron and acetic acid) is to be preferred when the use of the more strongly acidic medium leads to the formation of undesirable by-products; nuclear chlorination, for example, often results when tin or zinc is used in association with concentrated hydrochloric acid. A suitable experimental procedure for the reduction of 2,4-dinitrotoluene to 2,4-diaminotoluene has been described.\(^{23}\)

Compounds which are sensitive to acidic conditions may sometimes be successfully reduced to amines under alkaline conditions; in these cases iron(II) sulphate is often used as the reducing agent. Reduction with metal under alkaline (or alternatively essentially neutral) conditions leads to the formation of intermediate products of the reduction of the nitro group (see Section 6.8.1, p. 953). Vigorous reduction under alkaline conditions using an excess of the reducing metal (e.g. zinc) may, however, lead to the complete reduction of the nitro group with the formation of the corresponding amine; this o-phenylenediamine (Expt 6.49) is conveniently obtained by reducing o-nitroaniline in this way.

Aromatic and heterocyclic nitro compounds are readily reduced in good yield to the corresponding amines (e.g. o-aminophenol, Expt 6.50) by sodium borohydride in aqueous methanol solution in the presence of a palladium-on-carbon catalyst. In this reduction there is no evidence for the formation of intermediates of the azoxybenzene or azobenzene type, although if the reaction is carried out in a polar aprotic solvent, such as dimethyl sulphoxide, azoxy compounds may sometimes be isolated as the initial products.

Ammonium or alkali metal sulphides or polysulphides exhibit a useful selective reducing action in that they smoothly reduce one nitro group in a polynitro compound to yield the corresponding nitroamine (e.g. m-nitroaniline, Expt 6.51).

The two methods described for the synthesis of ethyl p-aminobenzoate (Expt 6.52) from p-nitrobenzoic acid offer interesting comparison. Prior esterification of the carboxylic acid group (Method 2) yields a nitroester which cannot be reduced by a metal–acid reducing system owing to the possibility of hydrolytic cleavage of the ester grouping; conversion of the nitro into the amino group in this case is therefore by catalytic hydrogenation with Adams’ platinum dioxide catalyst. In Method 1, metal–acid reduction of the nitro group yields the
amino acid, p-aminobenzoic acid, a reaction in which the final mixture requires careful basification to effect precipitation of the product, which is then esterified to give ethyl p-aminobenzoate. This compound (Benzocaine) is used as a local anaesthetic.

**Experiment 6.48 ANILINE**

\[
\text{Ph}\cdot\text{NO}_2 + 6\text{H} \xrightarrow{\text{Sn/HCl}} \text{Ph}\cdot\text{NH}_2 + 2\text{H}_2\text{O}
\]

Into a 500-ml round-bottomed flask equipped with a reflux condenser, place 25 g (21 ml, 0.25 mol) of nitrobenzene and 45 g (0.38 mol) of granulated tin. Measure out 100 ml of concentrated hydrochloric acid. Pour about 15 ml of this acid down the condenser and shake the contents of the flask steadily. The mixture becomes warm and before long the reaction should be quite vigorous; if it boils very vigorously, moderate the reduction somewhat by temporarily immersing the flask in cold water. When the initial reaction slackens of its own accord, pour another 15 ml of hydrochloric acid down the condenser, shake the flask steadily to ensure thorough mixing and cool again if the reduction becomes too violent. Do not cool more than is necessary to keep the reaction under control; keep the mixture well shaken. Proceed in this way until all the 100 ml of acid has been added. Finally heat the mixture on a boiling water bath for 30–60 minutes, i.e. until the odour of nitrobenzene is no longer perceptible and a few drops of the reaction mixture when diluted with water yield a perfectly clear solution. During the course of the reduction, particularly during the cooling, aniline chlorostannate may separate as a white or yellow crystalline complex.

Cool the reaction mixture to room temperature and add gradually a solution of 75 g of sodium hydroxide in 125 ml of water; if the mixture boils during the addition of the alkali, cool again. The hydroxide of tin which is first precipitated should all dissolve and the solution should be strongly alkaline: the aniline separates as an oil. Equip the flask for steam distillation as in Fig. 2.102, and pass steam into the warm mixture until, after the distillate has ceased to pass over as a turbid liquid, a further 120 ml of clear liquid are collected. Since aniline is appreciably soluble (c. 3%) in water, it must be 'salted out' by saturating the distillate with salt. Use about 20 g of commercial salt for each 100 ml of liquid. Transfer the distillate, saturated with salt, to a separatory funnel, add about 40 ml of ether and shake to ensure intimate mixing of the solution and the ether; relieve the pressure within the funnel by momentarily lifting the stopper. (All flames in the vicinity must be extinguished during the extraction.) Allow the two layers to separate; run off the lower aqueous layer into a beaker, and pour the remaining ethereal layer through the mouth of the funnel into a 200-ml flask. Return the aqueous solution to the funnel and extract with a further 40 ml of ether. Proceed as before, and pour the ethereal extract into the flask. Dry the combined ethereal solutions with a few grams of anhydrous potassium carbonate (1): shake the well-stoppered flask for several minutes.

Filter the ethereal solution through a fluted filter paper and remove the ether by flash distillation, using a 50-ml round-bottomed flask to which has been added a few boiling chips. Since ether is extremely volatile and also highly flammable, the flask must be heated by means of an electrically heated...
water bath. When all the ethereal solution has been introduced into the flask, and no more ether distils on a boiling water bath, run out the water from the condenser, and distil the aniline either by direct heating over a wire gauze or, preferably, using an air bath (Fig. 2.46). A small quantity of ether may pass over during the early part of the distillation; it is therefore advisable to interpose a uralite board between the receiver and the flame. Collect the fraction b.p. 180–184°C, in a weighed conical flask. The yield of aniline is 18 g (97%).

Record the i.r. spectrum and note the absorptions at c. 3400 cm⁻¹ (NH₂, sym. and asym. stretching vibrations), 1625 cm⁻¹ (NH₂ bending vibration), 1600, 1590, 1500, 1450 cm⁻¹ (ring breathing vibrations), and 750 and 690 cm⁻¹ (monosubstitution). The p.m.r. spectrum (CCl₄ or CDCl₃, TMS) shows a singlet (c. δ 3.32) for the NH₂-group which disappears when the sample is shaken with deuterium oxide; the aromatic region of the spectrum reveals overlapping multiplets. The m.s. shows principal fragment ions at m/z 93 (M, base peak), 92 (M – H), 66 (M – HCN), 65 (66 – H or 92 – HCN), and 39 (65 – C₂H₅).

Pure aniline has a b.p. of 184°C. When freshly distilled it is a colourless liquid, but becomes discoloured on standing, particularly when exposed to light, owing to atmospheric oxidation. The colour may usually be removed by distillation from a little zinc dust.

Note. (1) Calcium chloride cannot be used to dry the ethereal solution because it combines with aniline (and other amines) to form molecular compounds. The best drying agent is sodium or potassium hydroxide (pellet form).

Cognate preparation. m-Phenylenediamine. In a 2-litre round-bottomed flask, provided with a reflux condenser, place 25 g (0.15 mol) of m-dinitrobenzene (Expt 6.18) and 100 g (0.84 mol) of granulated tin; add 200 ml of concentrated hydrochloric acid in 15 ml portions. When all the acid has been introduced, complete the reduction by heating on a water bath for 1 hour. Dilute with 750 ml of water, heat nearly to boiling and pass hydrogen sulphide into the liquid until all the tin is precipitated as the sulphide. Filter a small quantity from time to time and test for completeness of precipitation with hydrogen sulphide. Allow the precipitate to settle overnight, decant the clear liquid and filter the residue through a large fluted filter paper (1). Add sodium hydroxide solution to the filtrate until the latter is strongly alkaline, and extract several times with ether. Dry over anhydrous potassium carbonate or sodium hydroxide pellets, remove the ether and then distil the residue: use an air condenser after all the ether has passed over. Collect the portion boiling between 280 and 284°C: this solidifies on standing to crystalline m-phenylenediamine, m.p. 63°C. The yield is 13 g (74%).

Note. (1) The dihydrochloride may be obtained by evaporating the filtrate on a water bath until crystals appear, and then cooling in ice. The crystals are filtered at the pump, washed with a little concentrated hydrochloric acid and dried in a vacuum desiccator over sodium hydroxide.

Experiment 6.49 o-PHENYLENEDIAMINE

\[
\text{o-NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2 + \text{Zn(OH)}_2 \xrightarrow{\text{H}^+} \text{o-NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2
\]
Equip a 750-ml three-necked flask with a reflux condenser and sealed mechanical stirrer, and place in it 46 g (0.33 mol) of o-nitroaniline, 27 ml of 20 per cent sodium hydroxide solution and 170 ml of rectified spirit. Stir the mixture vigorously and heat it on a water bath to gentle boiling. Remove the source of heat from beneath the bath, and introduce 5 g portions of zinc powder at such a rate that the solution is kept boiling (1); add 90 g (1.4 mol) of zinc powder (2) in all. Reflux the mixture, with stirring, for 1 hour; the colour of the solution changes from deep red to nearly colourless. Filter the hot mixture at the pump; return the zinc residue to the flask and extract it with two 100 ml portions of hot rectified spirit. Combine the extracts with the filtrate, add 2 g of sodium dithionite (Na₂S₂O₄) and concentrate the solution under reduced pressure (water pump) on a steam bath to a volume of 80–100 ml; use a rotary evaporator (Fig. 2.112). Cool the solution in a freezing mixture of ice and salt, collect the pale yellow crystals on a Buchner funnel, wash once with 10–15 ml of ice-water and dry in a vacuum desiccator. The yield of crude o-phenylenediamine, m.p. 98–100 °C, is 33 g. This is sufficiently pure for most practical purposes. If a pure material is required (3), dissolve the crude product in 100–115 ml of hot water containing 1 g of sodium dithionite and add a few grams of decolourising carbon, filter and cool in an ice–salt mixture. Collect the colourless crystals of pure o-phenylenediamine on a Buchner funnel, wash with 10 ml of ice-water and dry in a vacuum desiccator; the yield is 28.5 g (79%), m.p. 100–101 °C. It darkens rapidly upon exposure to light.

The i.r. spectrum (KBr disc) shows absorptions at c. 3400 cm⁻¹ (NH₂ stretching), 1625 cm⁻¹ (NH₂ bend), 1600, 1500, 1450 cm⁻¹ (ring breathing) and 750 cm⁻¹ (four adjacent hydrogens). The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 3.28 [s, 4H, (NH₂)₂] and 6.67 (s, 4H, C_AR—H); interestingly the chemical shift values of the aromatic hydrogens are all similarly affected by the presence of the amino groups, and this region is not structurally informative. The m.s. shows principal fragment ions at m/z 108 (M, base peak), 107 (M – H), 81 (M – HCN), 80 (107 – HCN) and 54 (81 – HCN).

**Notes.** (1) Sometimes the reaction stops suddenly; it is then necessary to add a further 10 ml of 20 per cent sodium hydroxide solution and warm to the boiling point: this causes the reaction to continue. Occasionally, the reduction becomes very vigorous: a wet towel and a bath of ice-water should be kept close at hand.

(2) This weight of zinc powder assumes 100 per cent purity: an equivalent amount of less pure material may be used (see Section 4.2.80, p. 467).

(3) The crude o-phenylenediamine may be converted into the dihydrochloride and the salt purified in the following manner. Dissolve it in 60 ml of concentrated hydrochloric acid and 40 ml of water containing 2 g of tin(II) chloride, and treat the hot solution with 2–3 g of decolourising carbon. Filter, add 100 ml of concentrated hydrochloric acid to the hot colourless filtrate and cool in a freezing mixture of ice and salt. Collect the colourless crystals of the dihydrochloride on a Buchner or sintered glass funnel, wash with a small volume of concentrated hydrochloric acid and dry in a vacuum desiccator over sodium hydroxide. The yield is 51 g.

**Experiment 6.50 o-AMINOPHENOL**

\[
\text{o-HO} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2 + \text{NaBH}_4/\text{Pd} \rightarrow \text{o-HO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2
\]
CAUTION: This preparation should be conducted in an efficient fume cupboard since hydrogen is evolved during the reaction.

Place a suspension of 0.5 g of 10 per cent palladium-on-charcoal (cf. Section 4.2.54, p. 452) in 50 ml of water in a 500-ml conical flask and add 3.9 g (0.10 mol) of sodium borohydride in 75 ml of water (1); introduce a magnetic follower bar. Pass a slow stream of nitrogen through the stirred mixture and add a solution of 7.0 g (0.05 mol) of o-nitrophenol in 250 ml of 2 M sodium hydroxide, dropwise from a separatory funnel, during 5 minutes. Stir at room temperature until the yellow colour disappears (about 10 minutes) and then filter. Acidify the filtrate with 2 M hydrochloric acid to destroy excess borohydride and then neutralise the solution with dilute sodium hydroxide. Extract the product with four 50 ml portions of ether and evaporate the dried (MgSO₄) extract on the rotary evaporator. o-Aminophenol is obtained as an off-white solid, m.p. 167-169 °C; the yield is 4.3 g (75%). The product may be recrystallised from water to give the purified phenol, m.p. 169-171 °C. The infrared spectrum of o-aminophenol as a Nujol mull shows strong absorptions at 3380 and 3300 cm⁻¹ due to the antisymmetric and symmetric N—H stretching vibrations. The p.m.r. spectrum (TFA) is complex and shows signals corresponding to the aromatic protons as overlapping multiplets at δ 7.53-6.92. This should be contrasted with the p.m.r. spectrum of the para isomer, p. 956.

Note. (1) Addition of the reagents in this order prevents the possible ignition of hydrogen which can take place on addition of dry palladium-charcoal to solutions of sodium borohydride.

**Experiment 6.51 m-NITROANILINE**

\[ m-O_2N \cdot C_6H_4 \cdot NO_2 \xrightarrow{[\text{HI}]} m-O_2N \cdot C_6H_4 \cdot NH_2 \]

Dissolve 18 g (0.075 mol) of crystallised sodium sulphide, Na₂S·9H₂O (1), in 50 ml of water; add 6.0 g (0.0714 mol) of finely powdered sodium hydrogen carbonate in small portions with constant stirring. When the carbonate has dissolved completely, add 50 ml of methanol and cool below 20 °C. Filter off the precipitated sodium carbonate at the pump, using a small Buchner funnel; if necessary add 2-3 g of filter-aid to the reaction mixture before filtering, and prepare a bed of filter-aid in the Buchner funnel since this will aid the retention of the finely divided solid. Wash the precipitate with three 8 ml portions of methanol. Retain the filtrate and washings; these contain about 3.9 g of NaSH in solution and must be used forthwith for the reduction.

Dissolve 6.7 g (0.04 mol) of m-dinitrobenzene in 50 ml of hot methanol in a 250-ml round-bottomed flask and add, with shaking, the previously prepared methanolic solution of sodium hydrogen sulphide. Attach a reflux condenser and boil the mixture for 20 minutes; ignore any further sodium carbonate which may precipitate. Allow the reaction mixture to cool and fit the condenser for distillation. Distil off most of the methanol (100-120 ml) from a water bath. Pour the liquid residue with stirring into about 200 ml of cold water. Collect the yellow crystals of m-nitroaniline by suction, wash with water and recrystallise from 75 per cent aqueous methanol. The yield of bright yellow crystals, m.p. 114 °C, is 3.7 g (69%).

Note in the i.r. spectrum the absorptions arising from the vibrational
modes of the NO₂ and NH₂ groups. The p.m.r. spectrum (CDCl₃ at 60 °C, TMS) shows a very complex pattern of overlapping multiplets at δ 6.8–7.7 arising from the four dissimilar aromatic protons. The spectrum should be contrasted with those given by the ortho and para isomers (the latter is noted on p. 920). The m.s. of the three isomers show the same fragment ions but having different relative abundance: the ortho isomer has m/z 138 (M, RA < 10%), 92 (M – NO₂, RA 80%), 65 (92 – HCN, RA 100%); the meta isomer has ions at m/z 138 (RA 40%), 108 (RA 100%), 92 (RA 50%), and 65 (RA 70%); the para isomer has ions at m/z 138 (RA 100%), 108 (RA 30%), 92 (RA 42%), and 65 (RA 30%).

Note. (1) Crystallised sodium sulphide is very deliquescent and only a sample which has been kept in a tightly stoppered bottle should be used.

Cognate preparation. Reduction of 2,4-dinitrophenol. It is an interesting student exercise to carry out the reduction of 2,4-dinitrophenol under the conditions described above for m-dinitrobenzene. The spectroscopic features of the isolated and purified product, together with the melting point, in comparison with the literature values for the possible isomers, should enable a deduction to be made on the regioselectivity of the reaction.

Experiment 6.52 ETHYL p-AMINOBENZOATE (Benzocaine)

Method 1

\[ p\text{-O}_2\text{N}\cdot \text{C}_6\text{H}_4\cdot \text{CO}_2\text{H} \xrightarrow{\text{Sn/HCl}} p\text{-H}_2\text{N}\cdot \text{C}_6\text{H}_4\cdot \text{CO}_2\text{H} \xrightarrow{\text{EtOH/HCl}} p\text{-H}_2\text{N}\cdot \text{C}_6\text{H}_4\cdot \text{CO}_2\text{Et} \]

Method 2

\[ p\text{-O}_2\text{N}\cdot \text{C}_6\text{H}_4\cdot \text{CO}_2\text{H} \xrightarrow{\text{EtOH/HCl}} p\text{-O}_2\text{N}\cdot \text{C}_6\text{H}_4\cdot \text{CO}_2\text{Et} \xrightarrow{\text{H}_2/\text{Pt}} p\text{-H}_2\text{N}\cdot \text{C}_6\text{H}_4\cdot \text{CO}_2\text{Et} \]

Method 1. p-Aminobenzoic acid. Place 15 g (0.09 mol) of p-nitrobenzoic acid (Expt 6.149) in a 1-litre round-bottomed flask fitted with a reflux condenser. Introduce 35 g (0.295 mol) of powdered tin and 75 ml of concentrated hydrochloric acid. Heat the mixture gently until the reaction commences, and remove the flame. Shake the flask frequently and take care that the insoluble acid adhering to the sides of the flask is transferred to the reaction mixture: occasional gentle warming may be necessary. After about 20 minutes, most of the tin will have reacted and a clear solution remains. Allow to cool somewhat and decant the liquid into a 1-litre beaker; wash the residual tin by decantation with 15 ml of water, and add the washings to the contents of the beaker. Add concentrated ammonia solution (d 0.88) until the solution is just alkaline to litmus and digest the suspension of precipitated hydrated tin oxide on a steam bath for 20 minutes. Add 10 g of filter-aid (‘Celite’), stir well, filter at the pump and wash with hot water. Transfer the filter cake to a beaker, heat on a water bath with 200 ml of water to ensure extraction of the product and refilter. Concentrate the combined filtrate and washings until the volume has been reduced to 175–200 ml: filter off any solid which separates. Acidify the liquid to litmus with glacial acetic acid and evaporate on a water bath until crystals commence to separate; cool in ice, filter the crystals at the pump and dry in the steam oven. The yield of p-aminobenzoic acid, m.p. 192 °C, is 9.5 g (77%).
Ethyl \( p \)-aminobenzoate (esterification of \( p \)-aminobenzoic acid). Place 80 ml of absolute ethanol in a 250-ml two-necked flask equipped with a double surface reflux condenser and a gas inlet tube. Pass dry hydrogen chloride (Section 4.2.38, p. 438) through the alcohol until saturated – the increase in weight is about 20 g – remove the gas inlet tube, introduce 12 g (0.088 mol) of \( p \)-aminobenzoic acid and heat the mixture under reflux for 2 hours. Upon cooling, the reaction mixture sets to a solid mass of the hydrochloride of ethyl \( p \)-aminobenzoate. It is better, however, to pour the hot solution into c. 300 ml of water (no hydrochloride separates) and add solid sodium carbonate carefully to the clear solution until it is neutral to litmus. Filter off the precipitated ester at the pump and dry in the air. The yield of ethyl \( p \)-aminobenzoate, m.p. 91 °C, is 10 g (69%). Recrystallisation from rectified (or methylated) spirit does not affect the m.p.

Method 2. Ethyl \( p \)-nitrobenzoate. Place 21 g (0.125 mol) of \( p \)-nitrobenzoic acid (Expt 6.149), 11.5 g (0.25 mol) of absolute ethanol, 3.8 g of concentrated sulphuric acid and 30 ml of sodium-dried benzene in a 250-ml round-bottomed flask, fit a reflux condenser and heat the mixture under reflux for 16 hours. Add 50 ml of ether to the cold reaction mixture, wash the extract successively with sodium hydrogen carbonate solution and water, dry with magnesium sulphate or calcium chloride and distil off the solvent on a water bath. Remove the last traces of benzene by heating in a bath at 100–110 °C. The residual ethyl \( p \)-nitrobenzoate (21 g, 86%) solidifies completely on cooling and melts at 56 °C.

Ethyl \( p \)-aminobenzoate (catalytic reduction of ethyl \( p \)-nitrobenzoate). The general experimental details may be adapted from those described in Section 2.17.1, p. 87. Place a solution of 9.75 g (0.05 mol) of ethyl \( p \)-nitrobenzoate in 100 ml of rectified spirit together with 0.1 g of Adams’ platinum dioxide catalyst in the hydrogenation flask, and shake in hydrogen in the usual manner. The theoretical volume of hydrogen (c. 3600 ml at 24 °C and 760 mmHg) is absorbed in 2.5 hours. Filter off the platinum with suction and rinse the reaction vessel with rectified spirit. Evaporate the alcohol from the combined filtrate and washings on a water bath; the residue solidifies on cooling and weighs 8.2 g. Dissolve the crude ethyl \( p \)-aminobenzoate in rectified spirit, add a little decolourising charcoal, boil and filter; heat the filtrate to the boiling point, add hot water to incipient crystallisation and allow to cool. The resulting pure benzocaine has m.p. 90 °C; the yield is 7 g (85%).

The p.m.r. spectrum (CDCl\(_3\), TMS) shows signals at \( \delta \) 1.31 (t, 3H, Me), 4.24 (q, 2H, \( -\text{CH}_2\text{Me} \)), 4.28 (s, 2H, \( \text{NH}_2 \)), 6.51 (d, 2H, \( \text{ortho-H}'\)'s to \( \text{NH}_2 \)), and 7.81 (d, 2H, \( \text{ortho-H}'\)'s to \( \text{CO}_2\text{Et} \)). The m.s. reveals principal fragment ions at \( m/z \) 165 (M), 137 (M – \( \text{C}_2\text{H}_4 \)), 120 (M – \( \text{OEt} \)), 92 (M – \( \text{CO}_2\text{Et} \)), and 65 (92 – HCN).

6.5.2 MOLECULAR REARRANGEMENTS OF THE HOFFMANN TYPE

The general procedure of treating carboxylic acid amides with alkaline hypohalite solution is illustrated and discussed in the aliphatic series (Section 5.16.6, p. 783) and is equally applicable to the synthesis of primary aromatic amines (e.g. anthranilic acid and 3-aminopyridine, Expt 6.53). It is of particular
use in those cases where it is required to introduce an amino group into a position on the aromatic ring which, because of the orienting effects of the substituents, cannot be effectively nitrated directly in order to use the direct nitration-reduction sequence.

For the preparation of anthranilic acid the starting material is phthalimide, the cyclic imide ring of which is opened by alkaline hydrolysis in the first step of the reaction to give the sodium salt of phthalimidic acid (the half amide of phthalic acid). The intermediate undergoes the Hofmann reaction in the manner outlined on p. 783 yielding o-aminobenzoic acid (anthranilic acid).

The conversion of a carboxylic acid into an amine by treatment with hydrazoic acid in concentrated sulphuric acid is known as the Schmidt reaction or rearrangement, which often gives higher yields than the related Hofmann rearrangement procedure.

$$R\cdot CO_2H + HN_3 \xrightarrow{H_2SO_4} RNH_2 + CO_2 + N_2$$

The use of the toxic and hazardous hydrazoic acid is avoided by generating it in situ by adding sodium azide gradually to the carboxylic acid in the presence of concentrated sulphuric acid and chloroform (eg. 3,5-dinitroaniline, Expt 6.54). The reaction involves the hydrolysis of an intermediate isocyanate (RNCO), which is formed by a mechanistic pathway analogous to that involved in the Hofmann reaction.

$$\begin{align*}
R\cdot CO_2H &\xrightarrow{H^+} R\cdot OH \\
H-N-N\equiv N &\xrightarrow{OH^-} R\cdot OH
\end{align*}$$

It should be noted that amines may be formed by hydrolysis of amides arising from the intramolecular Beckmann rearrangement of ketoximes (p. 1047); this rearrangement is a further example of the migration of a nucleophilic carbon species from a carbon to an electron-deficient nitrogen.

**Experiment 6.53 ANTHRANILIC ACID**

Prepare a solution of 30 g of sodium hydroxide in 120 ml of water in a 350-ml conical flask and cool to 0 °C or below in a bath of ice and salt. Add 26.2 g
(8.4 ml, 0.16 mol) of bromine in one portion and shake (or stir) until all the bromine has reacted. The temperature will rise somewhat; cool again to 0 °C or below. Meanwhile, prepare a solution of 22 g of sodium hydroxide in 80 ml of water. Add 24 g (0.163 mol) of finely powdered phthalimide (Expt 6.155) in one portion to the cold sodium hypobromite solution in the form of a smooth paste with water, rapidly with stirring. Remove the flask from the cooling bath and shake vigorously until a clear yellow solution is obtained (c. 5 minutes). Add the prepared sodium hydroxide solution rapidly and in one portion, heat the solution to 80 °C for about 2 minutes and filter if necessary. Cool in ice and add concentrated hydrochloric acid slowly and with stirring until the solution is just neutral (about 60 ml are required). (It is recommended that a little of the alkaline solution be set aside in case too much acid is added.) Precipitate the anthranilic acid completely by the gradual addition of glacial acetic acid (20–25 ml are required): it is advisable to transfer the mixture to a 1-litre beaker as some foaming occurs. Filter off the acid at the pump and wash with a little cold water. Recrystallise from hot water with the addition of a little decolourising carbon; collect the acid on a Buchner funnel and dry at 100 °C. The yield of pure anthranilic acid, m.p. 145 °C, is 14 g (62%).

**Cognate preparation. 3-Aminopyridine.** Prepare a cold sodium hypobromite solution from 32 g (10 ml, 0.2 mol) of bromine and 25 g (0.62 mol) of sodium hydroxide in 250 ml of water. Add in one portion 20 g (0.163 mol) of finely powdered nicotinamide (Expt 6.169) and stir vigorously for 15 minutes. Warm the solution in a water bath at 75 °C for 45 minutes. Isolate the crude product by continuous ether extraction (Section 2.22) of the cooled reaction mixture after saturation with sodium chloride. Dry the extract over potassium hydroxide pellets and remove the ether. Crystallise the dark residue from a 4:1 mixture of benzene–light petroleum (b.p. 60–80 °C) with the aid of decolourising charcoal. The yield of almost colourless product, m.p. 63 °C, is 9.3 g (61%).

**Experiment 6.54  3,5-DINITROANILINE**

\[
\text{3,5-} (\text{NO}_2)_2 \text{C}_6 \text{H}_3 \cdot \text{CO}_2 \text{H} + \text{HN}_3 \xrightarrow{\text{H}_2\text{SO}_4} 3,5- (\text{NO}_2)_2 \text{C}_6 \text{H}_3 \cdot \text{NH}_2
\]

Place a solution of 50 g (0.25 mol) of 3,5-dinitrobenzoic acid (Expt 6.160) in 90 ml of oleum (10% SO₃) and 20 ml of concentrated sulphuric acid in a 1-litre four-necked flange flask equipped with a reflux condenser, mechanical stirrer, a dropping funnel and thermometer (fume cupboard). Add 100 ml of chloroform and raise the temperature to 45 °C. Stir rapidly and add 17.5 g (0.27 mol) of sodium azide in small portions while maintaining the temperature at 35–45 °C. The reaction is accompanied by foaming, which usually commences after about 3 g of sodium azide has been introduced. After all the sodium azide has been added raise the temperature so that the chloroform refluxes vigorously and maintain this temperature for 3 hours. Then cool the reaction mixture, pour it cautiously on to 500 g of crushed ice and dilute with 3 litres of water. After 1 hour, separate the yellow solid by filtration at the pump, wash well with water and dry at 100 °C. The yield of 3,5-dinitroaniline, m.p. 162–163 °C, is 39 g (90%). The m.p. is unaffected by recrystallisation from dilute ethanol.
6.5 PRACTICAL ORGANIC CHEMISTRY

The i.r. spectrum (KBr disc) clearly shows absorptions at c. 3400 and 1625 cm\(^{-1}\) (stretching and bending modes of the \(\text{NH}_2\)), 1525 and 1340 cm\(^{-1}\) (\(\text{NO}_2\) group), 1600, 1590, 1450 cm\(^{-1}\) (ring breathing); the presence of the \(\text{NO}_2\)-group makes the assignment of the substitution pattern unreliable. The p.m.r. spectrum (Me\(_2\)CO-\(d_6\), TMS) has signals at \(\delta\) 5.96 (broad s, 1H, NHD), 7.84 (d, 2H, ortho-H’s to \(\text{NH}_2\)), and 8.05 (t, 1H, ortho-H’s to both \(\text{NO}_2\) groups).

6.5.3 THE REPLACEMENT OF A HALOGEN BY AN AMINO GROUP

Unlike the ready replacement of a halogen in an alkyl halide with an amino group (Section 5.16.4, p. 779), the corresponding reaction with an aryl halide only proceeds under vigorous conditions, and generally the reaction is not preparatively useful. Thus aniline may be formed from chlorobenzene only by treatment with sodamide in liquid ammonia. A detailed study of the mechanism of the reaction led to the recognition for the first time of the reaction intermediate, benzyne. Other more convenient methods for the formation of benzyne have subsequently been developed, and the investigation of the trapping reactions of this intermediate has led to the introduction of a range of new synthetic reactions. An illustrative example is to be found in Expt 6.7.

The presence of electron-withdrawing groups (notably the nitro group) sited in the ortho or para positions of an aryl halide facilitates the halogen replacement. Here the mechanism proceeds by an addition–elimination sequence and it is discussed and illustrated in the formation of 2,4-dinitroaniline and 2,4-dinitrophenylhydrazine (Section 6.8.2, p. 959), and in the use of 1-fluoro-2,4-dinitrobenzene in the derivatisation of an amino group in an amino acid (Section 9.6.23, p. 1279).

6.5.4 THE REPLACEMENT OF A PHENOLIC HYDROXYL GROUP BY AN AMINO GROUP

The direct replacement of the hydroxyl group in simple phenols by an amino or substituted amino group requires drastic conditions and the method is not suitable for laboratory preparations. With the polyhydric phenols, and more particularly with the naphthols, such replacements occur more readily. Thus 2-naphthol is converted into 2-naphthylamine by heating with ammoniacal ammonium sulphite solution at 150°C in an autoclave. The reaction (the Bucherer reaction) depends upon the addition of the hydrogen sulphite ion to the keto form of the naphthol and the subsequent reaction with ammonia.

\[
\text{H}_2\text{H} \rightleftharpoons \left[ \text{H}_2\text{H} \right] \xrightarrow{\text{HSO}_3^\text{+}} \text{H}_2\text{H} \xrightarrow{\text{NH}_3,\overset{\text{H}_2\text{O}}{\rightleftharpoons}} \text{H}_2\text{H}
\]

The reaction is reversible; thus 2-naphthylamine can be converted into 2-
naphthol by heating with aqueous sodium hydrogen sulphite solution and then adding alkali and boiling until all the ammonia is expelled.

2-Naphthylamine is no longer manufactured and its laboratory preparation should never be attempted because of its potent carcinogenic properties. For many preparative purposes (e.g. see 2-bromonaphthalene, cognate preparation in Expt 6.72, and 2-naphthoic acid, Expt 6.154), 2-naphthylamine-1-sulphonic acid may be used. This is obtained commercially by cautious treatment of 2-naphthol with sulphuric acid—the sulphonic acid group entering the 1-position—followed by a Bucherer reaction.

The Bucherer reaction is illustrated and its reversibility demonstrated in Expt 6.55, wherein the amino group of 2-amino-5-naphthol-7-sulphonic acid is replaced by the p-tolylamino group via the corresponding naphthol intermediate.

Experiment 6.55 2-/>-TOLYLAMINO-5-NAPHTHOL-7-SULPHONIC ACID

Refux a mixture of 10.8 g (0.1 mol) of pure p-toluidine, 10.8 g (0.057 mol) of 2-amino-5-naphthol-7-sulphonic acid ('J' acid), 8.4 g (0.08 mol) of sodium metabisulphite and 25 ml of water for 30 hours in a 250-ml three-necked flask, equipped with a reflux condenser and mechanical stirrer. Add sodium carbonate until the mixture is alkaline and remove the excess of p-toluidine by steam distillation. Keep the residual solution in a refrigerator until crystallisation is complete, filter with suction on a Buchner funnel and wash with 10 ml of saturated sodium chloride solution. Dissolve the product in c. 35 ml of hot water to which sufficient hydrochloric acid is added to render the mixture acid to Congo red. Keep in a refrigerator until crystallisation is complete, filter with suction, wash with a little ice-cold hydrochloric acid, followed by a small volume of ice-cold water. Dry the residual 2-p-tolylamino-5-naphthol-7-sulphonic acid at 100 °C; the yield is 9.5 g (60%).

6.5.5 ALKYLATION AND REDUCTIVE ALKYLATION PROCEDURES FOR THE PREPARATION OF SECONDARY AND TERTIARY AMINES

Simple N-alkyl- and N,N-dialkylanilines are readily prepared commercially by the alkylation of aniline with the appropriate alcohol. For example, N-methylaniline is prepared by heating a mixture of aniline hydrochloride (55 parts) and methanol (16 parts) at 120 °C in an autoclave. For N,N-dimethylaniline, aniline and methanol are mixed in the proportion 80:78, 8 parts of concentrated sulphuric acid are added and the mixture heated in an
autoclave at 230–235 °C at a pressure of 25–30 atmospheres. N-Ethyl- and N,N-diethylaniline are prepared similarly. In the laboratory, alkylation of the amino group, to yield secondary and tertiary amines, is effected by reaction with the appropriate alkyl halide; Expt 6.56 includes the preparation of N-benzylaniline and general procedures for the synthetis of a range of N-alkyl- and N,N-dialkylanilines.

N-Alkylanilines may be purified by converting them into the N-nitroso derivative with nitrous acid followed by reduction of the separated nitroso compound with tin and hydrochloric acid, thus regenerating the N-alkylaniline. For example:

\[
\text{Ph} \cdot \text{NH} \cdot \text{Me} + \text{NaNO}_2 \xrightarrow{\text{HCl}} \text{Ph} \cdot \text{N(NO)} \cdot \text{Me} + \text{Sn/HCl} \rightarrow \text{Ph} \cdot \text{NH} \cdot \text{Me}
\]

N,N-Dialkylanilines may be purified by refluxing with an excess of acetic anhydride: any unchanged aniline and N-alkylaniline is converted into the relatively non-volatile acetyl derivative.

\[
\text{Ph} \cdot \text{NH}_2 + (\text{Me-CO})_2\text{O} \rightarrow \text{Ph} \cdot \text{NH} \cdot \text{CO} \cdot \text{Me} + \text{Me-CO}_2\text{H}
\]

\[
\text{Ph} \cdot \text{NH} \cdot \text{R} + (\text{Me-CO})_2\text{O} \rightarrow \text{Ph} \cdot \text{N(CO-Me)} \cdot \text{R} + \text{Me-CO}_2\text{H}
\]

Upon fractionation the acetic acid and unreacted acetic anhydride pass over first, followed by the pure N,N-dialkylaniline.

A convenient method for preparing in good yield a pure N,N-dialkylaniline or substituted aniline (Expt 6.57) directly from the corresponding amine consists on heating the latter with the appropriate trialkyl phosphate.

\[
3\text{ArN} \cdot \text{H}_2 + 2(\text{RO})_3\text{PO} \rightarrow 3\text{ArN} \cdot \text{R}_2 + 2\text{H}_3\text{PO}_4
\]

Secondary amines can be prepared from the primary amine and carbonyl compounds by way of the reduction of the derived Schiff bases, with or without the isolation of these intermediates. This procedure represents one aspect of the general method of reductive alkylation discussed in Section 5.16.3, p. 776. With aromatic primary amines and aromatic aldehydes the Schiff bases are usually readily isolable in the crystalline state and can then be subsequently subjected to a suitable reduction procedure, often by hydrogenation over a Raney nickel catalyst at moderate temperatures and pressures. A convenient procedure, which is illustrated in Expt 6.58, uses sodium borohydride in methanol, a reagent which owing to its selective reducing properties (Section 5.4.1, p. 519) does not affect other reducible functional groups (particularly the nitro group) which may be present in the Schiff base; contrast the use of sodium borohydride in the presence of palladium-on-carbon, p. 894.

\[
\text{Ar} \cdot \text{NH}_2 + \text{OHC} \cdot \text{Ar} \rightarrow \text{Ar} \cdot \text{N} = \text{CH} \cdot \text{Ar} \xrightarrow{\text{NaBH}_4} \text{Ar} \cdot \text{NH} \cdot \text{CH}_2 \cdot \text{Ar}
\]

**Experiment 6.56 N-BENZYLANILINE**

\[
\text{Ph} \cdot \text{CH}_2\text{Cl} + \text{Ph-NH}_2 \xrightarrow{\text{Na}_2\text{CO}_3} \text{Ph} \cdot \text{CH}_2 \cdot \text{NH} \cdot \text{Ph}
\]

Equip a 500-ml three-necked flask with a separatory funnel, a mechanical stirrer and a reflux condenser; mount the assembly on a water bath. Place 35 g of pure sodium hydrogen carbonate, 35 ml of water and 124 g (121 ml, 1.33 mol) of aniline in the flask, and 42 g (38 ml, 0.33 mol) of freshly distilled
benzyl chloride (b.p. 177–179 °C) in the separatory funnel protected by a calcium chloride guard-tube. Heat the flask and contents to 90–95 °C, stir vigorously and run in the benzyl chloride slowly (about 1 hour). Continue the heating and stirring for a further 3 hours. Allow to cool. Filter with suction, separate the organic layer from the filtrate and wash it with 25 ml of saturated salt solution. Dry with magnesium sulphate and filter again with suction. Distil from a flask with fractionating side-arm (compare Fig. 2.108) under reduced pressure: aniline (about 80 g) distils at 81 °C/12 mmHg and the temperature rises rapidly. Collect the benzylaniline at 170–190 °C/12 mmHg (most of it distils at 178–180 °C/12 mmHg); this solidifies on cooling, melts at 34–36 °C, and is sufficiently pure for most purposes. The yield is 52 g (85%). If required perfectly pure, it may be recrystallised from about 35 ml of light petroleum, b.p. 60–80 °C; cool the solution in a freezing mixture to induce crystallisation, filter at the pump, wash with a little cold light petroleum, press and dry. The recrystallised N-benzylaniline has m.p. 36 °C.

**Notes on the preparation of secondary alkylarylamines.** The preparation of *N*-propyl-, *N*-isopropyl- and *N*-butylanilines can be conveniently carried out by heating the alkyl bromide with an excess (2.5–4 mol) of aniline for 6–12 hours. The tendency for the alkyl halide to yield the corresponding tertiary amine is thus repressed and the product consists almost entirely of the secondary amine and the excess of primary amine combined with the hydrogen bromide liberated in the reaction. The separation of the primary and secondary amines is easily accomplished by the addition of an excess of 50 per cent zinc chloride solution: aniline and its homologues form sparingly soluble additive compounds of the type B₂ZnCl₂ whereas the alkylanilines do not react with zinc chloride in the presence of water. The excess of primary amine can be readily recovered by decomposing the chlorozincate with sodium hydroxide solution followed by steam distillation or solvent extraction. The yield of secondary amine is about 70 per cent of the theoretical.

The experimental details for *N*-propylaniline are as follows. Reflux a mixture of 230 g (2.5 mol) of aniline and 123 g (1 mol) of propyl bromide for 8–10 hours. Allow to cool, render the mixture alkaline and add a solution of 150 g (1.1 mol) of zinc chloride in 150 g of water. Cool the mixture and stir: after 12 hours, filter at the pump and drain well. Extract the thick paste several times with boiling light petroleum, b.p. 60–80 °C (it is best to use a Soxhlet apparatus), wash the combined extracts successively with water and dilute ammonia solution, and then dry over anhydrous potassium carbonate or magnesium sulphate. Remove the solvent on a water bath, and distil the residue through a well-lagged fractionating column. Collect the *N*-propylaniline at 218–220 °C; the yield is 80 g (59%). Treat the pasty solid chlorozincate with an excess of sodium hydroxide solution and steam distil: 130 g of pure aniline are recovered.

**Notes on the preparation of tertiary alkylarylamines.** Pure dialkylanilines may be prepared by refluxing the monoalkylaniline (1 mol) with an alkyl bromide (2 mol) for 20–30 hours; the solid product is treated with excess of sodium hydroxide solution, the organic layer separated, dried and distilled. The excess of alkyl bromide passes over first, followed by the dialkylaniline. *N*,*N*-

If the tertiary amines are suspected of being contaminated with primary and/or secondary amines, they may be purified by treatment with acetic anhydride: the following procedure is illustrative. Into a 250-ml round-bottomed flask, fitted with a reflux condenser, place 50 g (52.5 ml, 0.414 mol) of a good commercial sample of dimethylaniline and 25 g (23 ml, 0.245 mol) of acetic anhydride. Heat under reflux for 3 hours and allow to cool. Transfer to a 100-ml distillation flask and distil using a water bath. Some acetic acid and the excess acetic anhydride passes over first, followed by pure dimethylaniline (a colourless liquid) at 193–194 °C. There is a small dark residue in the flask. The yield depends upon the purity of the commercial sample but is not usually less than 40 g.

**Purification of N-methylaniline.** The laboratory preparation of N-methyl- and N-ethylanilines is hardly worth while since commercial grades of good quality (97–99% pure) are available. The following procedure, however, illustrates a useful and instructive method of purifying crude samples of secondary alkylarylamines via the derived N-nitroso compound [CAUTION: (1)].

**N-Nitroso-N-methylaniline** (methylphenylnitrosamine). Place 53.5 g (0.5 mol) of commercial N-methylaniline, 72.5 ml of concentrated hydrochloric acid and 200 g of crushed ice in a 500-ml beaker equipped with a mechanical stirrer. Support a separatory funnel with a long bent stem containing a solution of 36 g (0.52 mol) of sodium nitrite in 125 ml of water over the beaker. Stir the solution and run in the sodium nitrite solution during 10 minutes; do not allow the temperature to rise about 10 °C and add more ice if necessary. Continue the stirring for a further hour. Separate the oily layer, wash it once with 50 ml of water and dry it with anhydrous calcium sulphate. Distil under reduced pressure. Collect the N-nitroso-N-methylaniline (a pale yellow liquid) at 120°C/13 mmHg. The yield is about 65 g (96%).

**Reduction of N-nitroso-N-methylaniline.** Into a 1-litre round-bottomed flask, fitted with a reflux condenser, place 39 g (0.29 mol) of N-nitroso-N-methylaniline and 75 g of granulated tin. Add 150 ml of concentrated hydrochloric acid in portions of 25 ml (compare Expt 6.48); do not add the second portion until the vigorous action produced by the previous portion has subsided, etc. Heat the reaction mixture on a water bath for 45 minutes, and allow to cool. Add cautiously a solution of 135 g of sodium hydroxide in 175 ml of water, and steam distil (see Section 2.25); collect about 500 ml of distillate. Saturate the distillate with salt, separate the organic layer, extract the aqueous layer with 50 ml of ether and combine the extract with the organic layer. Dry with anhydrous potassium carbonate, remove the ether on a water bath and distil the residual liquid collecting the pure methylaniline at 193–194 °C as a colourless liquid. The yield is 23 g (74%).

**Note.** (1) The potentially carcinogenic nature of N-nitroso compounds is again emphasised (see Section 2.3.4, p. 49).
Experiment 6.57  \( N,N\text{-DIETHYLANILINE} \)

\[ 3\text{Ph}\cdot\text{NH}_2 + 2(\text{MeO})_3\text{PO} \rightarrow 3\text{Ph}\cdot\text{NMe}_2 + 2\text{H}_3\text{PO}_4 \]

Place 28 g (27.5 ml, 0.3 mol) of pure aniline and 28 g (23 ml, 0.2 mol) of purified trimethyl phosphate in a 500-ml round-bottomed flask equipped with a reflux condenser. Heat gently at first and remove the flame when the vigorous and exothermic reaction commences. When the latter subsides, two layers are present; heat under gentle reflux for two hours. Cool the mixture to about 50 °C, add a solution of 25 g of sodium hydroxide in 100 ml of water, reflux the mixture for 1 hour, then pour into a 600-ml beaker and allow to cool to room temperature. Pour off the oily layer of amine from the solid sodium phosphate, add water to the latter and extract the aqueous solution with ether. Dry the combined oil and ether extract with magnesium sulphate, distil off the ether, treat the residue with an equal volume of acetic anhydride and allow to stand overnight. (The acetic anhydride treatment will remove any monoalkylaniline present.) Then add hydrochloric acid (20 ml of the concentrated acid and 30 ml of water), shake until the base dissolves, extract the solution with two 30 ml portions of ether and add 25 per cent sodium hydroxide solution to the water layer to liberate the base. Collect the oil by extracting the mixture with ether, dry the ethereal solution with magnesium sulphate and remove the ether on a water bath. Distil the residue, using an air condenser, and collect the dimethylaniline at 192–193 °C. The yield is 28 g (76.5%).

The m.s. shows principal fragment ions at \( m/z \) 121 (M), 120 (M − H, base peak), 105 (120 − Me or 121 − CH₄), 104 (120 − CH₄), 77 (M − NMe₂), and 51 (77 − C₂H₂).

Cognate preparation. \( N,N\text{-DIETHYLANILINE} \). Use 28 g of pure aniline and 36 g (34 ml, 0.2 mol) of purified triethyl phosphate, and proceed exactly as described for dimethylaniline. The reaction is not so vigorous initially. Separation into two layers occurs after 30 to 90 minutes. The yield of diethylaniline, b.p. 215–216 °C, is 41–45 g (91–100%).

Experiment 6.58  \( N-(m\text{-NITROBENZYL})\text{ANILINE} \)

\[ m\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO} + \text{H}_2\text{N}\cdot\text{Ph} \rightarrow \]

\[ m\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CH}=\text{N}\cdot\text{Ph} \xrightarrow{\text{NaBH}_4} m\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{NH}\cdot\text{Ph} \]

\( N-(m\text{-Nitrobenzylidene})\text{aniline} \). In a 100-ml round-bottomed flask fitted with a reflux condenser, place 7.5 g (0.05 mol) of \( m\text{-nitrobenzaldehyde} \), 4.6 g (0.05 mol) of aniline and 20 ml of rectified spirit (1). Heat the solution under reflux, using a water bath, for 20 minutes, add water until a slight cloudiness persists and set the solution on one side to cool. The oil which separates may be induced to crystallise by rubbing with a glass rod. Collect the solid deposit by filtration and wash well with cold aqueous ethanol; 10 g (88%) of air-dried crude Schiff base is obtained which is sufficiently pure for conversion into the amine. Recrystallise a small portion from aqueous methanol to give light-fawn crystals having m.p. 65–66 °C.

\( N-(m\text{-Nitrobenzyl})\text{aniline} \). Fit a two-necked round-bottomed flask with a reflux condenser, place a stopper in the side-neck and insert a magnetic
follower. Mount the flask on a water bath sited on a magnetic-stirrer unit. In the flask place 10 g (0.044 mol) of the above Schiff base and add 100 ml of methanol. Warm the solution to about 40°C and with stirring add portionwise, over a period of 30 minutes, 1.7 g (0.044 mol) of sodium borohydride; a steady evolution of hydrogen occurs. Now heat the solution under reflux for a further 15 minutes, then add 100 ml of water and cool. Collect the solid amine which, after air-drying, has m.p. 80–81°C; upon recrystallisation from aqueous methanol 9 g (90%) of pure \( N-(m\text{-nitrobenzyl})\)aniline, m.p. 84–85°C, is obtained.

Note. (1) The Schiff base may be prepared by heating the components in the absence of solvent at 100°C for 15 minutes, cooling, and then stirring the product with methanol to induce crystallisation.

Cognate preparations. \( N-(p\text{-Methoxybenzyl})\)aniline. Prepare the Schiff base, \( N-(p\text{-methoxybenzylidene})\)aniline from 6.8 g (0.05 mol) of anisaldehyde and 4.6 g (0.05 mol) of aniline in 20 ml of rectified spirit under the conditions described above. The yield of crude product is 8.5 g (81%); recrystallisation of a small portion gives white plates, m.p. 57–58°C. Reduce 7 g (0.034 mol) of crude product with 1.1 g (0.034 mol) of sodium borohydride. The yield of pure \( N-(p\text{-methoxybenzyl})\)aniline, m.p. 46–47°C, is 6.1 g (85%).

\( N\text{-Benzyl-}m\text{-nitroaniline}. \) Prepare the Schiff base from 5.3 g (0.05 mol) of benzaldehyde and 6.9 g (0.05 mol) of \( m\text{-nitroaniline} \) in 30 ml of rectified spirit. Yield of crude product is 10 g (88%); the pure compound has m.p. 71–72°C. Reduce 7.8 g (0.034 mol) of crude Schiff base with 1.1 g (0.034 mol) of sodium borohydride. Pure \( N\text{-benzyl-}m\text{-nitroaniline} \) is obtained as orange-yellow crystals, m.p. 106–107°C; the yield is 7.0 g (90%).

6.5.6 SOME METHODS FOR THE PROTECTION OF THE AMINO AND IMINO GROUPS

The most commonly used protecting group for the aromatic amino and imino groups is the \( N\text{-acetyl} \) group. Furthermore this protecting group restricts the activating influence of the amino group towards electrophilic ring substitution reactions. The general methods of formation are detailed in Section 9.6.21, p. 1273 (see also Section 6.6.2, p. 916). Other methods of protection which are generally suitable are described under aliphatic amines (Section 5.16.7, p. 784).

6.6 SUBSTITUTION PRODUCTS OF AROMATIC AMINES

1. Nuclear substitution products (Expts 6.59 to 6.66).

The important spectroscopic features (\( i.r. \), \( p.m.r. \), \( m.s. \), and \( u.v.-\text{visible} \)) which are observed with the varied range of substitution products of aromatic amines are descriptively discussed under appropriate preparative sections.

6.6.1 NUCLEAR SUBSTITUTION PRODUCTS

The nuclear substitution reactions that are considered in this section are (a) halogenation, (b) nitrosation, (c) sulphonation and (d) ortho formylation. All
these reactions involve the introduction of the substituent into an arylamine, and the regioselectivity is governed by the ortho/para orientating effect of the amino (or alkylamino) group. As appropriate, experimental conditions are described which control the extent of substitution. The examples provide interesting comparison with the substitution reactions of acylated amines (Section 6.6.2, p. 916).

HALOGENATION
The free amino group strongly activates the aromatic ring towards electrophilic attack and aromatic substitution of amines often results in polysubstitution. For example, the bromination of aniline yields largely 2,4,6-tribromoaniline (Expt 6.59).

Monosubstitution of the free amine may be achieved by using a less reactive electrophile. Thus aniline and o-toluidine may be mono-iodinated (Expt 6.60) by treatment with iodine (in the presence of sodium hydrogen carbonate or calcium carbonate to remove the liberated hydrogen iodide), the substituent entering the position para to the amino group. Direct iodination can also be effected by using the more powerfully electrophilic reagent, iodine monochloride ($I^-Cl$) with p-aminobenzoic acid both of the positions ortho to the amino group are substituted to give 4-aminoo-3,5-diiodobenzoic acid (cognate preparation in Expt 6.60).

Several reactive chloro compounds have been used to attempt to effect the controlled monochlorination of aromatic amines. One such reagent is $N$-chlorosuccinimide, with which the chlorination of aniline, for example, can be largely restricted to monosubstitution, although a mixture of isomers (ortho–para, 1.9:1) is obtained. One approach to the achievement of specific ortho chlorination is illustrated by the synthesis of o-chlorobenzenilide (Expt 6.61), readily hydrolysable to o-chloroaniline. The anilide is formed, by a type of $S_N^1$ mechanism indicated below, when $N$-phenylhydroxylamine is benzoylated and the product is treated with thionyl chloride. The reaction has been successfully applied to several substituted $N$-phenylhydroxylamines, prepared by the controlled reduction of the corresponding substituted nitro compounds (cf. Expt 6.87).

\[
\begin{align*}
\text{HO·NH} & \quad \text{Ph·COCl} \\
& \quad \text{NaHCO}_3 \\
& \quad \text{SOCl}_2 \\
\text{HO·N·CO·Ph} & \quad \text{Cl·CO·Ph}
\end{align*}
\]

NITROSATION
The nitrosonium ion (NO), generated in situ from sodium nitrite in the presence of hydrochloric acid at 0–5 °C, is also a weak electrophile and with tertiary amines, e.g. $N,N$-dimethylaniline, ring substitution occurs leading to the $p$-nitroso derivative (Expt 6.62).
Secondary aromatic amines under these conditions form initially the \( \text{N-nitroso} \) derivative (see notes on the purification of secondary amines in Expt 6.56), which when treated with hydrogen chloride in anhydrous ethanol–ether solution rearranges to the nuclear substituted nitrosoamine (eg. \( p \)-nitroso-\( N \)-methyleneaniline, cognate preparation in Expt 6.62). This rearrangement proceeds via the intermediate formation of the electrophilic nitrosyl chloride:

\[
\begin{align*}
\text{O} \quad \text{H} \\
\text{Cl} \quad \text{N} \quad \text{N} \quad \text{CH}_3 \\
\text{Cl} \quad \text{N} \quad \text{=O} \\
\text{H} \quad \text{N} \quad \text{HCH}_3 \\
\quad \text{H} \quad \text{N} \quad \text{HCH}_3 \\
\quad \text{H} \quad \text{N} \quad \text{HCH}_3
\end{align*}
\]

SULPHONATION
When conditions for the electrophilic substitution are strongly acidic, extensive protonation of the nitrogen lone electron pair occurs and its activating influence is considerably diminished. For example, if aniline is treated with an excess of concentrated sulphuric acid, and the resulting mixture (which contains aniline sulphate) is heated at 180°C until a test portion when mixed with sodium hydroxide solution no longer liberates aniline, \( p \)-aminobenzenesulphonic acid (sulphanilic acid) is formed; this separates as the dihydrate upon pouring the cooled mixture into water. The mechanism of this reaction is uncertain; a possible pathway is the rearrangement of the intermediate phenylsulphamic acid (1). The product is more appropriately represented by the zwitterionic structure (2) (Expt 6.63).

\[
\begin{align*}
\text{NH}_2 \\
\text{H}_2\text{SO}_4 \quad \text{NH}_3 \cdot \text{HSO}_4 \quad \text{HN} \cdot \text{SO}_3 \text{H}
\end{align*}
\]

2-Aminobenzenesulphonic acid (orthanilic acid, Expt 6.64) is readily prepared by the reduction of 2-nitrobenzenesulphonic acid. The latter may be prepared by the hydrolysis of the corresponding sulphonyl chloride which is obtained from di-o-nitrophenyl disulphide. The preparation of this disulphide involves the use of the reactive aryl halide, 2-chloronitrobenzene (cf. Expts 6.93
ORTHODOXY FORMYLATION

Ortho-formylation and its ring-substituted analogues are important starting materials in the formation of various heterocyclic ring systems. The parent compound has been prepared by the reduction of ortho-nitrobenzaldehyde or by the oxidation of ortho-toluidine. Such procedures are obviously accompanied by undesirable side reactions resulting from the susceptibility of the carbonyl and amino groups respectively to the reaction conditions. The presence of other nuclear substituents could clearly provide further problems in chemoselectivity. A procedure involving the specific ortho formylation of a para-substituted amine, using 1,3-dithiane as the formyl equivalent, is worthy of note (cf. ortho formylation of phenols, p. 993). The reaction sequence is formulated and illustrated by the conversion of p-toluidine into 2-acetamido-5-methylbenzaldehyde (Expt 6.66).

Experiment 6.59 2,4,6-TRIBROMOANILINE

\[ \text{Ph-NH}_2 + 3\text{Br}_2 \longrightarrow \text{H}_2\text{N-C}_6\text{H}_2\text{Br}_3 \]

Dissolve 10 g (0.11 mol) of aniline in 40 g of glacial acetic acid and stir well with a mechanical stirrer while running in slowly a solution of 52.8 g (17 ml, 0.33 mol) of bromine (CAUTION) in 34 ml of glacial acetic acid. The beaker should be cooled in ice during the addition as the reaction is exothermic. The final product (a pasty mass) should be coloured yellow by the addition of a little more bromine if necessary. Pour into excess of water, filter at the pump, wash well with water, press thoroughly and dry. The yield of tribromoaniline, m.p. 119–120 °C, is quantitative. Recrystallise a small portion from industrial (or rectified) spirit; m.p. 120 °C.

The m.s. provides a good example of the fragmentation pattern of a compound having three bromine atoms; \( m/z \) 333 (M, RA 29%), 331 (M, RA 99%), 329 (M, RA 100%), 327 (M, RA 32%), 170 and 168 (M—Br₂, two each of RA 22.5%). The p.m.r. spectrum (CDCl₃, TMS) has \( \delta \) 4.59 (broad s, 2H, NH₂), and 7.50 (s, 2H, C₃,₅—H).

Conversion to 2,4,6-tribromoacetanilide. Dissolve 1 g of 2,4,6-tribromoaniline in 20 ml of acetic anhydride and add 2 drops of concentrated sulphuric acid. After 10 minutes, pour the reaction mixture into excess of warm water. Filter off the tribromoacetanilide, wash and dry; the m.p. is 231 °C. Recrystallise from alcohol; the m.p. is raised to 232 °C.

Experiment 6.60 p-IODOANILINE

\[ \text{Ph-NH}_2 + \text{I}_2 + \text{NaHCO}_3 \longrightarrow \text{p-I-C}_6\text{H}_4\text{NH}_2 + \text{NaI} + \text{CO}_2 + \text{H}_2\text{O} \]

Into a 1-litre beaker, provided with a mechanical stirrer, place 37 g (36 ml, 0.4 mol) of aniline, 50 g (0.6 mol) of sodium hydrogen carbonate and 350 ml of water; cool to 12–15 °C by the addition of a little crushed ice. Stir the mixture,
and introduce 85 g (0.33 mol) of powdered, resublimed iodine in portions of 5–6 g at intervals of 2–3 minutes so that all the iodine is added during 30 minutes. Continue stirring for 20–30 minutes, by which time the colour of the free iodine in the solution has practically disappeared and the reaction is complete. Filter the crude p-idoaniline with suction on a Buchner funnel, drain as completely as possible and dry it in the air. Save the filtrate for the recovery of the iodine (1). Place the crude product in a 750-ml round-bottomed flask fitted with a reflux double surface condenser, add 325 ml of light petroleum, b.p. 60–80 °C, and heat in a water bath maintained at 75–80 °C. Shake the flask frequently and after about 15 minutes, slowly decant the clear hot solution into a beaker set in a freezing mixture of ice and salt, and stir constantly. The p-idoaniline crystallises almost immediately in almost colourless needles; filter and dry the crystals in the air. Return the filtrate to the flask for use in a second extraction as before (2). The yield of p-idoaniline, m.p. 62–63 °C, is 60 g (82%).

Notes. (1) The iodine may be recovered from the aqueous filtrate, containing sodium iodide, in the following manner. Add 33 ml of concentrated sulphuric acid and a solution of 65 g of sodium dichromate in 65 ml of water. Allow the iodine to settle, wash it three times by decantation, filter and allow to dry on a clock glass. The weight of crude iodine is about 50 g.
(2) Two extractions usually suffice, but if much organic material remains, a third extraction should be made. If the p-idoaniline from the second and third extractions is coloured, it should be refluxed for a short period in light petroleum solution with a little decolourising carbon and filtered through a hot water funnel (CAUTION: flammable).

Cognate preparations. 2-Amino-5-iodotoluene. Triturate 20 g (0.14 mol) of dry o-toluidine hydrochloride and 35.5 g (0.14 mol) of powdered iodine in a mortar and then grind in 17.5 g of precipitated calcium carbonate. Transfer the mixture to a conical flask, and add 100 ml of distilled water with vigorous shaking of the flask. Allow the mixture to stand for 45 minutes with occasional agitation, then heat gradually to 60–70 °C for 5 minutes, and cool. Transfer the contents of the flask to a separatory funnel, extract the amine with three 80 ml portions of ether, dry the extract with anhydrous calcium chloride or magnesium sulphate and remove the excess of solvent. The crude 2-amino-5-iodotoluene separates in dark crystals. Recrystallise from 50 per cent alcohol; nearly white crystals, m.p. 87 °C, are obtained, 26 g (80%).

4-Amino-3,5-diiodobenzoic acid. In a 2-litre beaker, provided with a mechanical stirrer, dissolve 10 g (0.073 mol) of pure p-aminobenzoic acid, m.p. 192 °C (Expt 6.52), in 450 ml of warm (75 °C) 12.5 per cent hydrochloric acid. Add a solution of 48 g (0.295 mol) of iodine monochloride (Section 4.2.44, p. 440) in 40 ml of 25 per cent hydrochloric acid and stir the mixture for one minute: during this time a yellow precipitate commences to appear. Dilute the reaction mixture with 1 litre of water whereupon a copious precipitate is deposited. Raise the temperature of the well-stirred mixture gradually and maintain it at 90 °C for 15 minutes. Allow to cool to room temperature, filter, wash thoroughly with water and dry in the air; the yield of crude acid is 24 g. Purify the product by dissolving it in dilute sodium hydroxide solution and precipitate with dilute hydrochloric acid: the yield of air-dried 4-amino-3,5-diiodobenzoic acid, m.p. > 350 °C, is 23 g (81%).
Experiment 6.61  o-CHLOROBENZANILIDE

\[
\text{HO-N-CO-Ph} \xrightarrow{\text{SOCl}_2} \text{HN-CO-Ph} \quad \text{Cl}
\]

A solution of thionyl chloride (1.42 g, 12 mmol) in dry benzene (CAUTION) or ether (10 ml) is added dropwise to a stirred solution of \(N\)-phenylbenzohydroxamic acid (2.13 g, 10 mmol, Expt 6.87) in dry benzene (CAUTION) or ether (100 ml) at 0–5 °C during 20 minutes. The reaction mixture is stirred at the same temperature for 30 minutes and at room temperature for 1 hour. Water (50 ml) is added. The solvent layer is washed with a 5 per cent solution of sodium hydroxide (10 ml) and then with water until free of alkali. After drying over anhydrous sodium sulphate and concentrating, o-chlorobenzanilide (1.90 g, 84%) is isolated, and is recrystallised from aqueous 30 per cent ethanol. The m.p. is 104 °C (1).

Note. (1) The benzanilide may be hydrolysed to o-chloroaniline using the conditions noted on p. 1050.

Experiment 6.62  p-NITROSO-\(N,N\)-DIMETHYLANILINE

\[
\text{C}_6\text{H}_5\cdot\text{N}(\text{CH}_3)_2 \xrightarrow{\text{HNO}_2} \text{p-ON-C}_6\text{H}_4\cdot\text{N}(\text{CH}_3)_2
\]

Dissolve 30 g (31.5 ml, 0.25 mol) of \(N,N\)-dimethylaniline in 105 ml of concentrated hydrochloric acid contained in a 600-ml beaker, and add finely crushed ice until the temperature falls below 5 °C. Stir the contents of the beaker mechanically (or, less satisfactorily, with a thermometer) and slowly add (c. 10 minutes) a solution of 18 g (0.26 mol) of sodium nitrite in 30 ml of water from a separatory funnel, the stem of which dips beneath the surface of the liquid. Maintain the temperature below 8 °C by the addition of ice, if necessary. When all the nitrite solution has been added, allow the mixture to stand for 1 hour, filter the yellow crystalline \(p\)-nitrosodimethylaniline hydrochloride at the pump, wash it with 40 ml of dilute hydrochloric acid (1:1), drain well and finally wash with a little alcohol. The yield is good and depends upon the purity of the original dimethylaniline. If the pure hydrochloride is required, it may be recrystallised from hot water in the presence of a little dilute hydrochloric acid; yellow needles, m.p. 177 °C. Recrystallisation is, however, unnecessary if the free base is to be prepared.

Transfer 30 g of the hydrochloride to a 500-ml separatory funnel, add 100 ml of water and shake until a thin paste of uniform consistency is obtained; add cold 10 per cent aqueous sodium hydroxide solution with shaking until the whole mass has become bright green (the colour of the free base) and the mixture has an alkaline reaction. Extract the free base by shaking with two 60 ml portions of benzene (1). Dry the combined benzene extracts with a little anhydrous potassium carbonate, and filter into a distilling flask fitted with a water condenser. Distil off about half of the benzene. Upon cooling the residual solution, the \(p\)-nitrosodimethylaniline crystallises in deep green leaflets. Filter these off and dry them in the air. The yield of \(p\)-nitrosodimethylaniline, m.p. 85 °C, from the hydrochloride is almost quantitative.
**Note.** (1) The base is only slightly soluble in ether, thus rendering its use uneconomical. It may be extracted with chloroform and precipitated from the dried chloroform solution with carbon tetrachloride.

**Cognate preparation**

\[
\begin{align*}
\text{C}_{6}\text{H}_{5}-\text{NO} & \xrightarrow{\text{ethanol}-\text{HCl}} \text{ON} & \text{C}_{6}\text{H}_{5}-\text{NH}\cdot\text{CH}_{3}
\end{align*}
\]

**p-Nitroso-N-methylaniline.** Dissolve 5 g of \(N\)-nitroso-\(N\)-methylaniline [CAUTION: see Expt 6.56, Note (1)] in 10 ml of anhydrous ether, and add 20 g of a saturated solution of hydrogen chloride in absolute ethanol. Allow to stand. After some time a mass of crystalline needles of the hydrochloride of \(p\)-nitroso-\(N\)-methylaniline separates. Filter with suction on a sintered glass funnel and wash with a mixture of alcohol and ether. Dissolve the solid in water and add a slight excess of sodium carbonate solution or dilute ammonia solution. Filter off the blue-green free base, and recrystallise it from benzene. The yield of \(p\)-nitroso-\(N\)-methylaniline, m.p. 118 °C, is 4.5 g (90%).

**Experiment 6.63 SULPHANILIC ACID**

\[
\begin{align*}
\text{Ph-}\text{NH}_{2} + \text{H}_{2}\text{SO}_{4} & \rightarrow p\text{-H}_{3}\text{N}\cdot\text{C}_{6}\text{H}_{4}\cdot\text{SO}_{3}\text{H}
\end{align*}
\]

Place 20.4 g (20 ml, 0.22 mol) of aniline in a 250-ml round-bottomed flask and cautiously add 74 g (40 ml) of concentrated sulphuric acid in small portions; swirl the mixture gently during the addition and keep it cool by occasionally immersing the flask in cold water. Support the flask in an oil bath, and heat the mixture at 180–190 °C (fume cupboard) for about 5 hours (1). The sulphonation is complete when a test portion (2 drops) is completely dissolved by 3–4 ml of c. 2 M sodium hydroxide solution without leaving the solution cloudy. Allow the product to cool to about 50 °C and pour it carefully with stirring into 400 g of cold water or of crushed ice. Allow to stand for 10 minutes, and collect the precipitated sulphanilic acid on a Buchner funnel, wash it well with water and drain. Dissolve the crude sulphanilic acid in the minimum volume of boiling water (450–500 ml); if the resulting solution is coloured, add about 4 g of decolourising carbon and boil for 10–15 minutes. Filter through a hot-water funnel or through a preheated Buchner funnel. Upon cooling, the sulphanilic acid dihydrate separates in colourless crystals. When the filtrate is quite cold, filter the crystals with suction, wash with about 10 ml of cold water and press thoroughly with a wide glass stopper. Dry between sheets of filter paper or in a desiccator containing anhydrous calcium chloride; in the latter case, the water of crystallisation (and hence the crystalline form) is lost. The yield of sulphanilic acid is 20–22 g (52–58%). The substance does not melt sharply and no attempt should be made to determine the melting point; the crystals are efflorescent.

**Note.** (1) If 40 ml of 10 per cent oleum is cautiously added to the aniline sulphate mixture, sulphonation proceeds much more rapidly and the time of heating is reduced from 5 hours to 1 hour.
Experiment 6.64 ORTHANILIC ACID (2-Aminobenzenesulphonic acid)

\[
\begin{align*}
\text{Di-o-nitrophynyl disulphide.} & \quad \text{Place 120 g (0.5 mol) of crystallised sodium sulphi de (1) and 500 ml of rectified spirit in a 1-litre round-bottomed flask provided with a reflux condenser. Heat the flask on a water bath until the sulphide dissolves. Then add 16 g (0.5 mol) of finely powdered sulphur and continue the heating until all the sulphur dissolves forming a brownish-red solution of sodium disulphide (2). Prepare a solution of 105 g (0.66 mol) of o-chloronitrobenzene in 175 ml of rectified spirit in a 2-litre round-bottomed flask equipped with a reflux condenser; by means of a pressure-equalising dropping funnel, add the sodium disulphide solution down the condenser slowly and at such a rate that the reaction is under control. Heat the mixture on a water bath, gently at first until the violent reaction subsides, and then with the water boiling vigorously for 2 hours. Allow to cool. Filter with suction on a Buchner funnel. Transfer the mixture of organic disulphide and sodium chloride to a 400-ml beaker and stir thoroughly with 175 ml of water to remove the salt. Filter at the pump, drain well and wash the crystalline residue on the filter with 35 ml of alcohol to remove any unreacted o-chloronitrobenzene. The residual di-o-nitrophenyl disulphide melts at 193–195 °C and weighs 70 g (68%).}

\text{Notes.} & \quad \text{(1) Crystallised sodium sulphide Na}_2\text{S-9H}_2\text{O is very deliquescent, and only a sample which has been kept in a tightly stoppered bottle should be used; crystals as dry as possible should be selected. Alternatively, an equivalent amount of analysed fused sodium sulphide may be employed; this dissolves somewhat more slowly in alcohol.}
\]

(2) If some sodium disulphide separates at the bottom of the flask, this should be dissolved in a little more rectified spirit and added to the chloronitrobenzene solution.

\text{o-Nitrobenzenesulphonyl chloride.} & \quad \text{Equip a 1-litre three-necked flask with an inlet tube for introducing chlorine well beneath the surface of the liquid, an efficient mechanical stirrer and a reflux condenser. Set up the assembly (cf. Fig. 2.59) in the fume cupboard and absorb the excess of chlorine in sodium hydroxide solution. Place 60 g (0.195 mol) of di-o-nitrophynyl disulphide, 300 ml of concentrated hydrochloric acid and 60 ml of concentrated nitric acid in the flask, pass a stream of chlorine from a cylinder into the mixture at the rate of 2 bubbles per second and warm the solution to 70 °C on a water bath. After about 30 minutes, the disulphide melts and the solution assumes an orange-red colour; after the melting stage has been reached, the passage of the chlorine and the heating are continued for 1 hour. Immediately separate}
the sulphonyl chloride from the supernatant liquid by decantation, wash with two 90 ml portions of water at about 70 °C and allow to solidify. Drain the water from the solid mass as completely as possible. Dissolve the sulphonyl chloride in 45 ml of glacial acetic acid at 50–60 °C, and rapidly filter the solution at the pump. Cool the filtrate in cold water and stir it vigorously so that the sulphonyl chloride separates in small crystals. Triturate the mixture well with 300 ml of cold water and decant through a Buchner funnel; repeat the process twice. Finally add 300 ml of cold water and 3 ml of concentrated ammonia solution to the mixture, stir well and filter immediately, through a Buchner funnel, wash with 60 ml of water, drain well and dry in the air. The yield of moderately pure o-nitrobenzenesulphonyl chloride, m.p. 64–65 °C, is 72 g (84%). The undried material may be used in the preparation of orthanilic acid.

Orthanilic acid. Fit a 1-litre three-necked flask with a sealed mechanical stirrer and a reflux condenser. Place 60 g of o-nitrobenzenesulphonyl chloride, 30 g of anhydrous sodium carbonate and 180 ml of water in the flask. Heat the mixture to boiling, with stirring; the hydrolysis of the sulphonyl chloride to the sulphonic acid is complete within 40 minutes after the compound has melted. Filter the orange-red solution and acidify (to litmus) with acetic acid (about 7.5 ml are required). Transfer the solution to the original flask (which has been thoroughly rinsed with water) equipped as before. Heat the solution to boiling, and add 105 g of finely divided iron filings (about 20 mesh) with vigorous stirring at the rate of about 7.5 g every 15 minutes. The mixture soon becomes deep brown and exhibits a tendency to froth. Complete the reaction by stirring for a further 4 hours, i.e. until a test portion when filtered yields an almost colourless filtrate; if the filtrate is orange or red, the heating and stirring must be continued. When the reduction is complete, add 2 g of decolourising carbon, filter the hot reaction mixture at the pump and wash the residue with three 15 ml portions of hot water: combine the washings with the main solution. Cool the filtrate to about 15 °C, and add 28.5 ml of concentrated hydrochloric acid slowly, and cool to 12–15 °C. Filter the acid with suction on a Buchner funnel, wash with a little cold water, followed by a little ethanol and dry upon filter paper in the air. The yield is 27 g (57%); the orthanilic acid has a purity of 97–99 per cent. If required perfectly pure it may be recrystallised from hot water; it decomposes at about 325 °C.

Experiment 6.65 METANILIC ACID (3-Aminobenzenesulphonic acid)

\[
\text{PhNO}_2 \xrightarrow{\text{oleum}} m\text{-O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H} \xrightarrow{\text{Fe/H}_2\text{O}^\ominus} m\text{-H}_3\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3^2
\]

CAUTION: This preparation should be carried out in a fume cupboard.

In a 500-ml bolt-head flask, provided with a mechanical stirrer, place 70 ml of oleum (20% SO₃) and heat it in an oil bath to 70 °C. By means of a dropping funnel, supported so that the stem is just above the surface of the acid, introduce 41 g (34 ml, 0.33 mol) of nitrobenzene slowly and at such a rate that the temperature of the well-stirred mixture does not rise above 100–105 °C. When all the nitrobenzene has been introduced, continue the heating at 110–115 °C for 30 minutes. Remove a test portion and add it to excess of water. If the odour of nitrobenzene is still apparent, add a further 10 ml of
fuming sulphuric acid, and heat at 110–115 °C for 15 minutes: the reaction mixture should then be free from nitrobenzene. Allow the mixture to cool and pour it carefully with vigorous stirring on to 200 g of finely crushed ice contained in a beaker. All the nitrobenzenesulphonic acid passes into solution; if a little sulphone is present, remove this by filtration. Stir the solution mechanically and add 70 g of sodium chloride in small portions: the sodium salt of \( m \)-nitrobenzenesulphonic acid separates as a pasty mass. Continue the stirring for about 30 minutes, allow to stand overnight, filter and press the cake well. The latter will retain sufficient acid to render unnecessary the addition of acid in the subsequent reduction with iron.

Place 84 g (1.5 mol) of iron filings and 340 ml of water in a 1.5- or 2-litre bolt-head flask equipped with a mechancial stirrer. Heat the mixture to boiling, stir mechanically and add the sodium \( m \)-nitrobenzenesulphonate in small portions during 1 hour. After each addition the mixture foams extensively: a wet cloth should be applied to the neck of the flask if the mixture tends to froth over the sides. Replace from time to time the water which has evaporated so that the volume is approximately constant. When all the sodium salt has been introduced, boil the mixture for 20 minutes. Place a small drop of the suspension upon filter paper and observe the colour of the 'spot': it should be a pale brown but not deep brown or deep yellow. If it is not appreciably coloured, add anhydrous sodium carbonate cautiously, stirring the mixture, until red litmus paper is turned blue and a test drop upon filter paper is not blackened by sodium sulphide solution. Filter at the pump and wash well with hot water. Concentrate the filtrate to about 200 ml, acidify with concentrated hydrochloric acid to Congo red and allow to cool. Filter off the metanilic acid and dry upon filter paper. A further small quantity may be obtained by concentrating the mother-liquor. The yield is 55 g (95%).

2-Amino-5-methylbenzaldehyde trimethylene mercaptal. To a rapidly stirred solution of 5.4 g (0.050 mol) of \( \text{p-toluidine} \) and 6.0 g (0.050 mol) of 1,3-dithiane in 600 ml of dry dichloromethane under nitrogen at \(-78 \degree \text{C}\) is added dropwise 5.4 g (0.050 mol) of \( \text{t-butyl hypochlorite} \) (Section 4.2.11, p. 422) in 25 ml of dry dichloromethane in diffuse light. The reaction mixture is stirred for 6 hours at \(-78 \degree \text{C}\). A solution of 5.4 g (0.100 mol) of sodium methoxide in
50 ml of absolute methanol at 25 °C is added while keeping the temperature below -70 °C. The reaction mixture is stirred for 30 minutes at -78 °C, then the cooling bath is removed, and the solution is warmed to room temperature. The solvent is removed in vacuo, 300 ml of dry toluene is added and the suspension heated under reflux for 12 hours. After cooling, the solution is concentrated in vacuo and the residue dissolved in 300 ml of dichloromethane, washed with two 100-ml portions of water, 100 ml of saturated sodium chloride solution and dried over magnesium sulphate. The solution is filtered and concentrated in vacuo leaving 12.1 g of a brown oil. After low-boiling materials are removed by distillation the residue is chromatographed on 450 g of Fisher basic alumina (Activity I) using 0.5 per cent methanol in ether. This yields 3.8 g of a mixture which is distilled under reduced pressure to give 2.8 g (25%) of product, b.p. 188–191 °C/0.10 mmHg; p.m.r. (CDCl₃, TMS) δ 7.14 (d, 1H, J = 2 Hz), 6.92 (d of d, 1H J = 2 and 8 Hz), 6.57 (d of d, 1H, J = 8 Hz), 5.27 (s, 1H), 3.93 (broad s, 2H), 3.2–2.7 (m, 4H), 2.22 (s, 3H), and 2.3–1.7 (m, 2H).

2-Acetamido-5-methylbenzaldehyde trimethylene mercaptal. Into a 25-ml round-bottomed flask are placed 300 mg of the foregoing amino compound, 5 ml of acetic anhydride and 3 ml of pyridine. The solution is heated on a steam bath for 5 minutes, allowed to cool and poured into 50 ml of water, whereupon the product precipitates. Sodium carbonate is added until the solution is basic. The product is collected by filtration, washed with water and dried under vacuum (320 mg, 90%). Further recrystallisation affords fine, white crystals, m.p. 159–160 °C.

2-Acetamido-5-methylbenzaldehyde. Into a 5-ml round-bottomed flask equipped with a mechanical stirrer and a nitrogen atmosphere are placed 0.7–0.8 mmol of red mercury(II) oxide, 0.7–0.8 mmol of boron trifluoride–etherate (Section 4.2.8, p. 421), and 2 ml of 15 per cent aqueous tetrahydrofuran. To this stirred suspension under nitrogen is added 100 mg of the foregoing mercaptal dissolved in the minimum of tetrahydrofuran. The reaction mixture is stirred for 1 hour at 25 °C, poured into 10 ml of ether and 2 ml of 10 per cent sodium carbonate solution is added. After mixing, the organic phase is separated, and the aqueous layer is extracted with two 5-ml portions of ether. The combined organic phases are washed with two 5-ml portions of water, and 5 ml of saturated sodium chloride solution and dried over anhydrous magnesium sulphate. The reaction mixture is then filtered and concentrated under reduced pressure to give 70 mg, m.p. 72–77 °C, of 2-acetamido-5-methylbenzaldehyde. Recrystallisation from cyclohexane–tetrahydrofuran followed by sublimation gives 61 mg (92% yield) of product, m.p. 77–78.5 °C.

### 6.6.2 Acylated Amines and Their Substitution Reactions

Acylation of an aromatic primary or secondary amine may be readily achieved by using an acid chloride in the presence of base; however, acetylation is more usually effected with acetic anhydride rather than the more obnoxious acetyl chloride.

In general, benzyolation of aromatic amines finds less application than acetylation in preparative work, but the process is often employed for the
identification and characterisation of aromatic amines (Section 9.6.21, p. 1273). In the Schotten–Baumann method of benzylation, the amine, or its salt, is dissolved or suspended in a slight excess of 8–15 per cent sodium hydroxide solution, a small excess (about 10–15% more than the theoretical quantity) of benzoyl chloride is then added and the mixture vigorously shaken in a stoppered vessel (or else the mixture is stirred mechanically). Benzylation proceeds smoothly and the sparingly soluble benzoic derivative separates as a solid. The use of the aqueous medium is possible because the sodium hydroxide only slowly hydrolyses the excess of benzoyl chloride to yield sodium benzoate and sodium chloride which remain in solution.

\[
\text{Ar-NH}_2 + \text{Ph-COCl} + \text{NaOH} \rightarrow \text{Ar-NH-CO-Ph} + \text{NaCl} + \text{H}_2\text{O}
\]

\[
\text{Ar}_2\text{NH} + \text{Ph-COCl} + \text{NaOH} \rightarrow \text{Ar}_2\text{N-CO-Ph} + \text{NaCl} + \text{H}_2\text{O}
\]

The benzoyl compounds frequently occlude traces of unchanged benzoyl chloride, which thus escapes hydrolysis by the alkali; it is therefore advisable, wherever possible, to recrystallise the benzoic derivatives from methanol, ethanol or rectified spirit, since these solvents will esterify the unchanged acid chloride and so remove the latter from the recrystallised material. Sometimes the benzoyl compound does not crystallise well; this difficulty may be frequently overcome by the use of \(p\)-nitrobenzoyl chloride or 3,5-dinitrobenzoyl chloride (Expt 6.161), which usually give highly crystalline derivatives of high melting point. Benzylic compounds are readily hydrolysed by heating with about 70 per cent sulphuric acid (alkaline hydrolysis is very slow for anilides).

\[
\text{Ar-NH-CO-Ph} + \text{H}_2\text{SO}_4 + \text{H}_2\text{O} \rightarrow \text{Ar-NH}_3^+\text{HSO}_4^- + \text{Ph-CO}_2\text{H}
\]

Primary amines react readily upon warming with acetic anhydride to yield, in the first instance, the monoacetyl derivative.

\[
\text{Ar-NH}_2 + (\text{Me-CO})_2\text{O} \rightarrow \text{Ar-NH-CO-Me} + \text{Me-CO}_2\text{H}
\]

If heating is prolonged and excess of acetic anhydride is employed, variable amounts of the diacetyl derivative are formed.

\[
\text{Ar-NH-CO-Me} + (\text{Me-CO})_2\text{O} \rightarrow \text{Ar-N(CO-Me)_2} + \text{Me-CO}_2\text{H}
\]

In general, however, the diacetyl derivatives are unstable in the presence of water, undergoing hydrolysis to the monoacetyl compound, so that when they (or a mixture of mono- and di-acetyl derivatives) are crystallised from an aqueous solvent, e.g. dilute ethanol, only the monoacetyl derivative is obtained. Highly substituted amines (e.g. Expt 6.59) react extremely slowly with acetic anhydride, but in the presence of a few drops of concentrated sulphuric acid as catalyst, acetylation occurs rapidly.

The disadvantages attending the use of acetic anhydride alone are absent when the acetylation is conducted in aqueous solution (see Section 9.6.21, p. 1273).

Conversion of the amino group into the acetamido group by acetylation modifies the interaction of the nitrogen lone pair with the \(\pi\)-electron system of the aromatic ring so that the ring is less powerfully activated towards electrophilic attack.
Protection of the amino group by acetylation, as in acetanilide, therefore usually permits monosubstitution reactions with appropriate electrophilic reagents to proceed smoothly. Thus with bromine, \( p \)-bromoacetanilide is the main product; the small quantity of the ortho isomer simultaneously formed can be easily eliminated by recrystallisation (Expt 6.67); hydrolysis of \( p \)-bromoacetanilide gives \( p \)-bromoaniline. Nitration leads similarly to \( p \)-nitroacetanilide which can be hydrolysed to \( p \)-nitroaniline (Expt 6.68).

**Experiment 6.67  \( p \)-BROMOACETANILIDE AND \( p \)-BROMOANILINE**

\[
\text{Ph} \cdot \text{NH} \cdot \text{CO} \cdot \text{Me} \xrightarrow{\text{Br}_2} \text{p-Br} \cdot \text{C}_6 \cdot \text{H}_4 \cdot \text{NH} \cdot \text{CO} \cdot \text{Me} \xrightarrow{\text{H}_2\text{O}^+} \text{p-Br} \cdot \text{C}_6 \cdot \text{H}_4 \cdot \text{NH}_2
\]

**Bromination of acetanilide.** Dissolve 13.5 g (0.1 mol) of finely powdered acetanilide in 45 ml of glacial acetic acid in a 350-ml conical flask. In another small flask dissolve 17 g (5.3 ml, 0.106 mol) of bromine in 25 ml of glacial acetic acid, and transfer the solution to a burette or a separatory funnel supported over the flask. (For precautions attending the use of bromine, see Section 4.2.9, p. 422. The preparation should be conducted in a fume cupboard.) Add the bromine solution slowly and with constant shaking to ensure thorough mixing: stand the flask in cold water. When all the bromine has been added, the solution will have an orange colour due to the slight excess of bromine; a part of the reaction product may crystallise out. Allow the final reaction mixture to stand at room temperature for 30 minutes with occasional shaking. Pour the reaction product into 400 ml of water; rinse the flask with about 100 ml of water. Stir the mixture well and if it is appreciably coloured, add just sufficient sodium metabisulphite solution to remove the orange colour. Filter the crystalline precipitate with suction on a Buchner funnel, wash thoroughly with cold water and press as dry as possible with a wide glass stopper. Recrystallise from dilute methanol or ethanol (industrial spirit). The yield of \( p \)-bromoacetanilide, colourless crystals m.p. 167 °C, is 18 g (84%).

The \( para \)-substitution pattern is confirmed by the p.m.r. spectrum (DMSO-\( d_6 \), TMS) which shows signals at \( \delta \) 2.10 (s, 3H, Me), 7.45 and 7.61 (d of d, 4H, the two pairs of aromatic protons), and 10.04 (broad s, 1H, NH). The m.s. has principal fragment ions at \( m/z \) 215 (M, \( ^{81} \text{Br} \)), 213 (M, \( ^{79} \text{Br} \)), 173 (215 - \( \text{CH}_2\text{CO} \)), 171 (213 - \( \text{CH}_2\text{CO} \)), 92 (173 - \( ^{81} \text{Br} \) and 171 - \( ^{79} \text{Br} \)) and 43 (\( \text{CH}_2\text{CO} \)).

**Hydrolysis of \( p \)-bromoacetanilide.** Dissolve 18 g (0.084 mol) of \( p \)-bromoacetanilide in 35 ml of boiling ethanol contained in a 500-ml round-bottomed flask equipped with a reflux condenser. With the aid of a pressure-equalising dropping funnel add 22 ml of concentrated hydrochloric acid down the condenser in small portions to the boiling solution. Reflux for 30–
40 minutes or until a test portion remains clear when diluted with water. Dilute with 150 ml of water, and fit the flask with a condenser set for downward distillation. Distil the mixture from an air bath (Fig. 2.46) and collect about 100 ml of distillate; the latter consists of ethyl acetate, ethanol and water. Pour the residual solution of p-bromoaniline hydrochloride into 100 ml of ice-water, and add, with vigorous stirring, 5 per cent sodium hydroxide solution until just alkaline. The p-bromoaniline separates as an oil, which soon crystallises. Filter the crystals at the pump, wash with cold water and dry in the air upon pads of filter paper. The yield is 14 g (97%), m.p. 66 °C. Recrystallisation from dilute alcohol, which results in appreciable loss, is usually unnecessary.

The assignment of signals in the p.m.r. spectrum (CDCl₃, TMS) is made possible from the greater difference, compared to the amide above, in the chemical shifts of the aromatic protons thus: δ 3.53 (broad s, 2H, NH₂), 6.57 (d, 2H, ortho-H's to NH₂) and 7.21 (d, 2H, ortho-H's to Br).

**Experiment 6.68 p-NITROACETANILIDE and p-NITROANILINE**

\[
\text{Ph-NH-CO-Me} \xrightarrow{\text{HNO}_3, \text{H}_2\text{SO}_4} \text{p-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{NH-CO-Me} \xrightarrow{\text{H}_2\text{O}} \text{p-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2
\]

**Nitration of acetanilide.** Add 25 g (0.185 mol) of finely powdered, dry acetanilide to 25 ml of glacial acetic acid contained in a 500-ml beaker; introduce into the well-stirred mixture 92 g (50 ml) of concentrated sulphuric acid. The mixture becomes warm and a clear solution results. Surround the beaker with a freezing mixture of ice and salt, and stir the solution mechanically. Support a separatory funnel, containing a cold mixture of 15.5 g (11 ml) of concentrated nitric acid and 12.5 g (7 ml) of concentrated sulphuric acid, over the beaker. When the temperature of the solution falls to 0–2 °C, run in the acid mixture gradually while the temperature is maintained below 10 °C. After all the mixed acid has been added, remove the beaker from the freezing mixture, and allow it to stand at room temperature for 1 hour. Pour the reaction mixture on to 250 g of crushed ice (or into 500 ml of cold water), whereby the crude nitroacetanilide is at once precipitated. Allow to stand for 15 minutes, filter with suction on a Buchner funnel, wash it thoroughly with cold water until free from acids (test the wash water) and drain well (1). Recrystallise the pale yellow product from ethanol or industrial spirit, filter at the pump, wash with a little cold alcohol and dry in the air upon filter paper (2). (The yellow o-nitroacetanilide remains in the filtrate.) The yield of p-nitroacetanilide, a colourless crystalline solid of m.p. 214 °C, is 20 g (60%).

Investigate by thin-layer chromatography the effectiveness of the recrystallisation process in the following way. Load a 20 × 5 cm thin-layer plate (Silica Gel G) with approximately 3 mm diameter spots of concentrated solutions (in acetone) of the crude and the recrystallised product. Concentrate a portion of the ethanolic mother-liquor and similarly apply to the plate. Develop the chromatogram with a toluene–ethyl acetate mixture (4:1) and dry the plate. Mark the positions of the visible spots and leave the plate in a tank of iodine vapour to reveal the rest of the components. The recrystallised p-nitroacetanilide (Rₚ 0.07) should be free from the pale yellow o-isomer (Rₚ 0.36); these compounds are revealed by the iodine treatment.
The mother-liquor contains two readily visible yellow components, which are \( p \)-nitroaniline \( (R_F 0.24) \) and \( o \)-nitroaniline \( (R_F 0.45) \), as well as both \( p \)- and \( o \)-nitroacetanilide.

The \( para \)-substitution pattern is confirmed by the p.m.r. spectrum (CDCl\(_3\), TMS) which shows signals at \( \delta 2.48 \) (s, 3H, Me), 7.82 (d, 2H, ortho-H's to \( NH_2 \)), 8.35 (d, 2H, ortho-H's to \( NO_2 \)), and 9.01 (s, 1H, NH). The m.s. shows principal fragment ions at \( m/z \) 180 (M), 138 (M – \( CH_2 CO \), base peak), 92 (138 – \( NO_2 \)), and 65 (92 – HCN).

**Hydrolysis of \( p \)-nitroacetanilide.** Boil a mixture of 15 g (0.083) of \( p \)-nitroacetanilide and 75 ml of 70 per cent w/w sulphuric acid (3) under a reflux condenser for 20–30 minutes or until a test sample remains clear upon dilution with 2–3 times its volume of water. The \( p \)-nitroaniline is now present in the liquid as the sulphate. Pour the clear hot solution into 500 ml of cold water and precipitate the \( p \)-nitroaniline by adding excess of 10 per cent sodium hydroxide solution or of concentrated ammonia solution. When cold (cool the mixture in ice-water, if necessary), filter the yellow crystalline precipitate at the pump, wash it well with water and drain thoroughly. Recrystallise it from a mixture of equal volumes of rectified (or industrial) spirit and water or from hot water. Filter, wash and dry. The yield of \( p \)-nitroaniline, m.p. 148°C, is 11 g (96%).

The p.m.r spectrum (DMSO-\( d_6 \), TMS) shows signals at \( \delta 6.67 \) (broad s, 2H, \( NH_2 \)), 6.79 (d, 2H, ortho-H's to \( NH_2 \)), and 8.09 (d, 2H, ortho-H's to \( NO_2 \)). The m.s. of the three isomers are noted on p. 896.

**Notes.** (1) Washing is accomplished most effectively by transferring the crude solid to a beaker, stirring well with wash water and refiltering.
(2) The recrystallised material and the crude product should be examined by t.l.c. analysis.
(3) The 70 per cent sulphuric acid is prepared by adding 60 ml of concentrated sulphuric acid cautiously and in a thin stream with stirring to 45 ml of water.

### 6.7 FORMATION OF DIAZONIUM SALTS AND THEIR USES

Primary aromatic amines on reaction with nitrous acid in the presence of hydrochloric acid (or other mineral acid) at about 0°C yield diazonium salts as discrete intermediates. The diazonium salts similarly derived from aliphatic primary amines decompose readily even at this temperature to yield the corresponding alcohol (and other products) with the evolution of nitrogen.

\[
Ar\cdot NH_2 + NaNO_2 + 2HCl \rightarrow Ar\cdot N\equiv N\mid Cl + NaCl + H_2O
\]

The acidified nitrite solution provides a source of the nitrosonium ion (1) which electrophilically replaces the hydrogen in the primary amino group to form the \( N \)-nitroso derivative (2). This has a tautomeric structure, the hydroxydiazao form (3) yielding the diazonium ion (4) under acidic conditions.

\[
Ar\cdot NH_2 \overset{@}{\underset{\ominus}{\rightleftarrows}} N=O \xrightarrow{H\ominus} Ar\cdot N-N=O \overset{\ominus}{\underset{H}{\rightleftarrows}} Ar\cdot N=N-OH
\]

(1) \hspace{20pt} (2) \hspace{20pt} (3)
\[
\text{Ar} \cdot \overset{\ominus}{\text{N} \equiv \text{N} - \text{OH}} + \overset{\ominus}{\text{H}} \rightarrow \text{Ar} \cdot \overset{\ominus}{\text{N} \equiv \text{N}} + \text{H}_2\text{O}
\]

\[ (4) \]

The experimental conditions necessary for the preparation of a solution of a diazonium salt, *diazotisation of a primary amine*, are as follows. The amine is dissolved in a suitable volume of water containing 2.5–3 equivalents of hydrochloric acid (or of sulphuric acid) by the application of heat if necessary, and the solution is cooled in ice when the amine hydrochloride (or sulphate) usually crystallises. The temperature is maintained at 0–5 °C and an aqueous solution of sodium nitrite is added portionwise until, after allowing 3–4 minutes for reaction, the solution gives an *immediate* positive test for excess of nitrous acid with an external indicator—moist potassium iodide—starch paper.* The precipitated amine hydrochloride (or sulphate), if any, dissolves during the diazotisation to give a clear solution of the highly soluble diazonium salt. The excess of acid (0.5–1 equivalents) maintains the proper condition of acidity required to stabilise the diazonium salt and hence to minimise secondary reactions, e.g. the interaction of some of the diazonium salt with unchanged amine to form a diazoamino compound, a reaction which occurs readily in neutral solution (see Expt 6.86). The reaction mixture must be kept very cold during the process (which is exothermic in character), otherwise the diazonium salt may be partially hydrolysed to the corresponding phenol (see below).

Some amines, such as the nitroanilines, react rather slowly at low temperatures, but since the diazonium compounds formed are somewhat more stable the diazotisation may be conducted at room temperature, when the reaction proceeds more rapidly. If the amine salt is only sparingly soluble in water, it should be suspended in the acid in a fine state of division (this is generally attained by cooling a hot solution and stirring vigorously), and it passes into solution as the soluble diazonium salt is formed.

A solution of sodium nitrite in concentrated sulphuric acid, which provides a nitrosonium hydrogen sulphate reagent, is a very effective diazotising medium which is particularly valuable for even more weakly basic amines, such as 2,4-dinitroaniline or the corresponding trinitro compound, picramide.

\[
\text{HNO}_2 + \text{H}_2\text{SO}_4 \rightleftharpoons [\text{H}_2\text{NO}_2]^\ominus[\text{HSO}_4]^\ominus \xrightarrow{\text{H}_2\text{SO}_4} [\text{NO}]^\ominus[\text{HSO}_4]^\ominus + \text{H}_2\text{O}^\ominus + \text{HSO}_4^\ominus
\]

This reagent is used here for the diazotisation of 4-amino-3,5-diiodobenzoic acid in the preparation of 3,4,5-triiodobenzoic acid (cognate preparation in Expt 6.70). It is also used for the bis-diazotisation of *m*-phenylenediamine (the

* In actual practice it is found that some time before the theoretical quantity of sodium nitrite has been added, the solution will give a blue coloration (presumably, in part, by atmospheric oxidation) within a few seconds of being placed upon the test paper. It must, however, be remembered that towards the end of the diazotisation the reaction with nitrous acid is somewhat slow, and it is imperative to wait a few minutes before making the test, and furthermore only an immediate blue coloration has any significance. It is advisable to dilute the drop of the test solution with a few drops of water on a watch glass before making the test. It is recommended that about 10 per cent excess of sodium nitrite of good quality (≥96% NaNO₂: e.g. sodium nitrite recryst.) be employed; this will serve as an additional check. If a slight excess of sodium nitrite is accidentally added, it may be decomposed by the addition of a little urea or sulphamic acid; alternatively a small amount of the primary amine, dissolved in the acid used, may be added.

921
To prepare the solid benzenediazonium chloride or sulphate, the reaction is conducted in the absence of water as far as possible. The source of nitrous acid is one of its organic esters (e.g. pentyl nitrite) and a solution of hydrogen chloride gas in absolute ethanol; upon the addition of ether only the diazonium salt is precipitated as a crystalline solid.

\[
\text{Ph-}^\ominus\text{NH}_3 + \text{Pn-O-NO} \xrightleftharpoons{\text{HCl}} \text{Ph-}^\ominus\text{N=N}^\ominus\text{Cl} + \text{PnCl} + 2\text{H}_2\text{O}
\]

Solid diazonium salts are very sensitive to shock when perfectly dry, and detonate violently upon gentle heating: they are, therefore, of little value for preparative work. Happily, most of the useful reactions of diazonium compounds can be carried out with the readily-accessible aqueous solutions, so that the solid (explosive) diazonium salts are rarely required.

**6.7.1 REACTIONS INVOLVING REPLACEMENT OF THE DIAZO GROUP**

Diazonium salts undergo a large number of reactions in which the diazo group is lost as molecular nitrogen and is replaced by a variety of other groups (e.g. OH, I, Br, Cl, F, CN, NO₂, SO₂H, Ar and H) which become attached to the aromatic ring. This section describes the experimental conditions necessary to effect such conversions.

When a solution of a diazonium salt is heated, nitrogen is evolved and the diazo group is replaced by a hydroxyl group in an S_N1 type of displacement reaction.

\[
\text{Ar}^\ominus\text{N=N} \xrightarrow{-N_2} \text{[Ar}^\ominus\text{]} + \text{H}_2\text{O} \xrightarrow{-H} \text{ArOH}
\]

The diazonium sulphate is used in preference to the diazonium chloride, since the presence of chloride ions gives rise to small quantities of the aryl chloride as a by-product. The solution must be acidic in order to avoid the coupling reaction between unreacted diazonium salt and the phenol (see Section 6.7.2, p. 946). For the preparation of phenols and cresols, the aqueous solution of the diazonium compound is warmed to about 50 °C; at higher temperatures the reaction may become unduly vigorous and lead to appreciable quantities of tarry compounds. For certain substituted amines, a higher temperature (e.g. boiling 40–60% sulphuric acid) is necessary to decompose the diazonium salt.
completely (e.g. m-nitrophenol, Expt 6.69). These strongly acidic conditions at elevated temperatures are clearly unsuitable where there are present in the diazonium salt acid-sensitive groups. In such cases the decomposition of the diazonium salt has been found to proceed smoothly at 0 °C in the presence of a copper(II) nitrate–copper(I) oxide reagent.\(^{27}\) As an illustration of this method, the conversion of p-toluidine into p-cresol is given in the cognate preparation of Expt 6.69. The method has been applied successfully to those cases where the diazonium salt undergoes undesirable side reactions, rather than conversion to the phenolic product. An example is provided by the reactions of the 6-nitro-2-methylbenzenediazonium ion:

\[
\begin{align*}
\text{Me} & \quad \text{Me} \\
\text{NO}_2 & \quad \text{NO}_2 \\
\text{N} & \quad \text{N} \\
\text{NO}_2 & \quad \text{NO}_2 \\
\text{N} & \quad \text{N} \\
\end{align*}
\]

When an aqueous solution of an aryl diazonium salt is treated with an equivalent of potassium iodide and warmed on a water bath, the aryl iodide is formed in good yield (e.g. iodo-benzene, Expt 6.70).

\[
\text{Ar}^\oplus\text{N}=\text{N}^\ominus\text{Cl} + \text{KI} \rightarrow \text{ArI} + \text{N}_2 + \text{KCl}
\]

This simple procedure cannot be applied in the preparation of the corresponding chloro and bromo compounds. Sandmeyer (1884) found that the replacement of the diazonium group by halogen can be successfully accomplished in the presence of the appropriate copper(I) salt, thus providing an excellent method for the preparation of nuclear-substituted aromatic compounds from the corresponding amines. The reaction has been extended to groups other than halogens, for example the cyano (—CN) and the thiocyanate (—SCN) group. A general procedure for carrying out the Sandmeyer reaction is as follows. The amine is diazotised in the presence of hydrochloric acid with sodium nitrite at 0–5 °C, and a solution of an equimolecular quantity of copper(I) chloride in hydrochloric acid is added: a deep brown, sparingly soluble complex of copper(I) chloride and the diazonium salt is formed, and when the temperature of the reaction mixture is raised, decomposition ensues accompanied by the evolution of nitrogen, the disappearance of the solid and the separation of an oily layer of the aryl chloride.

\[
\begin{align*}
\text{Ar.NH}_2 & \rightarrow \text{NaNO}_2 \rightarrow \text{HCl} \rightarrow \text{ArN}=\text{N}^\ominus\text{Cl} \rightarrow \text{[Complex]} \rightarrow \text{heat} \rightarrow \text{ArCl} + \text{N}_2
\end{align*}
\]

The aryl chloride is formed when the diazonium–copper(I) chloride complex decomposes by a radical mechanism summarised below. Copper catalyses this decomposition because it can undergo interconversion between the +1 and +2 oxidation states as a result of electron transfer.

\[
\begin{align*}
\text{Ar}^\oplus\text{N}=\text{N}^\ominus\text{Cl} & \rightarrow \text{Ar}^\ominus\text{N}=\text{N}^\oplus\text{Cl} + \text{Cu}^\ominus\text{Cl}
\text{Ar}^\ominus\text{N}=\text{N}^\oplus\text{Cl} + \text{Cu}^\ominus\text{Cl} & \rightarrow \text{Ar}^\ominus + \text{N}_2 + \text{CuCl}_2
\text{Ar}^\ominus\text{Cl} + \text{Cu}^\ominus\text{Cl} & \rightarrow \text{ArCl} + \cdot\text{CuCl}
\end{align*}
\]
Details of the preparation of p-chlorotoluene are given in Expt 6.71, which also includes o-chlorotoluene, chlorobenzene, m-chloronitrobenzene and o-chlorobenzoic acid as examples of cognate preparations.

In the preparation of bromo compounds by the Sandmeyer reaction (e.g. p-bromotoluene and the cognate preparations in Expt 6.72), the amine is generally diazotised in sulphuric acid solution (or in hydrobromic acid solution), and the resulting arylazidonium sulphate (or bromide) is treated with a solution of copper(I) bromide in an excess of hydrobromic acid; the addition complex is then decomposed by gentle heating and the bromo compound isolated by steam distillation. For the preparation of 2-bromonaphthalene the use of 2-naphthylamine (which is a potent carcinogen) as a starting material is avoided by using 2-naphthylamine-1-sulphonic acid (see Section 6.5.4, p. 900). Diazotisation and reaction with copper(I) bromide yields 2-bromonaphthalene-1-sulphonic acid; heating with aqueous sulphuric acid eliminates the sulphonic acid group (see also Expt 6.104) to give 2-bromonaphthalene.

\[
\begin{align*}
\text{SO}_3\text{H} & \quad \text{NaNO}_2 \quad \text{HCl} \quad \text{CuBr/HBr} \\
\text{SO}_3\text{H} \quad \text{N}=\text{N} & \quad \text{Br} \quad \text{H}_2\text{O} \\
\end{align*}
\]

One of the drawbacks of the Sandmeyer reaction is the number of competing side reactions leading to the formation of biaryls, azo compounds and phenols. A recent procedure to maximise the yield of aryl halide involves treatment of the arylamine with t-butyl nitrite and anhydrous copper(II) halide (the chloride or the bromide) in acetonitrile at 65 °C. The method is illustrated by the preparation of p-chloronitrobenzene (Expt 6.73); the overall reaction may be represented as:

\[
2\text{Ar-NH}_2 + 2\text{R-O-NO} + \text{CuX}_2 \rightarrow 2\text{ArX} + 2\text{ROH} + \text{CuO} + \text{H}_2\text{O} + \text{N}_2
\]

Gattermann (1890) found that finely divided (i.e. freshly precipitated) copper or copper bronze acts catalytically in the decomposition of solutions of diazonium salts.

\[
\text{Ar-N}=\text{N} \quad \text{Cu} \quad \rightarrow \quad \text{Ar} + \text{N}_2
\]

The yields in the Gattermann reaction, however (e.g. o-bromotoluene, Expt 6.74), are usually not as high as those obtained by the Sandmeyer method. Copper powder is also employed in the preparation of sulphinic acids (e.g. benzenesulphinic acid, Expt 6.75) which are obtained when a solution of a diazonium sulphate is saturated with sulphur dioxide and decomposed by the addition of copper powder.

\[
\text{Ar-N}=\text{N} \quad \text{HSO}_4 \quad + \quad \text{SO}_2 \quad + \quad \text{Cu} \quad \rightarrow \quad \text{Ar-SO}_2\text{H} + \text{N}_2 + \text{CuSO}_4
\]

The Sandmeyer reaction may also be applied to the preparation of aryl
nitriles. The solution of the diazonium salt, which should preferably be carefully neutralised with sodium or calcium carbonate to avoid excessive evolution of hydrogen cyanide in the subsequent stage, is added to a solution of copper(i) cyanide in excess sodium or potassium cyanide solution (e.g. p-tolunitrile, Expt 6.76); sometimes improved yields are obtained by substituting nickel cyanide for copper(i) cyanide. Hydrolysis of the aryl nitrile with sodium hydroxide solution, followed by acidification, yields the corresponding acid (see Section 6.13.2, p. 1062). The Sandmeyer reaction thus affords an important indirect method of introducing the carboxylic acid group into an aromatic ring.

\[
\text{Ar-NH}_2 \xrightarrow{\text{NaN}_{2}/\text{HCl}} \text{Ar-N}_2^\ominus \xrightarrow{\text{CuCN/KCN}} \text{Ar-CN} \xrightarrow{\text{(i) HO}} \text{Ar-COOH}
\]

The controlled thermal decomposition of dry aryl diazonium fluoroborates to yield an aryl fluoride, boron trifluoride and nitrogen is known as the Balz–Schiemann reaction (Expt 6.77).

\[
\text{Ar-N}=\text{N}^\ominus \text{BF}_4 \xrightarrow{\text{heat}} \text{ArF} + \text{N}_2 + \text{BF}_3
\]

In general the required diazonium fluoroborate is obtained as a precipitate when a concentrated solution of sodium fluoroborate is added to a solution of a diazonium salt. In an alternative procedure (e.g. the preparation of p-fluoroanisole, cognate preparation in Expt 6.77), the amine is diazotised in solution in aqueous fluoroboric acid. The diazonium fluoroborates are less sensitive to shock and heat than most diazonium salts and may be prepared and handled in the dry state with relative safety. Most diazonium fluoroborates have definite decomposition temperatures and the rates of decomposition, with few exceptions, are easily controlled. Diazonium fluoroborates containing the nitro group, however, usually decompose suddenly and with violence on heating; in such cases the fluoroborate should be mixed with 3–4 times its weight of dry sand and heated cautiously until decomposition commences.

The diazonium hexafluorophosphates, prepared similarly from the appropriate diazonium chloride solution and hexafluorophosphoric acid, may in general be used instead of the fluoroborates with advantage. The thermal decomposition of diazonium hexafluorophosphates to aryl fluorides generally proceeds smoothly and in better yield.\textsuperscript{29}

A further interesting application of the diazo reaction is in the preparation of the otherwise difficultly accessible o- and p-dinitrobenzenes (Expt 6.78). The requisite nitroaniline is converted into the diazonium fluoroborate which is then decomposed in aqueous suspension in the presence of sodium nitrite with the aid of copper powder.

It is frequently observed that in the replacement reactions discussed above significant amounts of biphenyl derivatives are present in the reaction product. Compounds of this type may be prepared deliberately by adding the aqueous diazonium salt solution to a liquid aromatic compound and then basifying the vigorously stirred two-phase system by adding sodium hydroxide (or sodium acetate) solution.

\[
\text{Ar}^\ominus \text{N}_2^\ominus \text{X} + \text{Ar}^2\text{H} + \text{HO} \rightarrow \text{Ar}^\ominus \text{Ar}^2 + \text{N}_2 + \text{X}^\ominus + \text{H}_2\text{O}
\]

The reaction (the Gomberg reaction or Gomberg–Bachmann–Hey reaction) probably involves the intermediate formation of the diazohydroxide, which
because it has a largely covalent structure passes substantially into the nonpolar organic phase. In this phase it decomposes into free aryl radicals which displace hydrogen from the added aromatic reactant.

\[
\text{Ar}^1 \overset{\text{N}}{\underset{\text{N}}{\sigma}} \text{Ar}^1 \overset{\text{N}}{\underset{\text{N}}{\sigma}} \overset{\text{OH}}{\longrightarrow} \text{Ar}^1 \underset{\text{N}}{\underset{\text{OH}}{\sigma}} \underset{\text{N}}{\sigma} \overset{\text{N}}{\underset{\text{N}}{\sigma}} \overset{\text{OH}}{\longrightarrow} \text{Ar}^1 \underset{\text{N}}{\underset{\text{OH}}{\sigma}} \underset{\text{N}}{\sigma} \overset{\text{N}}{\underset{\text{N}}{\sigma}} \overset{\text{OH}}{\longrightarrow} \]

\[
\text{Ar}^1 \text{N}=\text{N} \overset{\text{O}}{\sigma} \text{N}=\text{N} \overset{\text{O}}{\longrightarrow} \text{Ar}^1 \text{N}=\text{N} \overset{\text{O}}{\longrightarrow} \text{Ar}^1 \overset{\text{N}}{\underset{\text{N}}{\sigma}} \overset{\text{O}}{\longrightarrow} \text{Ar}^1 \overset{\text{N}}{\underset{\text{O}}{\sigma}} \overset{\text{N}}{\sigma} \overset{\text{N}}{\sigma} \overset{\text{Ar}}{\longrightarrow} \]

\[
\text{Ar}^1 \cdot + \text{Ar}^2 \text{H} \overset{\text{Ar}^1 \text{N}=\text{O}}{\longrightarrow} \text{Ar}^1 - \text{Ar}^2 + \text{Ar}^1 \text{N}_2 \text{OH}
\]

In the example (Expt 6.79) the reaction of the diazonium salt from \(\alpha\)-chloroaniline with benzene to yield 2-chlorobiphenyl is illustrative. It should be noted, however, that when the liquid aromatic compound in which substitution to occur is of the type \(\text{ArZ}\), the directive influences which are used to explain electrophilic substitution processes are not operative. Thus irrespective of the nature of the substituent \(Z\), ortho–para substitution predominates; this result supports the assumption that the substitution process is radical in type. Although the classical reaction occurs in a two-phase system, the use of the more stable diazonium fluoroborates together with the phase-transfer catalyst 18-crown-6 can sometimes be more convenient. The literature method for the preparation of 4-chlorobiphenyl in this way is given as a cognate preparation in Expt 6.79.\(^3\)

The process of deamination involves the replacement of the diazonium group by hydrogen, thus effecting the overall removal of the primary amino group. In a simple procedure illustrated by the preparation of 1,3,5-tribromobenzene from 2,4,6-tribromoaniline (Expt 6.80), the amine is converted into the diazonium sulphate in ethanol solution. Heating the solution brings about the reductive removal of the diazo group, the ethanol being oxidised to acetaldehyde.

\[
\text{Ar}^1 \overset{\text{N}}{\underset{\text{O}}{\sigma}} \text{N}=\text{N} \overset{\text{O}}{\longrightarrow} \text{H} \text{SO}_4 \overset{\text{O}}{\longrightarrow} \text{EtOH} \longrightarrow \text{ArH} + \text{Me} \cdot \text{CHO} + \text{H}_2 \text{SO}_4 + \text{N}_2
\]

The value of the deamination process in synthesis is illustrated by a classical example – the synthesis of \(m\)-bromotoluene, described and formulated in Expt 6.81. The key to the sequence is the bromination of \(p\)-acetotoluidide which occurs at the position ortho to the more strongly electron-releasing acetamido group. This is meta to the methyl group, a position which is virtually unattacked in the direct bromination of toluene. The acetamido group can then be readily removed by sequential hydrolysis, diazotisation and reduction. Other reducing agents may be used in place of ethanol, e.g. an alkaline sodium stannite solution is quite effective; this reagent is prepared by adding sodium hydroxide to an aqueous solution of tin(II) chloride until the initial precipitate just redissolves.

An effective reagent is aqueous hypophosphorus acid, and an example of its use has been described in detail for the synthesis of 3,3′-dimethylbiphenyl from 4,4′-diamino-3,3′-dimethylbiphenyl (o-tolidine).\(^3\) As the latter compound is carcinogenic its preparation is ill-advised. More recently the deamination of diazonium salts with t-butyl nitrite in dimethylformamide has been shown to have wide applicability.\(^3\) The reaction proceeds smoothly at 65 °C with the evolution of nitrogen gas, the volume of which may be measured and used to monitor the reaction. The mechanism of the reaction is thought to involve the following radical sequence in which the solvent (DMF = solH), is the hydrogen donor.

926
The general procedure is quoted in Expt 6.80 (cognate preparations) with reference to the preparation of m-nitrotoluene and 2,5-dichloroaniline.

CAUTION: Diazonium compounds have been used for the preparation of:

(a) Thiophenols – by treatment with a solution of sodium hydrogen sulphide, for example:

\[
\text{Anthranilic acid} \xrightarrow{\text{NaNO}_2, \text{HCl}} \text{Nitrilic acid} \xrightarrow{\text{NaSH}} \text{Thiosalicylic acid}
\]

(b) O-Alkyl-S-aryl dithiocarbonates – by reaction with aqueous potassium O-ethyl dithiocarbonate (see Expt 5.209), and thence to thiophenols by treatment with potassium hydroxide, for example:

\[
\text{C}_6\text{H}_5\text{N}≡\text{N}^-\text{Cl} + \text{C}_2\text{H}_5\text{O}·\text{CS}^-\text{SK} \rightarrow \text{C}_6\text{H}_5\text{S}·\text{CS}·\text{OC}_2\text{H}_5 \rightarrow \text{C}_6\text{H}_5\text{SH}
\]

(c) Disulphides – by interaction with a solution of sodium disulphide.

It cannot be too strongly emphasised that in all these reactions violently explosive diazo sulphides and related compounds may be formed, and another less hazardous method for the preparation of the desired compound should be used, if possible. The following reactions are known to lead to dangerous explosions:

(i) diazotised o-nitroaniline, m-chloroaniline, 5-chloro-2-aminotoluene or 2-naphthylamine and sodium disulphide;
(ii) diazotised m-nitroaniline and potassium O-ethyl dithiocarbonate; and
(iii) diazotised aniline, p-bromoaniline, toluidines and naphthylamines and sodium hydrogen sulphide.

**Experiment 6.69 m-NITROPHENOL**

\[
\text{m-O}_2\text{N}·\text{C}_6\text{H}_4·\text{NH}_2 \xrightarrow{\text{NaNO}_2, \text{H}_2\text{SO}_4} \text{m-O}_2\text{N}·\text{C}_6\text{H}_4·\text{N}≡\text{N}^-\text{HSO}_4 \xrightarrow{\text{H}_2\text{O}, \text{H}_2\text{SO}_4} \text{m-O}_2\text{N}·\text{C}_6\text{H}_4\text{OH}
\]

Add 101 g (55 ml) of concentrated sulphuric acid cautiously to 75 ml of water contained in a 1-litre beaker and introduce 35 g (0.25 mol) of finely powdered m-nitroaniline (Expt 6.51). Add 100–150 g of finely crushed ice and stir until the m-nitroaniline has been converted into the sulphate and a homogeneous paste results. Cool to 0–5 °C by immersion of the beaker in a freezing mixture, stir mechanically and add a cold solution of 18 g (0.26 mol) of sodium nitrite in 40 ml of water over a period of 10 minutes until a permanent colour is immediately given to potassium iodide–starch paper: do not allow the temperature to rise above 5–7 °C during the diazotisation. Continue the stirring for 5–10 minutes and allow to stand for 5 minutes; some m-
nitrobenzenediazonium sulphate may separate. Decant the supernatant liquid from the solid as far as possible.

While the diazotisation is in progress, cautiously add 165 ml of concentrated sulphuric acid to 150 ml of water in a 1-litre round-bottomed flask. Heat the mixture just to boiling. Add the supernatant liquid (diazonium solution) from a separatory funnel supported over the flask at such a rate that the mixture boils very vigorously (about 30 minutes). Then add the residual damp solid (or suspension) in small portions; avoid excessive frothing. When all the diazonium salt has been introduced, boil for a further 5 minutes and pour the mixture into a 1-litre beaker set in ice-water, and stir vigorously to obtain a homogeneous crystal magma. When cold, filter at the pump, drain well and wash with four 20 ml portions of ice-water. Recrystallise by dissolving the crude product in hot dilute hydrochloric acid (1:1 by volume), decant from any residual dark oil, filter and cool to 0 °C, when light yellow crystals separate (1). Spread these upon a large sheet of filter paper, and dry in the air in a warm room. The mother-liquor deposits a further crop (about 2 g) upon standing for 24 hours. The yield of m-nitrophenol, m.p. 96 °C, is 23 g (66%). Record the i.r. and p.m.r. spectra and compare them with those of the ortho and para isomers.

Note. (1) When working with larger quantities of material, it is more convenient (and a better yield is obtained) to purify the air-dried product by distillation under diminished pressure using a short air condenser of wide bore and a few fragments of porous porcelain (or alternatively a pine wood splinter) to prevent bumping. Collect the pure m-nitrophenol at 160–165 °C/12 mmHg; allow the flask to cool before admitting air otherwise the residue may decompose with explosive violence. The recovery is over 90 per cent of the pure m-nitrophenol.

Cognate preparation. p-Cresol. Use of copper ions in the decomposition. 27 p-Toluidine (5.34 g, 50 mmol) is dissolved in 50 ml of hot 35 per cent sulphuric acid and then allowed to cool to below 15 °C. Ice (50 g) is added and the amine bisulphate precipitated. A solution of 4.4 g (64 mmol) of sodium nitrite in 50 ml of ice-water is added dropwise under the surface of the ice-cooled solution with stirring at such a rate as to maintain the temperature at 0–5 °C. After the solution has been stirred for an additional 5 minutes, a few crystals of urea are added to decompose any excess sodium nitrite. To the cold (0 °C) solution of the p-toluenediazonium bisulphate is added a solution of 187 g (775 mol) of copper(II) nitrate trihydrate in 1.75 litres of water. With vigorous stirring 6.63 g (45 mmol) of copper(I) oxide is added to the solution. The liquid becomes dark blue and rapidly changes to green. About 1 minute after the addition of the copper(I) oxide the nitrogen evolution ceases and a negative test with alkaline 2-naphthol indicates that the reaction is complete. The mixture is extracted with ether and the combined ethereal extracts are extracted with aqueous alkali. Acidification of the alkaline extract and re-extraction with ether, followed by drying of the ether extract and evaporation gives p-cresol in 88 per cent yield.

Experiment 6.70 IODOBENZENE

\[ \text{Ph} \cdot \text{NH}_2 + \text{NaNO}_2 \xrightarrow{\text{HCl}} \text{Ph} \cdot \text{N} = \text{N} \text{Cl} \xrightarrow{\text{Kl}} \text{PhI} + \text{N}_2 + \text{KCl} \]

Dissolve 20 g (19.6 ml, 0.125 mol) of aniline in a mixture of 55 ml of
concentrated hydrochloric acid (1) and 55 ml of water contained in a 500-ml round-bottomed flask. Place a thermometer in the solution and immerse the flask in a bath of crushed ice (2); cool until the temperature of the stirred solution falls below 5 °C. Dissolve 16 g (0.23 mol) of sodium nitrite in 75 ml of water and chill the solution by immersion in the ice bath; add the sodium nitrite solution (3) in small volumes (2–3 ml at a time) to the cold aniline hydrochloride solution, and keep the latter well shaken. Heat is evolved by the reaction. The temperature should not be allowed to rise above 10 °C (add a few grams of ice to the reaction mixture if necessary) otherwise appreciable decomposition of the diazonium compound and of nitrous acid will occur. Add the last 5 per cent of the sodium nitrite solution more slowly (say, about 1 ml at a time) and, after shaking for 3–4 minutes, test a drop of the solution diluted with 3–4 drops of water with potassium iodide–starch paper (4); if no immediate blue colour is obtained at the point of contact with the paper, add a further 1 ml of the nitrite solution, and test again after 3–4 minutes. Continue until a slight excess of nitrous acid is present.

To the solution of benzenediazonium chloride add a solution of 36 g (0.216 mol) of potassium iodide in 40 ml of water slowly and with shaking. Nitrogen is evolved. Allow the mixture to stand for a few hours. Fit the flask with an air condenser and heat it cautiously in a boiling water bath until evolution of gas ceases. Allow to cool. Decant as much as possible of the upper aqueous layer and render the residual aqueous and organic layers alkaline by the cautious addition of 10 per cent sodium hydroxide solution, i.e. until a drop of the well-shaken mixture withdrawn on a glass rod imparts a blue colour to red litmus paper. The alkali converts any phenol present into sodium phenoxide, which, unlike phenol itself, is not volatile in steam. Steam distil until no more oily drops pass over (Fig. 2.102). Transfer the distillate to a separatory funnel and run off the lower layer of iodobenzene into a small conical flask. The crude iodobenzene should have a pale yellow colour; if it is dark in colour, return it to the separatory funnel and shake it with a little sodium metabisulphite solution until a pale yellow colour is obtained, then remove the heavy layer as before. Dry with about 1 g of anhydrous calcium chloride or magnesium sulphate: filter through a fluted filter paper into a small distilling flask equipped with a short air condenser. Distil using an air bath (Fig. 2.46) and collect the fraction, b.p. 185–190 °C (5). The yield of iodobenzene (an almost colourless liquid) is 33 g (75%); the compound gradually develops a yellow colour upon exposure to light.

Notes. (1) In computing the volume of acid required in the diazotisation process, it is helpful to remember that 100 ml of concentrated hydrochloric acid, d 1.18, contain 42.4 g of HCl, and 100 ml of concentrated sulphuric acid, d 1.84, contain 176 g H₂SO₄.
(2) For preparations on a larger scale, the lowering of temperature may be conveniently achieved by the addition of a quantity of crushed ice equal in weight to that of the hydrochloric acid and water. The mixture should be stirred mechanically.
(3) It is advisable to add the sodium nitrite solution, particularly in preparations on a larger scale, with the aid of a dropping funnel with the tip of the stem extending well below the surface of the liquid: this will prevent loss of nitrous acid by surface decomposition into oxides of nitrogen.
(4) It is advisable to test the potassium iodide–starch paper with acidified sodium nitrite solution: the commercial test paper is, particularly if it has been kept for a considerable period, sometimes almost useless. The solution must contain an excess of acid at all times, i.e. it must give a blue colour on Congo red paper.
The iodobenzene is conveniently distilled under reduced pressure and the fraction, b.p. 77–80 °C/20 mmHg or 63–64 °C/8 mmHg, collected. The product has a higher degree of purity than that obtained directly from benzene (Expt 6.24).

Cognate preparations. p-Iodotoluene. Use 27 g (0.25 mol) of p-toluidine, 63 ml of concentrated hydrochloric acid and 63 ml of water: warm, if necessary, until all the amine dissolves. Cool the solution with vigorous stirring to 0–5 °C by immersion in a freezing mixture of ice and salt and the addition of a little crushed ice. Diazotise by the introduction, with stirring, of a solution of 18.5 g (0.27 mol) of sodium nitrite in 40 ml of water; maintain the temperature of the solution at 0–5 °C if possible, but do not allow it to rise above 10 °C. Add a solution of 44 g (0.265 mol) of potassium iodide in an equal weight of water gradually and with stirring. Allow to stand for 1 hour at the laboratory temperature and then heat cautiously on a water bath until evolution of nitrogen ceases. Allow to cool: a dark-coloured oil settles to the bottom and soon solidifies. Pour off as much of the aqueous layer as possible, add 1–2 g of sodium metabisulphite to remove the dark colour (gentle warming may be necessary) and then render the mixture alkaline with 10 per cent sodium hydroxide solution in order to retain any cresol which may be formed. Steam distil the mixture; if the p-iodotoluene solidifies in the condenser, turn off the condenser water for a few moments until the solid melts and runs down into the receiver. Filter off the solid in the receiver and recrystallise it from ethanol. The yield of p-iodotoluene (colourless plates), m.p. 35 °C, b.p. 211–212 °C, is 50 g (92%).

p-Iodonitrobenzene. Stir a mixture of 50 g (0.36 mol) of p-nitroaniline (Expt 6.68), 75 g (41 ml) of concentrated sulphuric acid and 300 ml of water for 1 hour. Cool the mixture to 0–5 °C, and diazotise with a solution of 25 g (0.36 mol) of sodium nitrite in 75 ml of water. Filter the cold solution, and add the filtrate with stirring to a solution of 100 g (0.6 mol) of potassium iodide in 300 ml of water. Collect the precipitated solid by suction filtration and recrystallise it from ethanol. The yield of p-iodonitrobenzene, m.p. 171 °C, is 73 g (82%).

p-Iodophenol. Dissolve 54.5 g (0.5 mol) of p-aminophenol (Expt 6.87) in a mixture of 60 g (32.5 ml) of concentrated sulphuric acid, 250 ml of water and 250 g of crushed ice in a large beaker or bolt-head flask. Cool the solution in a freezing mixture, stir mechanically and add during 1 hour a solution of 34.5 g (0.5 mol) of sodium nitrite in 75 ml of water. Stir for a further 20 minutes, and then add 18.5 g (10 mol) of concentrated sulphuric acid. Pour the cold diazonium solution into an ice-cold solution of 100 g (0.6 mol) of potassium iodide in 100 ml of water contained in a beaker provided with a mechanical stirrer. After 5 minutes, add 1 g of copper bronze (which has been washed with ether), with continued stirring, and warm the solution slowly on a water bath. Maintain the temperature at 75–80 °C until the evolution of nitrogen ceases; the iodophenol separates as a dark heavy oil. Cool to room temperature, extract the reaction mixture with three 80 ml portions of dichloromethane, wash the combined extracts with dilute sodium metabisulphite solution or sodium thiosulphate solution and dry with magnesium sulphate. Remove the solvent on a water bath (rotary evaporator) and distil the residue under diminished pressure. Collect the p-iodophenol at 138–140 °C/5 mmHg; this solidifies on cooling. Recrystallise from about 1 litre of
light petroleum (b.p. 80–100 °C). The yield of colourless product, m.p. 94 °C, is 78 g (70%).

**o-Iodobenzoic acid.** Dissolve 14 g (0.1 mol) of anthranilic acid (Expt 6.53) in 100 ml of water containing 14 ml of concentrated sulphuric acid, cool to 5 °C and diazotise by the gradual addition of a cold solution of 7 g (0.101 mol) of sodium nitrite in 25 ml of water to an end-point with starch–iodide paper. Introduce into the clear solution, with stirring, a solution of 26 g (0.156 mol) potassium iodide in 50 ml of 1 m sulphuric acid, heat the mixture to boiling for 10 minutes and then cool. Collect the o-iodobenzoic acid by suction filtration, and recrystallise from hot water. The yield is almost quantitative; m.p. 162 °C.

**3,4,5-Triiodobenzoic acid.** Dissolve 6.8 g (0.0175 mol) of 4-amino-3,5-diiodobenzoic acid (Expt 6.60) in 30 ml of cold concentrated sulphuric acid, add a large excess (3.0 g, 0.0435 mol) of powdered sodium nitrite and allow the mixture to stand at 0 °C for 2 hours. Treat the cold diazonium solution with a solution of 17.0 g (0.12 mol) of potassium iodide in 40 ml of water; a dark red precipitate separates. Warm the mixture on a water bath until evolution of nitrogen ceases, and remove any residual iodine with a little sodium metabisulphite. Filter the yellow precipitate of crude 3,4,5-triiodobenzoic acid, and recrystallise from dilute ethanol. The yield of pure acid, m.p. 289–290 °C, is 6.8 g (78%).

**1,3-Diiodobenzene.** Add 45 g (0.65 mol) of sodium nitrite carefully and with stirring to 470 ml of concentrated sulphuric acid at 70 °C contained in a 2-litre beaker; ensure that the temperature does not exceed 75 °C during the addition. Cool the resulting solution in an ice bath with stirring and add dropwise a solution of 32.4 g (0.3 mol) of m-phenylenediamine (Expt 6.48) in 215 ml of glacial acetic acid; do not allow the temperature to rise above 25 °C. When diazotisation is complete, replace the ice in the cooling bath by an iced–salt mixture, and when the temperature of the tetrazonium salt solution falls below 0 °C (1), run in steadily 500 ml of distilled water with vigorous stirring, keeping the temperature of the solution below 10 °C. Then run the cold diluted solution with rapid stirring into a solution of 100 g (0.6 mol) of potassium iodide in 200 ml of water. The temperature of the reaction mixture rises to about 30 °C; allow it to remain with vigorous stirring for 45 minutes. Finally heat the mixture at 75 °C for 2 hours and leave it at room temperature overnight. Isolate the product by steam distillation; collect about 2 litres of distillate, make it just alkaline with 50 per cent aqueous sodium hydroxide and extract with ether. Remove the ether from the washed, dried extract and crystallise the residual solid from a mixture of ethanol and ether with the aid of decolourising charcoal. A further crystallisation gives almost white crystals of pure 1,3-diiodobenzene, yield 60 g (61%), m.p. 36–37 °C.

**Note.** (1) Excessive cooling may cause the tetrazonium salt to crystallise out and make stirring difficult.

### Experiment 6.71 *p*-CHLOROTOLUENE

\[
\begin{align*}
 p\text{-Me} \cdot C_6H_4 \cdot NH_2 + NaNO_2 \overset{HCl}{\rightarrow} p\text{-Me} \cdot C_6H_4 \cdot N\equiv N \overset{CuCl}{\rightarrow} p\text{-Me} \cdot C_6H_4 Cl
\end{align*}
\]

In a 1.5- or 2-litre round-bottomed flask, prepare copper(i) chloride from
105 g (0.42 mol) of crystallised copper(II) sulphate as detailed in Section 4.2.22, p. 428. Either wash the precipitate once by decantation or filter it at the pump and wash it with water containing a little sulphurous acid; dissolve it in 170 ml of concentrated hydrochloric acid. Stopper the flask loosely (to prevent oxidation) and cool it in an ice–salt mixture whilst the diazotisation is being carried out.

Dissolve 36 g (0.33 mol) of p-toluidine in 85 ml of concentrated hydrochloric acid and 85 ml of water contained in a 750-ml conical flask or beaker. Cool the mixture to 0°C in an ice–salt bath with vigorous stirring or shaking and the addition of a little crushed ice. The salt, p-toluidine hydrochloride, will separate as a finely divided crystalline precipitate. Add during 10–15 minutes a solution of 24 g (0.35 mol) of sodium nitrite in 50 ml of water (1); shake or stir the solution well during the diazotisation, and keep the mixture at a temperature of 0–5°C by the addition of a little crushed ice from time to time. The hydrochloride will dissolve as the very soluble diazonium salt is formed; when all the nitrite solution has been introduced, the solution should contain a trace of free nitrous acid. Test with potassium iodide–starch paper (see footnote, p. 921).

Pour the cold diazonium chloride solution slowly and with shaking into the cold copper(I) chloride solution (2). The mixture becomes very thick, owing to the separation of an addition product between the diazonium salt and the copper(I) chloride (Me·C₆H₄·N⁺⁰Cl⁻·CuCl). Allow the mixture to warm up to room temperature without external heating, and shake occasionally (3). When the temperature reaches about 15°C, the solid addition complex commences to break down with the liberation of nitrogen and the formation of an oily layer of p-chlorotoluene. Warm the mixture on a water bath to about 60°C to complete the decomposition of the double salt; shake occasionally. When the evolution of nitrogen ceases, steam distil the mixture (compare Fig. 2.102) until no more oily drops are present in the distillate. Transfer the distillate to a separatory funnel, and remove the layer of p-chlorotoluene. Wash it successively with 30 ml of 10 per cent sodium hydroxide solution (to remove any p-cresol which may be present), water, an equal volume of concentrated sulphuric acid (to remove a trace of azo compound that usually colours the crude product and cannot be removed by distillation) and water (to remove the acid). Dry with 3–4 g of anhydrous calcium chloride or magnesium sulphate, decant or filter through a small fluted filter paper and distil from an air bath (Fig. 2.46) using an air condenser. Collect the p-chlorotoluene at 158–162°C (a colourless liquid; m.p. 6–7°C); the yield is 33 g (78%).

The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 2.29 (s, 3H, Me), and a four-proton multiplet, that has the appearance of an AB spectrum, in which the difference in the chemical shift (Δν) approaches the value of the coupling constant (see Fig. 3.58); the values for these pairs of protons have been calculated as 6.98 and 7.12. The p.m.r. spectrum of the ortho isomer (cognate preparation below) shows signals at δ 2.37 (s, 3H, Me; note the more significant deshielding influence of the ortho chlorine in this case), and 6.9–7.4 (m, 4H, C₆H₋₄—H). The m.s. of the two isomers are similar with variations in RA of particular fragment ions: for the para isomer the values of m/z are 128 (M, ³⁷Cl), 126 (M, ³⁵Cl), 127 and 125 (M – H), 91 (M – ³⁷Cl or ³⁵Cl, base peak).
Notes. (1) The sodium nitrite solution is conveniently added from a dropping funnel; it is recommended, particularly for preparations on a larger scale, that the tip of the stem of the funnel dip well below the surface of the liquid.
(2) The diazonium salt solution decomposes on standing and hence must be mixed with the copper(i) chloride solution without delay. Mechanical stirring is an advantage.
(3) For preparations on a larger scale, mechanical stirring is essential and should be continued for 2–3 hours after the solution has attained room temperature.

Cognate preparations. o-Chlorotoluene. Proceed as for p-chlorotoluene, but use 36 g of o-toluidine. Collect the o-chlorotoluene at 155–158 °C; the yield is 33 g.

m-Chloronitrobenzene. This preparation is very similar to that of p-chlorotoluene, but certain modifications must be introduced. The quantities required are: 46 g (0.35 mol) of m-nitroaniline (Expt 6.51), 85 ml of concentrated hydrochloric acid, 85 ml of water, a solution of 24 g (0.35 mol) of sodium nitrite in 50 ml of water (if the resulting diazonium salt solution is not clear, it must be filtered), and copper(i) chloride from 105 g (0.42 mol) of crystallised copper(II) sulphate (Section 4.2.22, p. 428), dissolved in 170 ml of concentrated hydrochloric acid. Run the diazonium salt solution into the solution of copper(i) chloride while the temperature is kept at 25–30 °C (water bath); at lower temperatures the decomposition of the unstable addition compound proceeds too slowly and would cause too violent an evolution of nitrogen upon warming, and at a higher temperature the formation of tarry by-products increases. Warm the mixture under a reflux condenser on a water bath until the evolution of nitrogen ceases. Steam distil (1); if the m-chloronitrobenzene solidifies in the condenser, turn off the condenser water for a few moments until the solid melts and runs down into the receiver. Allow the steam distillate to cool, decant the water and shake the solid with 200 ml of 1 per cent sodium hydroxide solution at 50 °C (to remove m-nitrophenol, if present). Allow the mixture to cool, filter with suction, wash with a little cold water and dry in the air. Determine the m.p. If this is not satisfactory, i.e. if it is appreciably below 44–45 °C, purify the product either by recrystallisation from a small volume of ethanol or preferably by distillation under diminished pressure and collect the fraction of b.p. 124–125 °C/18 mmHg or 116–117 °C/12 mmHg; the distillate solidifies to a pale yellow solid, m.p. 44–45 °C. The yield is 35 g (67%), depending upon the purity of the original m-nitroaniline.

Note. (1) The steam distillation may be omitted, if desired, by utilising the following method of purification. Allow the reaction mixture to cool, decant the aqueous layer and dissolve the residue in about 150 ml of toluene. Wash the toluene solution with water, 1 per cent sodium hydroxide solution and finally with water; dry with magnesium sulphate, distil off the toluene on a water bath (rotary evaporator) and distil the residue under diminished pressure.

o-Chlorobenzoic acid. Dissolve 14 g (0.1 mol) of anthranilic acid (Expt 6.53) in a solution of 20 ml of concentrated hydrochloric acid and 100 ml of water. Cool to about 5 °C, and diazotise by the gradual addition of a cold solution of 7 g (0.1 mol) of sodium nitrite in 25 ml of water to an end-point with starch–potassium iodide paper (see footnote, p. 921). In the meantime prepare a solution of copper(I) chloride as follows. Dissolve 26 g (0.104 mol) of
crystallised copper(ii) sulphate and 12 g of sodium chloride in 50 ml of water in a 750-ml round-bottomed flask. Heat the solution to boiling, then add 80 ml of concentrated hydrochloric acid and 14 g of copper turnings, and continue the heating under reflux until the solution is practically colourless. (Alternatively, prepare the copper(i) chloride by the method given in Section 4.2.22, p. 428.) Cool in ice, and then add the cold diazonium solution slowly and with shaking. The reaction proceeds rapidly and with frothing: allow the mixture to stand for 2–3 hours with frequent shaking. Filter the precipitated o-chlorobenzoic acid and wash it with a little cold water. Recrystallise the crude acid from hot water containing a little alcohol to which a little decolourising carbon has been added. The yield of pure o-chlorobenzoic acid, m.p. 138–139°C, is 14 g (87%).

Experiment 6.72 p-BROMOTOLUENE

\[
p\text{-Me} \cdot C_6 H_4 \cdot NH_2 + \text{NaNO}_2 \xrightarrow{H_2 SO}_4 p\text{-Me} \cdot C_6 H_4 \cdot N=\text{N} \rightarrow \text{HSO}_4 + \text{CuBr} \rightarrow p\text{-Me} \cdot C_6 H_4 Br
\]

Prepare a solution of copper(i) bromide in a 2.5-litre two-necked flask by heating under reflux 31.5 g (0.124 mol) of copper(ii) sulphate pentahydrate, 10 g (0.158 mol) of copper turnings, 77 g (0.55 mol) of crystallised sodium bromide, 15 g (8.2 ml) of concentrated sulphuric acid as described in Section 4.2.21, p. 428.

In a 1-litre flask mix 53.5 g (0.5 mol) of p-toluidine and 400 ml of water, and then add cautiously 98 g (53.5 ml) of concentrated sulphuric acid; warm until the p-toluidine dissolves. Cool the flask in a bath of ice and salt to 0–5 °C; add about 100 g of crushed ice to the contents of the flask in order to accelerate the cooling. Add slowly and with frequent shaking a solution of 35 g (0.5 mol) of sodium nitrite in 60 ml of water until a slight excess of sodium nitrite is present (see footnote, p. 921); keep the temperature of the mixture below 10 °C.

Equip the 2.5-litre two-necked flask containing the copper(i) bromide solution for steam distillation (compare Fig. 2.102) and insert into the side-neck a tube (7–8 mm in diameter) leading almost to the bottom of the flask via a screw-capped adapter; attach a short-stemmed separatory funnel to this tube by means of a short length of rubber tubing and support the funnel in a ring clamped to a retort stand. Heat the copper(i) bromide solution to boiling, add the toluene-p-diazonium sulphate solution from the separatory funnel while steam is passed rapidly through the mixture. In order to reduce the amount of decomposition of the diazonium salt solution, transfer only about one-fourth to the separatory funnel (the remainder being kept in the freezing mixture) and run this into the copper(i) bromide solution: when the funnel is nearly empty, transfer a further portion of the cold diazonium solution to it without interrupting the addition. Add all the diazonium solution in this way during 20–30 minutes. Continue the steam distillation until no more organic matter distils. Render the distillate alkaline with 20 per cent sodium hydroxide solution (to remove any p-cresol present), shake well and separate the crude p-bromotoluene. In order to obtain a colourless product, wash the crude substance with 40–50 ml of warm (30 °C) concentrated sulphuric acid, then with water, sodium hydroxide solution, and finally with water. If the p-bromotoluene solidifies, warm the wash liquids to 30 °C.
before use; unless this is done, considerable loss may occur. Dry over magnesium sulphate or anhydrous calcium chloride, warm, filter and distil through an air-cooled condenser. Collect the \( p \)-bromotoluene at 182–184°C. The yield is 60 g (70\%); m.p. 25–26°C.

The para-substitution pattern is clearly confirmed by the p.m.r. spectrum (CDCl\(_3\), TMS) which shows signals at \( \delta \) 2.25 (s, 3H, Me), 6.92 (d, 2H, ortho-H's to Me), and 7.30 (d, 2H, ortho-H's to Br). The ortho and meta isomers show multiplets in the aromatic proton region. All the isomers show absorption in the 650–830 cm\(^{-1}\) region of their i.r. spectra (thin film); i.e. at c. 810 cm\(^{-1}\) for the para isomer (2 adj. H's), at c. 750 cm\(^{-1}\) for the ortho isomer (5 adj. H's), and at c. 770 cm\(^{-1}\) (3 adj. H's) and at 830 cm\(^{-1}\) (1H) for the meta isomer. The m.s. of the isomers are noted in Expt 6.81.

Cognate preparations. \( o \)-Bromotoluene. Use 53.5 g of \( o \)-toluidine and other components as above. The yield of \( o \)-bromotoluene, b.p. 178–181°C, is of the same order.

\( o \)-Bromochlorobenzene. Place a mixture of 64 g (0.5 mol) of \( o \)-chloroaniline and 175 ml of constant boiling point hydrobromic acid (d 1.48; 100 ml contains 71 g of HBr) in a 1-litre flask set in an ice–salt bath, and cool it to 0–5°C by the addition of a little ice. Add, with shaking or stirring, a solution of 35 g (0.5 mol) of sodium nitrite in 70 ml of water until a slight excess of nitrous acid is present (starch–potassium iodide paper test; see footnote, p. 921); maintain the temperature below 10°C by the addition of ice if necessary.

Prepare copper(II) bromide from 75 g (0.33 mol) of crystallised copper(II) sulphate as detailed in Section 4.2.21, p. 428, and dissolve it in 40 ml of 48 per cent hydrobromic acid; heat the solution to boiling and add \( o \)-chlorobenzene-diazonium bromide solution as detailed above. When all the latter has been introduced, continue to pass steam through the mixture until no more organic material distils. Follow the procedure, including purification, given for \( p \)-bromotoluene. Collect the \( o \)-bromochlorobenzene (a colourless liquid) at 200–202°C. The yield is 85 g (89\%).

This procedure may also be employed for \( m \)-bromochlorobenzene, b.p. 191–194°C, from \( m \)-chloroaniline; \( m \)-dibromobenzene, b.p. 215–217°C, from \( m \)-bromoaniline; and \( o \)-bromoanisole, b.p. 114–116°C/29 mmHg, from \( o \)-anisidine (the sulphuric acid washing is omitted in the last example).

2-Bromonaphthalene. Dissolve 112 g (0.5 mol) of 2-naphthylamine-1-sulphonic acid (1), with stirring, in 850 ml of 0.6 M sodium hydroxide solution: add, with stirring, an aqueous solution of 35 g (0.5 mol) of sodium nitrite, and filter the resulting solution. Place 250 ml of concentrated hydrochloric acid and 100 g of crushed ice in a 2-litre beaker, and equip the latter with a mechanical stirrer. Introduce the filtered solution of sodium nitrite and sodium 2-naphthylamine-1-sulphonate (2) slowly with stirring, and maintain the temperature at 0–5°C by adding crushed ice. Collect the reddish-brown precipitate which forms on a large Buchner funnel and wash it with about 500 ml of ice-water. While the diazotisation is in progress, suspend 160 g (1.1 mol) of copper(II) bromide (from 300 g of crystallised copper(II) sulphate; Section 4.2.21, p. 428) in 75 ml of 48 per cent hydrobromic acid and 200 ml of water. Add the damp cake of the diazonium compound portionwise and with vigorous stirring to the copper(II) bromide suspension contained in a 2-litre
beaker. After the vigorous evolution of nitrogen has subsided heat the mixture to 95–100 °C on a steam bath and then filter the hot mixture through a large Buchner funnel. Pour the filtrate back into the beaker and add 112 g of potassium chloride with stirring. Allow the resulting paste to cool to room temperature, filter with suction and wash with 250 ml of 20 per cent aqueous potassium chloride. Dry the reddish-brown precipitate of 2-bromonaphthalene-1-sulphonic acid in the air overnight, and transfer it to a 2-litre round-bottomed flask. Add dilute sulphuric acid (prepared from 200 ml of the concentrated acid and 200 g of crushed ice), attach a reflux condenser and reflux the mixture gently, using an electric heating mantle, for 12–16 hours. Cool to room temperature; pour on to about 500 g of crushed ice. Transfer the mixture with the aid of 500 ml of toluene to a large separatory funnel, shake well, remove the toluene layer and wash the latter with water until the washings are neutral to litmus. Dry the toluene solution with magnesium sulphate, remove the toluene using a rotary evaporator and distil the residue under reduced pressure. Collect the bromonaphthalene at 100–101 °C/2 mmHg or at 140 °C/20 mmHg; this solidifies to a pale yellow solid, m.p. 56–57 °C. The yield is 67 g (65%).

The pale yellow colour cannot be removed by redistillation or recrystallisation; the coloured product probably contains some amino compound rendering it unsuitable for conversion into a Grignard reagent. A pure white product may be obtained by the following procedure. Dissolve 50 g of the coloured compound in 200 ml of hexane and pass the solution through a column of activated alumina (80–200 mesh; dimensions about 9 cm × 3 cm); wash the column with 750 ml of hexane. Remove the hexane by distillation: 49 g of pure 2-bromonaphthalene, m.p. 58 °C, remains. This is sufficiently pure for use in Grignard reactions.

Notes. (1) Tobias acid, available from Fluka AG Chemische Fabrik; see Section 6.5.4, p. 900. (2) If the solid sodium salt is available, 123 g may be dissolved in 850 ml of distilled water and a solution containing 35 g of sodium nitrite added.

**Experiment 6.73 p-CHLORONITROBENZENE**

\[
2p-O_2N\cdot C_6H_4\cdot NH_2 + 2Bu^t-O\cdot NO + \text{CuCl}_2 \rightarrow 2p-O_2N\cdot C_6H_4Cl + \text{Bu}^t\text{OH} + \text{CuO} + \text{H}_2\text{O} + 2\text{N}_2
\]

Anhydrous copper(II) chloride (1.62, 12 mmol) (1), t-butyl nitrite (1.55 g, 15 mmol) (2), and anhydrous acetonitrile (40 ml) (3) are added to a three-necked round-bottomed flask equipped with a reflux condenser, an addition funnel and a gas outlet tube. The resulting, rapidly stirred (magnetic stirrer) mixture is warmed to 65 °C. p-Nitroaniline (1.38 g, 10 mmol) in 2 ml of acetonitrile is slowly added over a period of 5 minutes to the reaction solution. During this addition the reaction solution turns completely black from an initial green colour as nitrogen is evolved (4). After gas evolution is complete the reaction is allowed to reach room temperature; the reaction solution is then poured into 200 ml of 20 per cent aqueous hydrochloric acid and extracted with 200 ml of ether. The organic layer is washed once with 200 ml of 20 per cent aqueous hydrochloric acid. The resulting ether solution is dried over magnesium sulphate and the ether removed under reduced
pressure. Recrystallisation from ethanol gives 1.43 g (92%) of p-chloronitrobenzene, m.p. 82 °C. The p.m.r. (CDCl₃, TMS) should be recorded and interpreted.

Notes. (1) Copper(ii) chloride is dried at 110 °C prior to use.
(2) t-Butyl nitrite is prepared from t-butyl alcohol by the method given for butyl nitrite (Section 4.2.1, p. 414).
(3) Reagent grade acetonitrile is distilled from calcium hydride prior to its use.
(4) Total gas evolution (at 65 °C complete generally within 10 minutes) is measured on the closed system by water displacement from a calibrated gas burette; the yield of gaseous products in this reaction is 220 ± 20 ml.

Experiment 6.74 *o*-BROMOTOLUENE

\[ \text{o-Me} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2 \xrightarrow{\text{NaNO}_2, \text{HBr}} \text{o-Me} \cdot \text{C}_6\text{H}_4 \cdot \text{N}^\ominus \text{N}^\ominus \xrightarrow{\text{Cu}} \text{o-Me} \cdot \text{C}_6\text{H}_4\text{Br} \]

In a 1- or 1.5-litre round-bottomed flask prepare a solution of 53.5 g (0.5 mol) of *o*-toluidine in 170 ml of 40 per cent w/w hydrobromic acid; cool to 5 °C by immersion in a bath of ice and salt. Diazotise by the gradual addition of a solution of 36.5 g (0.53 mol) of sodium nitrite in 50 ml of water; stopper the flask after each addition and shake until all red fumes are absorbed. Keep the temperature between 5 and 10 °C. When the diazotisation is complete, add 2 g of copper powder or copper bronze (Section 4.2.19, p. 426), attach a reflux condenser to the flask and heat very cautiously on a water bath. *Immediately* evolution of gas occurs, cool the flask in crushed ice; unless the flask is rapidly removed from the water bath, the reaction may become so violent that the contents may be shot out of the flask. When the vigorous evolution of nitrogen moderates, heat the flask on a water bath for 30 minutes. Then dilute with 400 ml of water, and steam distil the mixture until about 750 ml of distillate are collected. Render the distillate alkaline with 10 per cent sodium hydroxide solution (about 50 ml) and separate the lower red layer of crude *o*-bromotoluene. Wash it with two 20 ml portions of concentrated sulphuric acid (which removes most of the colour) and then twice with water. Dry with magnesium sulphate or anhydrous calcium chloride, and distil from a flask fitted with a lagged fractionating column. Collect the *o*-bromotoluene at 178–181 °C. The yield is 40 g (47%). The spectral features are noted in Expts 6.72 and 6.81.

Experiment 6.75 BENZENESULPHINIC ACID

\[ \text{Ph} \cdot \text{NH}_2 \xrightarrow{\text{NaNO}_2, \text{H}_2\text{SO}_4} \text{Ph} \cdot \text{N}^\ominus \text{N}^\ominus \text{HSO}_4^\ominus \xrightarrow{\text{SO}_2, \text{Cu}} \text{Ph} \cdot \text{SO}_2\text{H} \]

Dissolve 9.3 g (9.1 ml, 0.1 mol) of aniline in a mixture of 19.6 g (10.7 ml) of concentrated sulphuric acid and 100 ml of water, and cool to about 5 °C. Diazotise by the addition of a solution of 7.0 g (0.1 mol) of sodium nitrite in 15 ml of water to an end-point with potassium iodide–starch paper; maintain the temperature below 10 °C. Add an ice-cold mixture of 40 g (22 ml) of concentrated sulphuric acid and 30 ml of water, cool in ice and pass sulphur dioxide into the solution until there is no further increase in weight (about 25 g). The solution should not develop any appreciable colour during this operation and should remain quite clear. When the solution is saturated with
sulphur dioxide, transfer it to a beaker provided with a mechanical stirrer, and add copper powder (Section 4.2.19, p. 426) or copper bronze (previously washed with ether) gradually until no more nitrogen is evolved (about 50 g of copper powder are required). Filter at the pump and wash the precipitate with several small amounts of dilute ammonia solution to remove any sulphinic acid which may have separated: add the washings to the filtrate. The combined filtrate and washings should be acid to Congo red paper. Treat it with concentrated iron(III) chloride solution as long as any precipitate forms. Filter the precipitate of iron(III) benzenesulphonate, and wash it with a little water. Decompose the iron(III) salt with a slight excess of 5 per cent sodium hydroxide solution, and filter the precipitated iron(III) hydroxide. Acidify the filtrate and extract the sulphonic acid with ether. Upon evaporation of the solvent, pure benzenesulphonlic acid, m.p. 84°C, is obtained as a colourless crystalline solid. The yield is 10 g (70%). It oxidises in the air.

Experiment 6.76 p-TOLUNITRILE (p-Tolyl Cyanide)

\[ p\text{-Me}\cdot C_6\text{H}_4\cdot \text{NH}_2 + \text{HCl} \rightarrow p\text{-Me}\cdot C_6\text{H}_4\cdot \text{N}^{\ominus} \text{N}^{\ominus} + \text{Cl}^{\ominus} \]

CAUTION: This and related cognate preparations must be carried out in an efficient fume cupboard.

Prepare copper(i) cyanide from 100 g (0.4 mol) of hydrated copper(ii) sulphate following the procedure described in Section 4.2.23, p. 429, transfer the product to a 1-litre round-bottomed flask and dissolve it in a solution of 52 g of potassium cyanide in 125 ml of water (CAUTION). Diazotise 36 g (0.33 mol) of p-toluidine, following the method given under p-chlorotoluene (Section 6.71). While keeping the solution cold, carefully add about 20 g of powdered anhydrous sodium carbonate with constant stirring until the solution is neutral to litmus. Warm the copper(i) cyanide solution on a water bath to about 60°C, and add the cold neutralised diazonium salt solution in small quantities at a time, shaking vigorously (1) after each addition and taking care to maintain the temperature of the mixture at 60-70°C. Attach a reflux condenser to the flask and heat on a boiling water bath for 15-20 minutes in order to complete the reaction. Equip the flask for steam distillation (Fig. 2.102), and pass steam into the mixture until no more yellow oil passes over; if the oil solidifies in the condenser tube, turn off the condenser water, and, after the material melts and flows through, slowly turn on the water again. Cool the distillate in ice-water, and when the crude p-tolunitrile has solidified, filter it at the pump and press well to remove liquid impurities. Dry upon filter paper or in a desiccator. Mix the dried product with 2-3 g of decolourising carbon, transfer to a small distilling flask and distil using an air condenser. Collect the pure p-tolunitrile at 215-219°C (2); this solidifies on cooling and melts at 29°C. The yield is 26 g (67%).

The para-substitution pattern is confirmed by the i.r. and p.m.r. spectra. Thus in the i.r. spectrum (melt) absorption may be observed at c. 2200 (CN) and 820 cm\(^{-1}\) (2 adj. H's) together with the characteristic absorption from the methyl group and the aromatic ring. The p.m.r. spectrum (CDCl\(_3\), TMS) shows signals at \(\delta\) 2.41 (s, 3H, Me), 7.23 (d, 2H, ortho-H's to Me), and 7.47 (d,
2H, ortho-H's to CN). These spectra should be compared to those obtained with o-tolunitrile (cognate preparation below).

**Notes.** (1) Mechanical stirring is preferable.
(2) The crude substance may also be distilled under diminished pressure and the p-tolunitrile collected at 104–106 °C/20 mmHg.

**Cognate preparation. o-Tolunitrile.** The preparation is similar to that described for p-tolunitrile except that p-toluidine is replaced by o-toluidine. The o-tolunitrile is isolated by steam distillation; the oil, which may be dissolved in a little toluene, is distilled. The o-tolunitrile passes over as an almost colourless liquid at 94–96 °C/20 mmHg. Note the i.r. absorption (thin film) at c. 2200 (CN) and 760 cm⁻¹ (4 adj. H's) together with the expected aromatic ring and methyl group absorptions. The p.m.r. spectrum (CDCl₃, TMS) has δ 2.51 (s, 3H, Me), and 7.02–7.66 (m, 4H, C₆H₅—H).

**Experiment 6.77 FLUOROBENZENE**

\[
\text{Ph} \cdot \text{NH}_2 \xrightarrow{\text{HCl}} \text{Ph} \cdot \text{N} = \text{N} \xrightarrow{\text{NaBF}_4} \text{Ph} \cdot \text{N} = \text{N} \xrightarrow{\Delta} \text{PhF}
\]

**CAUTION:** *This preparation should be carried out in an efficient fume cupboard and behind a suitable safety screen.*

Dissolve 46.5 g (45.5 ml, 0.5 ml) of aniline in a mixture of 126 ml of concentrated hydrochloric acid and 126 ml of water contained in a 1-litre beaker. Cool to 0–5 °C in a bath of ice and salt, and add a solution of 36.5 g (0.53 mol) of sodium nitrite in 75 ml of water in small portions; stir vigorously with a thermometer and maintain the temperature below 10 °C, but preferably at about 5 °C by the addition of a little crushed ice if necessary. The diazotisation is complete when a drop of the solution diluted with 3–4 drops of water gives an immediate blue coloration with potassium iodide-starch paper; the test should be performed 3–4 minutes after the last addition of the nitrite solution. Prepare a solution of 76 g (0.69 mol) of sodium fluoroborate (1) in 150 ml of water, cool and add the chilled solution slowly to the diazonium salt solution; the latter must be kept well stirred and the temperature controlled so that it is below 10 °C. Allow to stand for 10 minutes with frequent stirring. Filter the precipitated benzenediazonium fluoroborate with suction on a Buchner funnel, drain well and wash the yellow solid with about 30 ml of ice-water, 15 ml of methanol and 30–40 ml of ether; suck the solid as free as possible from liquid after each washing (2). Spread the salt upon absorbent filter paper and allow to dry overnight, if possible in a current of air. The yield of benzenediazonium fluoroborate is 60–65 g; the pure salt melts with decomposition at 119–120 °C.

Assemble the apparatus shown in Fig. 6.3; this is self-explanatory. The distilling flask has a capacity of 250 ml and the beaker contains 150 ml of 10 per cent sodium hydroxide solution. Place half of the yield of the dry benzenediazonium fluoroborate in the distilling flask. Heat the solid gently with a small luminous flame at one point near its surface until decomposition begins; withdraw the flame and allow the reaction to continue as long as it will (3). Continue the cautious heating from time to time as may be necessary to keep the reaction going. When the decomposition appears to be complete, heat the flask more strongly to drive off any remaining fluorobenzene. Allow
to cool, add the other half of the benzenediazonium fluoroborate through a glazed paper funnel and decompose it as before; finally heat the flask strongly until no more fumes of boron trifluoride are evolved in order to drive off the last traces of fluorobenzene. Most of the fluorobenzene collects in the first, cooled, receiver. Wash the combined distillates three times with an equal volume of 10 per cent sodium hydroxide solution (4) or until the washings are almost colourless; this will remove any phenol present. Remove the last sodium hydroxide washing as completely as possible, and then shake with an equal volume of almost saturated salt solution. Dry over anhydrous calcium chloride or magnesium sulphate, and distil the fluorobenzene (a colourless liquid) at 84–85 °C. The yield is 24 g (50%).

Notes. (1) The use of sodium fluoroborate solution supersedes the less convenient fluoroboric acid and permits the preparation to be carried out in ordinary glass vessels. If it is desired to employ fluoroboric acid HBF₄, it can be prepared by adding 100 g of AR boric acid in small proportions to 325 g of AR hydrofluoric acid (40% HF) cooled in ice; the hydrofluoric acid is contained in a polypropylene beaker, in a beaker coated with wax or in a lead vessel. One-third of the above solution should be employed in the preparation. Handle with great care.

Note on precautions to be adopted when using hydrofluoric acid. Attention is directed to the fact that hydrofluoric acid in contact with the skin produces extremely painful burns. In case of accident, the burned surface, which becomes white, is held under running water until the natural colour returns. A paste made from magnesium oxide and glycerine should be applied immediately; this is said to be helpful in preventing the burn becoming serious. It is advisable to wear acid-resisting rubber gloves and protective goggles.

(2) Careful washing with methanol and ether is necessary to remove from the crude product any moisture which tends to make the material unstable and liable to spontaneous decomposition.

(3) If the reaction becomes too vigorous, it may be necessary to cool the flask by covering it with a damp cloth. Normally the decomposition proceeds smoothly under the intermittent heating. If the salt is damp, the reaction may proceed more vigorously and unless the flask is cooled, it may pass beyond control.

(4) The density of fluorobenzene is about 1.025 at room temperature; it is important to use the correct strength of sodium hydroxide solution in order to obtain a clear separation of the layers.

Cognate preparations. p-Fluorotoluene. Diazotise 53.5 g (0.5 mol) of p-toluidine in a mixture of 126 ml of concentrated hydrochloric acid and 126 ml of water contained in a 1-litre beaker following the procedure given in Expt 6.71. Add a chilled solution of 76 g (0.69 mol) of sodium fluoroborate in 150 ml of water slowly and with good stirring to the cold diazonium salt
solution. Continue stirring for about 15 minutes. Filter the toluene-p-diazonium fluoroborate on a Buchner or sintered glass funnel, wash with about 30 ml of ice-water, 15 ml of methanol and 30–40 ml of ether. Dry overnight upon absorbent paper in a vacuum desiccator or, if possible, in a current of air. The yield of toluene-p-diazonium fluoroborate is 78 g (76%); it melts with decomposition at 114°C. Decompose the salt in two equal lots, and work up as for fluorobenzene. The yield of pure p-fluorotoluene (a colourless liquid), b.p. 116-117°C, is 27 g (50%).

**p-Fluoroanisole.** To 105 ml (2 mol) of c. 42 per cent fluoroboric acid (CAUTION: corrosive chemical) diluted with an equal volume of water, contained in a 600 ml beaker, add 31 g (0.25 mol) of p-anisidine. Place the beaker in an ice bath and stir the solution mechanically. Add a solution of 17.5 g (0.25 mol) of sodium nitrite in 35 ml of water slowly and maintain the temperature at about 10°C. Stir the solution vigorously towards the end of the reaction, cool the mixture to 0°C and filter with suction on a sintered glass funnel. Wash the precipitate successively with 30–40 ml of cold 5 per cent fluoroboric acid, 40 ml of ice-cold methanol and several times with ether. Dry overnight by spreading the salt thinly on absorbent paper supported upon a screen or wire netting allowing circulation underneath. The yield of p-methoxybenzenediazonium fluoroborate is 54 g (98%). Decompose the dry salt as detailed for fluorobenzene. Return the small amount of product in the receiver to the distilling flask and steam distil. Extract the steam distillate with two 50 ml portions of ether, wash the ethereal solution with 50 ml of 10 per cent sodium hydroxide solution, followed by water and dry over magnesium sulphate. Remove the ether on a steam bath and distil the residue. Collect the p-fluoroanisole at 156–157°C. The yield is 16 g (51%).

**Experiment 6.78 o-DINITROBENZENETH**

\[
\text{O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2 + \text{HCl} \xrightarrow{\text{NaNO}_2} \text{O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{N} = \text{N} \cdot \text{Cl} + \text{H}_2\text{O} \\
\text{NaBF}_4 \\
\text{O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{N} = \text{N} \cdot \text{Cl} + \text{H}_2\text{O} \xrightarrow{\text{NaNO}_2} \text{O}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{N} = \text{N} \cdot \text{BF}_4 + \text{H}_2\text{O}
\]

**CAUTION:** This preparation should be carried out behind a safety screen.

Dissolve 34 g (0.25 mol) of o-nitroaniline in a warm mixture of 63 ml of concentrated hydrochloric acid and 63 ml of water contained in a 600-ml beaker. Place the beaker in an ice–salt bath, and cool to 0–5°C while stirring mechanically; the o-nitroaniline hydrochloride will separate in a finely divided crystalline form. Add a cold solution of 18 g (0.26 mol) of sodium nitrite in 40 ml of water slowly and with stirring to an end-point with potassium iodide–starch paper; do not allow the temperature to rise above 5–7°C. Introduce, while stirring vigorously, a solution of 40 g (0.36 mol) of sodium fluoroborate in 80 ml of water. Stir for a further 10 minutes, and filter the solid diazonium fluoroborate with suction on a Buchner funnel. Wash it immediately once with 25 ml of cold 5 per cent sodium fluoroborate solution, then twice with 15 ml portions of rectified (or industrial) spirit and several times with ether; in each washing stir the fluoroborate well before applying suction. The o-nitrobenzenediazonium fluoroborate weighs about 50 g (86%); the pure substance melts with decomposition at 135°C.

Dissolve 200 g (2.9 mol) of sodium nitrite in 400 ml of water in a 2-litre
beaker provided with an efficient mechanical stirrer, and add 40 g of copper powder (either the precipitated powder or copper bronze which has been washed with a little ether). Suspend the fluoroborate in about 200 ml of water and add it slowly to the well-stirred mixture. Add 4–5 ml of ether from time to time to break the froth. The reaction is complete when all the diazonium compound has been added. Transfer the mixture to a large flask and steam distil until no more solid passes over (about 5 litres of distillate). Filter off the crystalline solid in the steam distillate and dry upon filter paper in the air; this o-dinitrobenzene (very pale yellow crystals) has m.p. 116 °C (i.e. is practically pure) and weighs 29 g (69%). It may be recrystallised from ethanol; the recrystallised solid melts at 116.5 °C.

The p.m.r. spectrum (DMSO-$d_6$, TMS) has ν 8.08 and 8.26 (A$_2$B$_2$ multiplet, values calculated from a mathematical analysis); this should be compared with the para isomer (Me$_2$CO), cognate preparation below, which has ν 8.50 (s, 4H, A$_4$ singlet), and with the meta isomer (Fig. 3.64).

**Cognate preparation. p-Dinitrobenzene.** Use 34 g (0.25 mol) of p-nitroaniline (Expt 6.68) and proceed exactly as above to the point where all the suspension of p-nitrobenzenediazonium fluoroborate has been added. Filter the reaction mixture with suction, wash the residue well with water, twice with 25 ml of 5 per cent sodium hydroxide solution and finally with water. Dry the solid at 100–110 °C, powder it and extract it with four 150 ml portions of boiling toluene. Remove the toluene with a rotary evaporator and recrystallise the residue from about 120 ml of boiling glacial acetic acid. The yield of p-dinitrobenzene (reddish-yellow crystals), m.p. 173 °C, is 30 g (71.5%). Further recrystallisation from ethanol affords pale yellow crystals of the same m.p. The p.m.r. spectrum is noted above.

**Experiment 6.79 2-CHLOROBIPHENYL**

\[
\begin{align*}
\text{Cl} \quad \text{NaNO}_2, \text{HCl} \quad \text{Cl} \quad \text{PhH} \quad \text{Me}_2\text{CO}_2\text{Na} \\
\text{Cl} \quad \text{N}_2\text{Cl} \quad \text{Cl}
\end{align*}
\]

**CAUTION:** This preparation should be conducted in an efficient fume cupboard.

Diazotise 32 g (0.25 mol) of o-chloroaniline in the presence of 40 ml of concentrated hydrochloric acid and 22.5 ml of water in the usual manner (compare Expt 6.70) with a concentrated solution of 18.5 g sodium nitrite in water. Transfer the cold, filtered diazonium solution to a 1.5-litre bolt-head flask surrounded by ice-water, introduce 500 ml of cold benzene (CAUTION), stir vigorously and add a solution of 80 g of sodium acetate trihydrate in 200 ml of water dropwise, maintaining the temperature at 5–10 °C. Continue the stirring for 48 hours: after the first 3 hours, allow the reaction to proceed at room temperature. Separate the benzene layer, wash it with water and remove the benzene by distillation at atmospheric pressure; distil the residue under reduced pressure and collect the 2-chlorobiphenyl at 150–155 °C/10 mmHg. The yield is 18 g (76%). Recrystallise from aqueous ethanol; m.p. 34 °C.

**Cognate preparations. 4-Bromobiphenyl.** Diazotise 43 g (0.25 mol) of p-
bromoaniline (Expt 6.67) in the presence of 40 ml of concentrated hydrochloric acid and 22.5 ml of water with a concentrated solution of 18.5 g of sodium nitrite in water. Mix the filtered diazonium solution with 500 ml of cold benzene (CAUTION), stir vigorously and add a solution of 30 g of sodium hydroxide in 150 ml of water dropwise (during 30–45 minutes) while maintaining the temperature at 5–10°C. Complete the reaction as for 2-chlorobiphenyl. The yield of 4-bromobiphenyl, b.p. 170–175°C/8 mmHg, m.p. 90°C (from ethanol), is 25 g (86%).

**4-Chlorobiphenyl (PTC procedure).**³ Potassium acetate (1.20 g, 0.0122 mol) is added in one portion to a stirred colourless mixture of 4-chlorobenzenediazonium fluoroborate (1.37 g, 0.061 mol) (1) and 18-crown-6 (0.08 g, 0.003 mol) in benzene (60 ml, CAUTION) at 20°C in a vessel protected from the light and purged with nitrogen. The mixture turns yellow immediately, and then red within a few minutes. Stirring is continued for 90 minutes, followed by filtration to remove the solid. The resulting solution is washed with brine, water, and then dried over anhydrous sodium sulphate and the solvent removed in vacuo. The resulting red oil is chromatographed on a short column of alumina using hexane as eluant from which is obtained 4-chlorobiphenyl (0.920 g, 80%), m.p. 76–77°C.

**Note.** (1) The 4-chlorobenzenediazonium fluoroborate may be prepared using the conditions described for p-methoxybenzenediazonium fluoroborate, Expt 6.77, p-fluoroanisole. This methoxy derivative could also be used in the above preparation to give 4-methoxybiphenyl, m.p. 89°C.

**Experiment 6.80 1,3,5-TRIBROMOBENZENE**

\[
2.4.6-\text{Br}_3\text{C}_6\text{H}_2\cdot\text{NH}_2 \rightarrow 2.4.6-\text{Br}_3\text{C}_6\text{H}_2\cdot\overset{\circ}{\text{N}}\overset{\circ}{\equiv}\text{N}\underset{\circ}{\text{HSO}_4} \underset{-\text{N}_2}{\rightarrow} 1.3.5-\text{C}_6\text{H}_3\text{Br}_3
\]

Dissolve 10 g (0.03 mol) of 2,4,6-tribromoaniline (Expt 6.59) by heating on a water bath with 60 ml of rectified spirit and 15 ml of benzene in a 200-ml two-necked flask fitted with a reflux condenser, the second neck being closed with a stopper. Add, from a burette or small graduated pipette, 5.3 g (3.5 ml) of concentrated sulphuric acid to the hot solution via the side-neck and gently swirl the liquid, replace the stopper and heat on a water bath until the clear solution boils. Remove the flask from the water bath, and add 3.5 g (0.05 mol) of powdered sodium nitrite in two approximately equal portions via the side-neck; after each addition, replace the stopper and shake the flask vigorously; when the reaction subsides, add the second portion of the sodium nitrite. Heat the flask on a boiling water bath as long as gas is evolved; shake well from time to time. Allow the solution to cool for 10 minutes, and then immerse the flask in an ice bath. A mixture of tribromobenzene and sodium sulphate crystallises out. Filter with suction on a Buchner funnel, wash with a small quantity of ethanol and then repeatedly with water to remove all the sodium sulphate. Dissolve the crude tribromobenzene (7.5 g) in a boiling mixture of 120 ml of glacial acetic acid and 30 ml of water (1), boil the solution with 2.5 g of decolourising carbon and filter through a hot water funnel or a preheated Buchner funnel: allow the solution to cool. Collect the crystals on a Buchner funnel and wash with a small quantity of chilled rectified spirit to remove the acetic acid. Dry in the air upon filter paper. The
yield of 1,3,5-tribromobenzene (colourless crystals), m.p. 122°C, is 6.5 g (68%).

Note. (1) Rectified spirit may also be employed for crystallisation.

Cognate preparation. Reductive deamination in dimethylformamide. The following procedure has been applied, inter alia, to the deamination of 4-methyl-2-nitroaniline to m-nitrotoluene, and 2,5-dichloroaniline to p-dichlorobenzene. To a rapidly stirred solution of t-butyl nitrite (15 mmol) in anhydrous dimethylformamide (10 ml, redistilled from calcium hydride) heated at 65°C in a three-necked round-bottomed flask equipped with a reflux condenser, addition funnel and gas outlet tube is added the aromatic amine (10 mmol) dissolved in the minimum amount of dimethylformamide. Gas evolution is immediate, continues throughout the addition steadily, and generally is complete 10 minutes after the addition of the amine. Total gas evolution is measured on a closed system by water displacement from a calibrated burette and is usually 220 ± 20 ml per 10 mmol of amine. After complete gas evolution, the reaction solution, which turns deep red from an initial yellow, is cooled and poured into 200 ml of 20 per cent aqueous hydrochloric acid. The aqueous solution is extracted with 200 ml of ether and the ether extract washed with 200 ml of 20 per cent aqueous hydrochloric acid. The resulting ether solution is dried over magnesium sulphate and the ether removed under reduced pressure. Solid products are suitably recrystallised and liquid products distilled through a 12.5 cm Vigreux column.

Note. (1) See Expt 6.73, Note (2).

\]

\[\rightarrow \text{Me} \cdot \text{CHO} + \text{N}_2\]

*p-Acetotoluidide and 4-acetamido-3-bromotoluene.* Prepare a solution of p-acetotoluidide in glacial acetic acid by boiling 107 g (1 mol) of p-toluidine with 400 ml of glacial acetic acid in a 1-litre, round-bottomed three-necked flask, provided with a reflux condenser, stirrer and thermometer, for 2 hours. Cool the solution when some p-acetotoluidide may separate as small crystals
as the temperature falls (1). When the temperature has fallen to about 45 °C, add 162.5 g (52.5 ml, 1.01 mol) of bromine from a separatory funnel at such a rate that the temperature of the well-stirred mixture is maintained at 50–55°C. A precipitate may separate during the addition which requires 30–40 minutes, but this dissolves later. Continue the stirring for a further 30 minutes after all the bromine has been added. Then pour the reaction mixture in a thin stream into a well-stirred mixture of 1 kg of crushed ice and 1 kg of water to which 14 g of solid sodium metabisulphite has been added. If the colour of the bromine persists, add a little more sodium metabisulphite. Filter the crystalline 4-acetamido-3-bromotoluene with suction on a Buchner funnel, wash thoroughly with water and press well. Dry in the air until the weight does not exceed 250 g (2); further purification is unnecessary before proceeding to the next stage.

4-Amino-3-bromotoluene hydrochloride. Transfer the partially dried 4-acetamido-3-bromotoluene to a 1.5-litre round-bottomed flask, add 250 ml of rectified spirit and reflux on a water bath until the solid dissolves completely. Introduce through the condenser 250 ml of concentrated hydrochloric acid to the boiling solution and continue the refluxing for a further 3 hours. During this time crystals of 4-amino-3-bromotoluene hydrochloride separate. Pour the hot mixture into a 1-litre beaker and cool thoroughly. Filter the crystals of the hydrochloride at the pump through a Buchner funnel and wash rapidly with two 50 ml portions of chilled rectified spirit. The yield of the hydrochloride is 150 g (67.5%).

4-Amino-3-bromotoluene. Suspend the hydrochloride in 400 ml of water in a 1-litre beaker equipped with a mechanical stirrer. Add a solution of 70 g of sodium hydroxide in 350 ml of water. The free base separates as a dark heavy oil. After cooling to 15–20 °C, transfer the mixture to a separatory funnel and run off the crude 4-amino-3-bromotoluene. This weighs 125 g (67%) and can be used directly in the next step (3).

m-Bromotoluene. To a cold mixture of 400 ml of rectified spirit and 100 ml of concentrated sulphuric acid contained in a 2.5-litre three-necked flask, provided with an efficient mechanical stirrer, add 125 g (0.67 mol) of crude 4-amino-3-bromotoluene. Stir the solution and cool to 5 °C; then add slowly a solution of 74 g (1.07 mol) of pure sodium nitrite in 135 ml of water from a separatory funnel taking care that the temperature does not rise above 10 °C. Continue the stirring for 20 minutes after all the nitrite solution has been added in order to complete the diazotisation (test with potassium iodide–starch paper for the presence of free nitrous acid). Add 17.5 g (0.28 mol) of copper bronze (which has been washed with ether) or copper powder (Section 4.2.19, p. 426) to the diazotised solution, and replace the stirrer by a long double surface condenser. Have an ice bath at hand to cool the flask if the reaction becomes too vigorous. Warm the flask cautiously on a water bath until a vigorous evolution of gas commences, then immerse at once in an ice bath to prevent loss through the condenser by too rapid evolution of nitrogen and acetaldehyde. When the reaction has subsided, again warm the flask gently, and finally heat on a boiling water bath for 10 minutes. At the end of the reaction, the colour of the solution changes from reddish-brown to yellow. Add 1 litre of water and steam distil the mixture as long as oily drops
pass over. Separate the heavy yellow oil, wash it with two 100 ml portions of 10 per cent sodium hydroxide solution, once with 50 ml of water, twice with 75 ml portions of ice-cold concentrated sulphuric acid, once with 50 ml of water, and finally with 50 ml of 5 per cent sodium carbonate solution. Dry with 2–3 g of magnesium sulphate or anhydrous calcium chloride, and filter through a little glass wool into a distilling flask. Distil, using an air condenser, and collect the m-bromotoluene (a colourless liquid) at 180–183 °C. The yield is 65 g (38% overall).

The essential i.r. and p.m.r. features for m-bromotoluene are noted in Expt 6.72. The m.s. of all the isomers shows principal fragment ions at m/z 172 (M, 81Br), 170 (M, 79Br), 91 (M – 81,79Br), and 65 (91 – C2H2).

Notes. (1) If the mixture is cooled in ice, most of the p-acetotoluidide separates out in a crystalline form. It may be recrystallised from ethanol.
(2) Unless the material is at least partly dried before hydrolysis, the yield of hydrochloride is reduced because of its solubility. If pure 4-acetamido-3-bromotoluene is required, the crude material may be recrystallised from 50 per cent ethanol with the addition of a little decolourising carbon; it separates as colourless needles, m.p. 116–117 °C (180 g, 79%).
(3) If pure 4-amino-3-bromotoluene is required, the crude base may be purified either by steam distillation or, more satisfactorily, by distillation under reduced pressure. The oil is dried with 5 g of sodium hydroxide pellets, and fractionally distilled under reduced pressure: a little p-toluidine may be present in the low boiling point fraction, and the pure substance is collected at 92–94 °C/13 mmHg or at 120–122 °C/30 mmHg. The purified amine solidifies on cooling and melts at 17–18 °C.

### 6.7.2 COUPLING REACTIONS

Azo compounds are prepared by the interaction of a diazonium salt with a phenol in the presence of sodium hydroxide or with an amine in the presence of sodium acetate. The coupling reaction is an electrophilic substitution involving the diazonium ion which reacts at the position of greatest electron availability, i.e. the position ortho or para to the electron releasing phenoxy or amino groups.

\[
\begin{align*}
\text{Ar–N}^{\ominus}&\text{N}^{\ominus} \quad \text{O} \quad \rightarrow \quad \text{Ar–N=N}^{-} \quad \text{H}^{+} \\
\text{Ar–N=N}^{-} \quad \text{H}^{+} &\rightarrow \quad \text{Ar–N=N} \quad \text{O} \\
\text{Ar–N=N} \quad \text{H}^{+} &\rightarrow \quad \text{Ar–N=N} \quad \text{OH}
\end{align*}
\]

\[
\text{Ar–N=N}^{\ominus} \quad \text{NR}_{2} \quad \rightarrow \quad \text{Ar–N=N}^{-} \quad \text{NR}_{2} \quad \rightarrow \quad \text{Ar–N=N} \quad \text{NR}_{2}
\]

2-Naphthol couples in the more reactive 1-position as in the synthesis of 1-phenylazo-2-naphthol (Expt 6.82). 1-Naphthol couples almost exclusively in position 4; when the diazo component is the p-nitrobenzenediazonium ion the product is Magneson II (Expt 6.83), which is employed as a test reagent for magnesium.
These simpler azo compounds are not of great practical value as dyestuffs owing to their slight solubility in water. The introduction of a sulphonic acid group into the molecule has no effect upon the colour, but renders the dye water-soluble—a fact of great commercial value. The simplest way of achieving this is to employ an amine, e.g. sulphanilic acid, in which the $\text{SO}_3\text{H}$ group is already present.

Sulphanilic acid, which has a dipolar or zwitterion structure (Section 6.6.1, p. 908), is sparingly soluble in water. It is best diazotised by bringing it into solution as the sodium salt by adding the calculated quantity of sodium carbonate, introducing the requisite quantity of sodium nitrite and pouring the solution on to a mixture of hydrochloric acid and ice; nitrous acid and the dipolar sulphanilic acid are liberated together and immediately react, and after a short time the internal diazonium salt separates from solution. Coupling with 2-naphthol in sodium hydroxide solution yields the useful dyestuff Orange II (Expt 6.84). When, $N,N$-dimethylaniline is used as the coupling component the product is methyl orange (Expt 6.85). This latter substance is more useful as an indicator than as a dye, for it changes colour at a certain concentration of hydrogen ions (pH 3.1–4.4). Treatment of a solution of methyl orange with a strong acid gives rise to a red form—which is essentially an internal salt stabilised by electron delocalisation.

![Diagram of azo compounds](image)

It is interesting to note that azo compounds may be conveniently reduced either by a solution of tin(II) chloride in hydrochloric acid or by sodium dithionite. Thus 1-phenylazo-2-naphthol yields both aniline and 1-amino-2-naphthol, and methyl orange gives $p$-amino-$N,N$-dimethylaniline and sulphanilic acid.

$$\text{Ph} - \text{N}=\text{N} \rightarrow \text{Ph} \cdot \text{NH}_2 + \text{HO}$$
Attention has previously been drawn (Section 6.7.1, p. 922) to the fact that unless an excess of hydrochloric (or mineral) acid is used in the diazotisation process, coupling occurs between the diazonium salt and the amino group in the amine to give diazoamino compounds. Thus benzenediazonium chloride and aniline yield diazoaminobenzene. This substance may be conveniently prepared by dissolving two equivalents of aniline in three equivalents of hydrochloric acid, and adding one equivalent of sodium nitrite in aqueous solution followed by two equivalents of sodium acetate (Expt 6.86).

If diazoaminobenzene is dissolved in aniline, to which a small quantity of aniline hydrochloride has been added, and the mixture kept at about 40 °C for a short time, it is converted into p-aminoazobenzene (Expt 6.86). The mechanism of this diazoamino–aminoazo rearrangement is dependent on (a) the heterolytic cleavage of a protonated diazoaminobenzene molecule to yield the benzenediazonium ion and aniline, and (b) a recoupling reaction, under weakly acidic conditions, of the diazonium ion at the para position of aniline.

Experiment 6.82 1-PHENYLazo-2-NAPHTHOL

Dissolve 5.0 g (4.9 ml, 0.054 mol) of aniline in 16 ml of concentrated hydrochloric acid and 16 ml of water contained in a small beaker or conical flask. Diazotise by the addition of a solution of 4.0 g (0.058 mol) of sodium nitrite in 20 ml of water; follow the method given in Expt 6.70. Prepare a
solution of 7.8 g (0.054 mol) of 2-naphthol in 45 ml of 10 per cent sodium hydroxide solution in a 250-ml beaker; cool the solution to 5°C by immersion in an ice bath, assisted by the direct addition of about 25 g of crushed ice. Stir the naphthol solution vigorously and add the cold diazonium salt solution very slowly: a red colour develops and red crystals of 1-phenylazo-2-naphthol soon separate. When all the diazonium salt solution has been added, allow the mixture to stand in an ice bath for 30 minutes with occasional stirring. Filter the solution through a Buchner funnel with gentle suction, wash well with water and drain thoroughly by pressing the crystals with the back of a large glass stopper. Recrystallise one-fourth of the product from glacial acetic acid (30–35 ml): retain the remainder for reduction by stannous chloride. Filter the recrystallised product with suction, wash with a little ethanol (or industrial spirit) to eliminate acetic acid and dry upon filter paper. The yield of deep red crystals is about 3 g. Pure 1-phenylazo-2-naphthol has m.p. 131°C; if the m.p. is low, recrystallise the dry product from ethanol.

Reduction with tin(II) chloride. 1-Amino-2-naphthol hydrochloride. Into a 350- or 500-ml round-bottomed flask, provided with a reflux condenser and containing 100 ml of industrial spirit, place the crude 1-phenylazo-2-naphthol reserved above and boil gently until most of the azo compound has dissolved. Meanwhile dissolve 20 g of a good grade of tin(II) chloride in 60 ml of concentrated hydrochloric acid (warming is necessary to produce a clear solution) (1), add this to the contents of the flask and boil under reflux for a further 30 minutes. All the azo compound dissolves rapidly and is reduced by the tin(II) chloride; the solution acquires a very pale brown colour. Decant the solution to a beaker and cool in ice: the 1-amino-2-naphthol hydrochloride separates as fine greyish-white crystals. Filter with suction, and wash with dilute hydrochloric acid (1:4). Recrystallise from the minimum volume of hot water which contains a few drops of tin(II) chloride solution in an equal weight of hydrochloric acid (this reduces atmospheric oxidation), cool the clear solution in an ice bath and collect the recrystallised product as before. Dry the colourless crystals in a desiccator. The yield is 3–4 g. The compound will remain colourless, or nearly so, if protected from light during storage.

Note. (1) Sodium dithionite, Na₂S₂O₄, may also be used for the reduction; see under methyl orange, Expt 6.85.

Experiment 6.83 4-(4'-NITROBENZENEazo)-1-NAPHTHOL (Magneson II)

\[
\begin{align*}
\text{O}_2\text{N} & \text{-} \overset{\text{N}_2\text{Cl}}{\text{N}} \text{-} \overset{\text{OH}}{\text{N}} \rightarrow \\
\text{O}_2\text{N} & \text{-} \overset{\text{N} = \text{N}}{\text{N}} \text{-} \overset{\text{OH}}{\text{N}}
\end{align*}
\]
Dissolve 5.0 g (0.036 mol) of \( p \)-nitroaniline (Expt 6.68) in a warm mixture of 13 ml of concentrated hydrochloric acid and 13 ml of water contained in a 250-ml beaker. Place the beaker in an ice–salt bath and cool to 0–5 °C whilst stirring vigorously; \( p \)-nitroaniline hydrochloride will separate in a finely divided crystalline form. Add a cold solution of 3.7 g (0.054 mol) of sodium nitrite in 8 ml of water slowly and with stirring to an end-point with potassium iodide–starch paper: do not allow the temperature of the solution to rise above 8 °C. Dissolve 5.2 g (0.035 mol) of 1-naphthol in a solution of 7 g of sodium hydroxide in 25 ml of water, cool in ice and add the diazotised solution slowly and with stirring. Then add concentrated hydrochloric acid slowly and with vigorous stirring to the cold mixture until it is strongly acid to Congo red paper. The colour will change from violet to dark red-brown. Filter with gentle suction, wash with water until free from acid and dry upon filter-paper in the air. The yield is 8 g (74%).

2,4-Dihydroxy-4'-nitroazobenzene ('Magneson I') may be similarly prepared by substituting resorcinol for 1-naphthol; it may be recrystallised from methanol and melts at 199–200 °C.

**Experiment 6.84 ORANGE II (\( \beta \)-Naphthol Orange)**

![Diagram of the reaction](image)

Diazotise 10.5 g (0.05 mol) of sulphanilic acid dihydrate as described under methyl orange (Expt 6.85), and keep the suspension of the diazonium compound in ice-water until required. Dissolve 7.2 g (0.05 mol) of a good grade of 2-naphthol in 40 ml of cold 10 per cent sodium hydroxide solution in a 600-ml beaker, cool to 5 °C and pour in, with stirring, the well-mixed suspension of diazotised sulphanilic acid. Coupling takes place readily and the dyestuff separates as a crystalline paste. Stir well and, after 10 minutes, heat the mixture until all the solid has dissolved. Add 20 g of sodium chloride (to decrease the solubility of the product further) and warm until this dissolves. Allow the solution to cool spontaneously in the air for 1 hour, and then cool in ice until crystallisation is complete. Collect the product on a Buchner funnel and apply gentle suction; wash with a little saturated salt solution, and dry at 80 °C. The product weighs about 22 g, and contains about 20 per cent of sodium chloride; further purification is unnecessary for dyeing purposes. To obtain pure, crystalline Orange II, dissolve the crude substance in the minimum volume of boiling water, allow to cool to about 80 °C, add about twice the volume of rectified (or industrial) spirit and allow crystallisation to proceed spontaneously. When cold, filter at the pump, wash the pure dyestuff (it is a dihydrate) with a little ethanol and dry in the air. The yield is 14 g (80%) (1).

Note. (1) For the reduction of Orange II to 1-amino-2-naphthol and its conversion to 1,2-naphthoquinone, see Expt 6.131.
Experiment 6.85 METHYL ORANGE

\[
\begin{align*}
\text{NaO}_3\text{S} - \text{NH}_2 & \xrightarrow{\text{NaNO}_2; \text{HCl}} \text{O}_3\text{S} - \text{N}=\text{N} \\
\text{PhNMe}_2 & \xrightarrow{\text{NaOH}} \text{N}=\text{N} - \text{NMe}_2
\end{align*}
\]

In a 250-ml conical flask place 10.5 g (0.05 mol) of sulphanilic acid dihydrate, 2.65 g (0.025 mol) of anhydrous sodium carbonate and 100 ml of water, and warm until a clear solution is obtained. Cool the solution under the tap to about 15°C, and add a solution of 3.7 g (0.059 mol) of sodium nitrite in 10 ml of water. Pour the resulting solution slowly and with stirring into a 600-ml beaker containing 10.5 ml of concentrated hydrochloric acid and 60 g of crushed ice (1). Test for the presence of free nitrous acid with potassium iodide–starch paper after 15 minutes. Fine crystals of the diazobenzene sulphonate will soon separate; do not filter these off as they will dissolve during the next stage of the preparation. Dissolve 6.05 g (6.3 ml, 0.05 mol) of dimethylaniline in 3.0 ml of glacial acetic acid, and add it with vigorous stirring to the suspension of diazotised sulphanilic acid. Allow the mixture to stand for 10 minutes; the red or acid form of methyl orange will gradually separate. Then add slowly and with stirring 35 ml of 20 per cent sodium hydroxide solution: the mixture will assume a uniform orange colour due to the separation of the sodium salt of methyl orange in fine particles. Direct filtration of the latter is slow, hence, while stirring the mixture with a thermometer, heat it almost to the boiling point. Most of the methyl orange will dissolve. Add about 10 g of sodium chloride (to assist the subsequent separation of the methyl orange) and warm at 80–90°C until the salt has dissolved. Allow the mixture to cool undisturbed for 15 minutes and then cool in ice-water; this gives a fairly easily filterable product. Filter off the methyl orange at the pump, but apply only gentle suction so as to avoid clogging the pores of the filter paper; rinse the beaker with a little saturated salt solution and drain well. Recrystallise from hot water (about 150 ml are required); filter the hot solution, if necessary, through a hot water funnel or through a preheated Buchner funnel. Reddish-orange crystals of methyl orange separate as the solution cools. Filter these at the pump, drain well, wash with a little ethanol, and finally with a small volume of ether. The yield is 13 g (80%). Methyl orange, being a salt, has no well-defined m.p.

Note. (1) An alternative procedure is to cool the solution containing the sodium sulphanilate and sodium nitrite in a bath of crushed ice to about 5°C and then add 10.5 ml of concentrated hydrochloric acid diluted with an equal volume of water slowly and with stirring; the temperature must not be allowed to rise above 10°C and an excess of nitrous acid should be present (the solution is tested after standing for 5 minutes). The subsequent stages in the preparation – addition of dimethylaniline solution, etc. – are as above.

Reduction of methyl orange to p-aminodimethylaniline. Method 1. Dissolve 2.0 g of methyl orange in the minimum volume of hot water and to the hot solution add a solution of 8 g of tin(II) chloride in 20 ml of concentrated hydrochloric acid until decolourisation takes place; gentle boiling may be necessary. Cool the resulting solution in ice; a crystalline precipitate
consisting of sulphanilic acid and some \( p \)-aminodimethylaniline hydrochloride separates out. In order to separate the free base, add 10 per cent sodium hydroxide solution until the precipitate of tin hydroxide redissolves. Extract the cold solution with three or four 20 ml portions of ether, dry the extract with anhydrous potassium carbonate and remove the ether by distillation. The residual base soon crystallises, particularly if it is stirred with a glass rod; it melts at 41 °C.

**Method 2.** Suspend 2.0 g of methyl orange in 4 ml of water, and add a small quantity of sodium dithionite \((\text{Na}_2\text{S}_2\text{O}_4)\). Heat the mixture and add more sodium dithionite until the colour is discharged. The sulphanilic acid remains in the solution as sodium sulphanilate and the \( p \)-aminodimethylaniline may be extracted with ether as in **Method 1**.

**Experiment 6.86 DIAZOAMINOBENZENE AND \( p \)-AMINOAZOBOZENZENE**

\[
\text{Ph} \cdot \text{N} = \text{N} \cdot \text{Cl} \xrightarrow{\text{Ph} \cdot \text{NH}_2} \text{Ph} \cdot \text{N} = \text{N} \cdot \text{NH} \cdot \text{Ph} \xrightarrow{\text{Ph} \cdot \text{N} = \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2 \cdot \text{p}}
\]

**Diazomaminobenzene.** In a 250-ml flask place 75 ml of water, 24 g (20 ml) of concentrated hydrochloric acid and 14 g (13.7 ml, 0.15 mol) of aniline. Shake vigorously (1) and then add 50 g of crushed ice. Run in a solution of 5.2 g (0.075 mol) of sodium nitrite in 12 ml of water, with constant shaking, during a period of 5–10 minutes. Allow to stand with frequent shaking (1) for 15 minutes, and add a solution of 21.0 g of crystallised sodium acetate in 40 ml of water during 5 minutes. A yellow precipitate of diazomaminobenzene begins to form immediately; allow to stand with frequent shaking for 45 minutes and do not allow the temperature to rise above 20 °C (add ice, if necessary). Filter the yellow diazomaminobenzene on a Buchner funnel, wash it with 250 ml of cold water, drain as completely as possible and spread it on a sheet of filter paper to dry. The yield of crude diazomaminobenzene, m.p. 91 °C, is 13 g (87%) (2). Recrystallise a small portion from light petroleum, b.p. 60–80 °C: the pure compound, m.p. 97 °C, is obtained.

**Notes.** (1) For preparations on a larger scale, mechanical stirring is recommended.
(2) The crude compound may be employed in the preparation of \( p \)-aminoazobenzene.

**Conversion into \( p \)-aminoazobenzene.** Dissolve 5 g (0.025 mol) of finely powdered diazomaminobenzene in 12–15 g of aniline in a small flask and add 2.5 g of finely powdered aniline hydrochloride (1). Warm the mixture, with frequent shaking, on a water bath at 40–45 °C for 1 hour. Allow the reaction mixture to stand for 30 minutes. Then add 15 ml of glacial acetic acid diluted with an equal volume of water: stir or shake the mixture in order to remove the excess of aniline in the form of its soluble acetate. Allow the mixture to stand, with frequent shaking, for 15 minutes: filter the aminoazobenzene at the pump, wash with a little water and dry upon filter paper. Recrystallise the crude \( p \)-aminoazobenzene (3.5 g, 70%; m.p. 120 °C) from 15–20 ml of carbon tetrachloride to obtain the pure compound, m.p. 125 °C. Alternatively, the compound may be recrystallised from dilute ethanol, to which a few drops of concentrated ammonia solution have been added.

To prepare the hydrochloride dissolve about 1 g of the compound (which need not be perfectly dry) in about 8 ml of ethanol. Add this solution to
boiling dilute hydrochloric acid (10 ml of the concentrated acid and 80 ml of water). Boil for 5 minutes, filter the hot solution if necessary and allow to cool.
p-Aminoazobenzene hydrochloride separates in steel-blue crystals. Filter, wash with a little dilute hydrochloric acid, and dry.

To recover the free base, dissolve the hydrochloride in the minimum volume of boiling ethanol, add concentrated ammonia solution dropwise until a clear solution results and the blue colour has become light brown. Add water carefully until a cloudiness appears, warm on a water bath until the cloudiness just disappears and allow to cool. Yellow crystals of p-aminoazobenzene separate on cooling.

Note. (1) The aniline hydrochloride may be prepared by treating 2 g of aniline with an excess (about 3 ml) of concentrated hydrochloric acid in a small beaker, cooling, filtering at the pump, washing with a small volume of ether and drying between filter paper.

6.8 MISCELLANEOUS AROMATIC NITROGEN COMPOUNDS

1. Intermediate products in the reduction of nitro compounds (Expts 6.87 to 6.91).
3. Arylureas and related compounds (Expts 6.96 to 6.98).

The important spectroscopic features (i.e., p.m.r., m.s., and u.v.-visible) which are observed in this varied range of nitrogen compounds are discussed descriptively under appropriate preparative sections.

6.8.1 INTERMEDIATE PRODUCTS IN THE REDUCTION OF NITRO COMPOUNDS

The reduction of an aromatic nitro compound with a powerful reducing agent (tin or tin(ii) chloride and hydrochloric acid; iron and dilute hydrochloric acid; hydrogen and a platinum catalyst) leads to a good yield of primary amine, e.g. aniline from nitrobenzene. By the use of milder reducing agents and by the control of the hydrogen ion concentration of the solution, a number of intermediate products may be isolated, some of which are products of direct reduction and others are formed through secondary reactions. The various stages of the reduction of nitrobenzene have been established by investigating the process electrolytically under conditions of varying pH, current density and electrode construction and composition. The sequence is as follows.

\[
\text{Ph-NO}_2 \xrightarrow{2H} \text{Ph-NO} \xrightarrow{2H} \text{Ph-NHOH} \xrightarrow{2H} \text{Ph-NH}_2
\]

Nitrobenzene  Nitrosobenzene  N-Phenylhydroxylamine  Aniline

The initial product, nitrosobenzene, is so easily reduced to N-phenylhydroxylamine that it has not been isolated from the reduction medium, but its presence has been established by reaction in solution with hydroxylamine to yield a benzenediazonium salt, which couples readily with 1-naphthylamine to form the dyestuff 2-phenylazo-1-naphthylamine.

\[
\text{Ph-NO + H}_2\text{NOH} + \text{HX} \rightarrow \text{Ph-N}^\ominus\text{N}^\ominus \text{X} + 2\text{H}_2\text{O}
\]
Under the catalytic influence of alkali, nitrosobenzene and N-phenylhydroxylamine react to yield azoxybenzene.

\[
\text{Ph-NO} + \text{Ph-NHOH} \xrightarrow{\text{OH}} \text{Ph-N=N-Ph}
\]

Further reduction in alkaline solution (e.g. with zinc powder) leads to azobenzene and hydrazobenzene.

\[
\text{Ph-N=N-Ph} \xrightarrow{2 \text{H}} \text{Ph-N=N-Ph} \xrightarrow{2 \text{H}} \text{Ph-NH-NH-Ph}
\]

Electrolytic reduction of hydrazobenzene gives aniline.

\[
\text{Ph-NH-NH-Ph} \xrightarrow{2 \text{H}} 2\text{Ph-NH}_2
\]

The various intermediate compounds may be prepared in the laboratory, and convenient methods are described below.

N-Phenylhydroxylamine (Expt 6.87) is formed when nitrobenzene is treated with a ‘neutral’ reducing agent, e.g. zinc powder and aqueous ammonium chloride solution. The compound rearranges, in the presence of acids, with the formation of p-aminophenol (Expt 6.87).

N-Phenylhydroxylamine may be converted into an N-benzoyl derivative by treating it in aqueous solution with benzoyl chloride while simultaneously removing, with sodium hydrogen carbonate, the liberated hydrogen chloride. On reaction with thionyl chloride this benzoyl derivative is converted into o-chlorobenzanilide (Expt 6.61) by way of an intermediate chlorosulphite ester, which then undergoes a specific ortho rearrangement.

\[
\text{Ph-NHOH} + \text{Ph-COCl} \xrightarrow{-\text{HCl}} \text{Ph-N(OH)-CO-Ph} \xrightarrow{\text{SOCl}_2}{-\text{HCl} - \text{SO}_2} \text{o-Cl-C_6H_4-NH-CO-Ph}
\]

Nitrosobenzene (Expt 6.88) may be obtained by the oxidation of N-phenylhydroxylamine with acid dichromate solution at 0°C. The solid product is colourless and is probably a dimer; it dissociates to a green monomer upon melting or in solution.

Azoxybenzene is readily prepared by reduction of nitrobenzene in an alkaline medium with a variety of mild reducing agents. Reducing sugars have been used successfully for the reduction of substituted nitro compounds to the corresponding azoxyarenes and the use of D-glucose for the reduction of nitrobenzene is illustrated in Expt 6.89.

Reduction of nitrobenzene in methanolic or ethanolic sodium hydroxide solution with zinc powder leads to azobenzene or hydrazobenzene according to the proportion of zinc powder employed (Expts. 6.90 and 6.91). Hydrazobenzene may be oxidised to azobenzene by sodium hypobromite solution at 0°C.

In the presence of acids, hydrazobenzene rearranges to give a mixture containing about 70 per cent of benzidine (4,4’-diaminobiphenyl) and about 30 per cent of 2,4’-diaminobiphenyl (diphenylene), the benzidine rearrangement. Benzidine is carcinogenic and its preparation and storage is under strict control.
Experiment 6.87  \(N\)-PHENYLHYDOXYLAMINE

\[
\text{Ph} \cdot \text{NO}_2 \xrightarrow{4\text{HI}_2 Zn/NH}_4 \text{Cl} \quad \text{Ph} \cdot \text{NHOH} + \text{H}_2\text{O}
\]

In a 2-litre beaker, equipped with a thermometer and mechanical stirrer, place 25 g of ammonium chloride, 800 ml of water and 50 g (41.6 ml, 0.41 mol) of redistilled nitrobenzene. Stir the mixture vigorously, and add 59 g (0.83 mol) of zinc powder of 90 per cent purity (Section 4.2.80, p. 467) during about 15 minutes; the rate of addition should be such that the temperature rapidly rises to 60–65 °C and remains in this range until all the zinc has been added. Continue the stirring for a further 15 minutes, by which time the reduction is complete as is shown by the fact that the temperature commences to fall. Filter the warm reaction mixture at the pump to remove the zinc oxide, and wash it with 100 ml of hot water. Place the filtrate in a conical flask, saturate it with common salt (about 300 g) and cool in an ice bath for at least 1 hour to ensure maximum crystallisation of the desired product. Filter the pale yellow crystals of phenylhydroxylamine with suction and drain well. The yield of crude, dry product is about 38 g; this contains a little salt and corresponds to about 29 g (66%) of pure phenylhydroxylamine as determined by its separation from inorganic materials by dissolution in ether. The substance deteriorates upon storage and is therefore used immediately for a secondary preparation (e.g. nitrosobenzene, Expt 6.88). If required perfectly pure, it may be recrystallised from benzene–light petroleum (b.p. 40–60 °C) or from benzene alone; the resulting pure compound is somewhat more stable and has a melting point of 81 °C.

\(N\)-Benzoylation of phenylhydroxylamine.  32 Phenylhydroxylamine (10 g, 0.105 mol) is dissolved in warm water (400 ml) and the solution cooled to room temperature and filtered if necessary. Benzoyl chloride (15 g, 0.106 mol, CAUTION) is added in small portions to the solution which is vigorously shaken; the acidity of the solution is monitored with litmus paper and neutralised by the addition of appropriate quantities of sodium hydrogen carbonate solution (1). After several minutes an off-white solid separates. When the smell of benzyol chloride has disappeared and the aqueous solution remains alkaline, the benzoylation reaction is complete; a small portion of the solution gives a negative reaction on warming with Fehling's solution. The solid is filtered and washed with water and finally well triturated with sodium hydrogen carbonate solution to remove any occluded acid (2). The crude product is boiled with water in which the monobenzoate is soluble but the dibenzoate remains as a dark brown oil. After decantation and cooling the monobenzoate separates as white needles, m.p. 121-122 °C.

Notes. (1) An alternative procedure 34 is to add the benzyol chloride in ether to a stirred suspension of phenylhydroxylamine in ether at 0 °C. When the reaction is complete the ether solution is washed with dilute alkali and water, dried and evaporated.

(2) Further purification may be effected by dissolving the crude product in aqueous ammonia (28%), in which the dibenzoate is insoluble, filtering, and acidifying with sulphuric acid, 32 or better hydrochloric acid. 35

Conversion of phenylhydroxylamine into \(p\)-aminophenol. Add 4.4 g of recrystallised phenylhydroxylamine to a mixture of 20 ml of concentrated
sulphuric acid and 60 g of ice contained in a 1-litre beaker cooled in a freezing mixture. Dilute the solution with 400 ml of water, and boil until a sample, tested with dichromate solution, gives the smell of quinone and not of nitrosobenzene or nitrobenzene (c. 10–15 minutes). Neutralise the cold reaction mixture with sodium hydrogen carbonate, saturate with salt, extract twice with ether and dry the ethereal extract with magnesium sulphate or anhydrous sodium sulphate. Distil off the ether; p-aminophenol, m.p. 186°C, remains. The yield is 4.3 g (98%).

The i.r. spectrum shows similarities to that of the ortho isomer with respect to the absorptions due to the NH and OH groups (p. 894). The p.m.r. spectrum (TFA, TMS) confirms the substitution pattern and shows signals at δ 7.12 (d, 2H, ortho-H's to NH₂), 7.45 (d, 2H, ortho-H's to OH), and 8.70 (OH and NH₂).

**Experiment 6.88 NITROSOBENZENE**

\[
\text{Ph-NO}_2 + \text{H}_2\text{O} \xrightarrow{\text{HI}} \text{Ph-NHOH} \xrightarrow{\text{IOI}} \text{Ph-NO + H}_2\text{O}
\]

In a 2-litre beaker, equipped with a thermometer and mechanical stirrer, place 30 g (0.56 mol) of ammonium chloride, 1 litre of water and 61.5 g (51 ml, 0.5 mol) of pure nitrobenzene. Stir the mixture vigorously, and add 75 g (1.03 mol, 90% purity; see Section 4.2.80, p. 467) of zinc powder during about 15 minutes; the rate of addition should be such that the temperature rises rapidly to 60–65°C and remains in this range until all the zinc has been added. Continue the stirring for a further 15 minutes, by which time the reduction is complete as shown by the fact that the temperature commences to fall. Filter the warm reaction mixture at the pump to remove the zinc oxide, and wash it with 600–700 ml of boiling water. Transfer the filtrate and washings to a 4-litre round-bottomed flask or beaker and cool immediately to 0–1°C by the addition of sufficient crushed ice and leave at least 250 g unmelted. Without delay, add with stirring a cold solution of concentrated sulphuric acid (150 ml of the concentrated acid added to sufficient ice to reduce its temperature to −5°C). Then add an ice-cold solution of 34 g (0.114 mol) of crystallised sodium dichromate in 125 ml of water as rapidly as possible to the stirred solution. After 2–3 minutes, filter the straw-coloured precipitate of nitrosobenzene on a Buchner funnel and wash it with 200 ml of water. Steam distil the nitrosobenzene as rapidly as possible; the nitrosobenzene tends to decompose at the elevated temperature. Cool the receiver in ice because the compound has a high vapour pressure at room temperature. The nitrosobenzene condenses to a green liquid, which solidifies to a white solid; care should be taken that the solid does not clog the condenser by turning off the water supply from time to time. Stop the distillation when yellow oily material appears in the condenser. Filter; grind the nitrosobenzene in a glass mortar with a little water. Filter at the pump, wash it with water until the washings are no longer brown and drain as completely as possible. Dry the solid between layers of filter paper. The yield of nitrosobenzene, m.p. 66–67°C, is 30 g (56%). A pure product, m.p. 68°C, may be obtained by recrystallisation from a small volume of ethanol with good cooling: the compound should be dried over anhydrous calcium chloride at atmospheric pressure. The substance may be kept 1–2 days at room temperature and for longer periods at 0°C.
The i.r. spectrum offers an interesting contrast with that of nitrobenzene in that only one stretching absorption of the NO group is observed (c. 1425 cm⁻¹). The m.s. reveals significant fragment ions at m/z 107 (M), 77 (M – NO, base peak), and 51 (77 – C₂H₂).

**Experiment 6.89 AZOXYBENZENE**

\[
\text{Ph} \cdot \text{NO}_2 + 6[\text{H}] \rightarrow \text{Ph} \cdot \text{N} = \text{N} \cdot \text{Ph} + 3\text{H}_2\text{O}
\]

Equip a 500-ml three-necked flask with an efficient stirrer (e.g. a Hershberg stirrer, Fig. 2.49) and a reflux condenser; stopper the third neck. Place a solution of 30 g of sodium hydroxide in 100 ml of water, and also 20.5 g (17.1 ml, 0.167 mol) of pure nitrobenzene in the flask, immerse it in a water bath maintained at 55–60°C, and add 21 g (0.117 mol) of anhydrous glucose in small portions, with continuous stirring, during 1 hour. Then heat on a boiling water bath for 2 hours. Pour the hot mixture into a 1-litre round-bottomed flask and steam distil (Fig. 2.102) to remove aniline and nitrobenzene. When the distillate is clear (i.e. after about 1 litre has been collected), pour the residue into a beaker cooled in an ice bath. The azoxybenzene soon solidifies. Filter with suction, grind the lumps of azoxybenzene in a mortar, wash with water and dry upon filter paper or upon a porous plate. The yield of material, m.p. 35–35.5°C, is 13 g (79%). Recrystallise from 7 ml of rectified spirit or of methanol; the m.p. is raised to 36°C.

The u.v.–visible absorption spectra (MeOH) of (a) hydrazobenzene (Expt 6.91), (b) azobenzene (Expt 6.90) and (c) azoxybenzene offer interesting comparison. This shows the bathochromic shifts which result from mesomeric interaction between the two phenyl groups via the nitrogen linkages: (a) \( \lambda_{\text{max}} \) 229 nm (\( \varepsilon \) 13 000), 235 nm (\( \varepsilon \) 12 500), 244 nm (\( \varepsilon \) 11 600), 315 nm (\( \varepsilon \) 11 700), 435 nm (\( \varepsilon \) 446); (b) \( \lambda_{\text{max}} \) 228 nm (\( \varepsilon \) 13 400), 314 nm (\( \varepsilon \) 18 200), 433 nm (\( \varepsilon \) 727); (c) \( \lambda_{\text{max}} \) 232 nm (\( \varepsilon \) 8680), 239 nm (\( \varepsilon \) 7530), 260 nm (\( \varepsilon \) 7530), 322 nm (\( \varepsilon \) 14 700).

**Experiment 6.90 AZOBENZENE**

\[
2\text{Ph} \cdot \text{NO}_2 \xrightarrow{4\text{Zn}, 8\text{NaOH}} \text{Ph} \cdot \text{N} = \text{N} \cdot \text{Ph} + 4\text{Na}_2\text{[ZnO}_2\text{]} + 4\text{H}_2\text{O}
\]

Support a 1-litre three-necked flask, equipped with a sealed stirrer unit and a reflux condenser, on a water bath, and place a solution of 65 g of sodium hydroxide in 150 ml of water, 50 g (41.5 ml, 0.41 mol) of pure nitrobenzene and 500 ml of methanol in the flask. Add 59 g (0.9 mol) of zinc powder (90% purity; see Section 4.2.80, p. 467) to the mixture, start the stirrer and reflux for 10 hours (1). Filter the mixture while hot, and wash the precipitate of sodium zincate with a little methanol. The strongly alkaline filtrate is not always clear: render it neutral to litmus by the cautious addition of concentrated hydrochloric acid, and filter again. Distil off the methanol from the filtrate, cool the residue in ice and filter off the solid azobenzene. The crude azobenzene contains occluded zinc salts. To remove these, add the crude product to 100 ml of 2 per cent hydrochloric acid, warm to about 70°C
in order to melt the azobenzene and stir mechanically for 5 minutes; continue the stirring while the mixture is immersed in ice-water in order to solidify the azobenzene. Filter, wash well with water, drain thoroughly and recrystallise from a mixture of 145 ml of rectified spirit and 12 ml of water; collect the azobenzene and dry in the air. The yield of pure azobenzene (reddish-orange crystals), m.p. 67–68 °C, is 31 g (86%) (2). The u.v.–visible spectrum is quoted in Expt 6.89.

Notes. (1) At the end of this time, the reddish mixture should be free from the odour of nitrobenzene; if it is not, reflux for 2–3 hours longer.
(2) Frequently the recrystallized azobenzene has m.p. 61 °C, which is unaffected by recrystallisation from ethanol. Upon distillation from a 50-ml distilling flask fitted with a short air condenser, the m.p. is raised to 67.5 °C and the recovery is about 90 per cent; one recrystallisation from diluted ethanol (as above) then gives perfectly pure azobenzene of m.p. 68.5 °C.

Experiment 6.91 HYDRAZOBENZENE (sym.-Diphenylhydrazine)

\[ 2\text{Ph} \cdot \text{NO}_2 \xrightarrow{5\text{Na}_2\text{O}} \text{Ph} \cdot \text{NH} \cdot \text{NH} \cdot \text{Ph} + 5\text{Na}_2[\text{ZnO}_2] + 4\text{H}_2\text{O} \]

Support a 1500-ml three-necked flask, equipped with a sealed stirrer unit and a double surface reflux condenser, on a water bath, and place a solution of 84 g of sodium hydroxide in 185 ml of water, 50 g (41.5 ml, 0.406 mol) of nitrobenzene and 500 ml of methanol in the flask. Add 78 g (1.07 mol, 90%) of zinc powder, start the stirrer and reflux for 10 hours. The solution gradually assumes the reddish colour of azobenzene and then, on further reduction, turns to a pale yellow (due to hydrazobenzene). If the colour is not almost completely discharged at the end of the refluxing period, add a further 11 g (0.15 mol; 90%) of zinc powder, and reflux for 2–3 hours longer. Filter the hot solution through a preheated Buchner funnel and wash the sodium zinate upon the filter with a little hot methanol. Pour the filtrate into a large flask (1), stopper it loosely and cool it in a freezing mixture of ice and salt to accelerate crystallisation. After 1 hour filter off the almost colourless crystals of hydrazobenzene at the pump as rapidly as possible (it is helpful to displace the air above the solution undergoing filtration in the funnel with a stream of nitrogen), wash with 50 per cent methanol to which a little sulphurous acid has been added until the filtrate is no longer alkaline. Dry in a vacuum desiccator. The resulting almost colourless hydrazobenzene (15 g; 40%; m.p. 125 °C) is sufficiently pure for most preparative purposes. If it is required pure (m.p. 126 °C with production of a yellow colour), it may be recrystallised from hot methanol containing a little ammonium sulphide or sulphurous acid (these assist in preventing atmospheric oxidation).

Owing to the great tendency of hydrazobenzene to undergo oxidation, all operations involving filtration should be carried out as rapidly as possible and air should not be drawn through it unnecessarily. The substance should be dried in a vacuum desiccator: it can only be preserved in a colourless condition if it is kept in an atmosphere of carbon dioxide or nitrogen or in sealed vessels. The u.v.–visible spectrum is quoted in Expt 6.89.

Notes. (1) If the methanol is distilled off before thorough cooling in a freezing mixture, the yield of hydrazobenzene is appreciably increased, but the product is considerably more coloured due to admixture with a trace of azobenzene. About 12 g of impure
hydrazobenzene may be recovered by distilling off the methanol from the filtrate after the colourless hydrazobenzene has been collected.

### 6.8.2 ARYLHYDRAZINES

Arylhydrazines may be prepared by reducing diazonium salts with excess warm sodium sulphite solution, followed by acidification with hydrochloric acid. The hydrochloride usually crystallises out on cooling and treatment of the latter with excess sodium hydroxide solution liberates the free base. The preparation of \( p \)-nitrophenylhydrazine by this method is illustrated in Expt 6.92.

The mechanism of this reduction probably involves the initial addition of a sulphite ion to the diazonium group to give an azosulphonate which undergoes further conjugate (1,4-) addition of the nucleophilic sulphite ion. The resulting intermediate is protonolytically cleaved on heating under acidic conditions:

\[
\begin{align*}
\text{Ar} \cdot \text{N} = \text{N} \text{–} & \text{S} \text{–} \text{SO}_3^- \quad \text{Ar} \cdot \text{N} = \text{N} \text{–} & \text{SO}_3^- \\
\rightarrow & \quad \text{Ar} \cdot \text{N} = \text{N} \text{–} & \text{S} \text{–} \text{O}_2^- \\
\end{align*}
\]

This method cannot be applied to polynitro amines, since these are so weakly basic that they can be diazotised only under special conditions in strongly acidic media (Section 6.7.1, p. 922). In such cases use may be made of the susceptibility to nucleophilic displacement of halogen when activated by ortho and para nitro groups. Thus the valuable reagent 2,4-dinitrophenylhydrazine (Expt 6.93) is readily prepared by reacting 1-chloro-2,4-dinitrobenzene with hydrazine. Reaction with ammonia similarly gives 2,4-dinitroaniline (cognate preparation in Expt 6.93).

A further example is provided by the reaction of 1-chloro-2,4,6-trinitrobenzene (picryl chloride) with \( N,N \)-diphenylhydrazine to give \( N,N \)-diphenylpicrylhydrazine (Expt 6.94). This compound is of interest in that
oxidation with lead dioxide yields the highly stable \( N,N \)-diphenylpicrylhydrazyl radical, which is obtained as an intensely coloured, paramagnetic solid. Stabilisation of the radical is promoted by the strongly electron-attracting trinitrophenyl residue resulting in extensive delocalisation of the odd electron. The \( N,N \)-diphenylhydrazine required for this preparation is obtained by reduction of \( N \)-nitroso-\( N,N \)-diphenylamine with zinc and acetic acid (Expt 6.95).

**Experiment 6.92 \( p \)-NITROPHENYLHYDRAZINE**

\[
p-O_2N \cdot C_6H_4 \cdot NH_2 \xrightarrow{\text{NaNO}_2, \text{HCl}} p-O_2N \cdot C_6H_4 \cdot N=NCl \xrightarrow{+4e, +4H^\oplus} p-O_2N \cdot C_6H_4 \cdot NH \cdot NH_2
\]

Dissolve 10 g (0.075 mol) of \( p \)-nitroaniline (Expt 6.68) in a mixture of 21 ml of concentrated hydrochloric acid and an equal volume of water, and cool rapidly to \( 0 \)°C in order to obtain the hydrochloride of the base in a fine state of division. Diazotise in the usual way (see Expt 6.70) by the gradual addition of a solution of 5.2 g (0.075 mol) of sodium nitrite in 12 ml of water. Continue the stirring for a few minutes, filter the solution rapidly and add it from a separatory funnel to an ice-cold solution of 41 g (0.156 mol) of sodium sulphite (96% \( \text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O} \)) in 100 ml of water containing 4 g of sodium hydroxide; stir the mixture during the addition which requires about 5 minutes. (If the diazonium solution is added too rapidly, an orange-red precipitate of sodium \( p \)-nitrobenzenediazosulphonate is produced, and is apt to form a resin.) Allow the solution to stand for 5 minutes, acidify with 70 ml of concentrated hydrochloric acid and heat on a water bath at 25°C for 3 minutes, when yellow needles commence to separate. Allow to stand overnight, filter off the crystals, heat them with 20 ml of concentrated hydrochloric acid and heat on a water bath for 7 minutes and allow to cool. Filter off the precipitate, consisting of \( p \)-nitrophenylhydrazine hydrochloride and sodium salts, dissolve it in water and treat the solution with a concentrated solution of sodium acetate: the free base will separate out in an almost pure state (7–8 g, 63–72%). The \( p \)-nitrophenylhydrazine may be recrystallised from ethanol and is obtained as light brown crystals, m.p. 158°C (decomp.).

**Experiment 6.93 2,4-DINITROPHENYLHYDRAZINE**

\[
2,4-(O_2N)_2C_6H_3Cl + NH_2NH_2 \rightarrow 2,4-(O_2N)_2C_6H_3 \cdot NH \cdot NH_2
\]

Suspend 35 g (0.27 mol) of finely powdered hydrazine sulphate in 125 ml of hot water contained in a 400-ml beaker, and add, with stirring, 118 g (0.87 mol) of sodium acetate hydrate or 85 g of potassium acetate. Boil the mixture for 5 minutes, cool to about 70°C, add 80 ml of rectified spirit, filter at the pump and wash with 80 ml of hot rectified spirit. Keep the filtered hydrazine solution for the next stage in the preparation.

Equip a 1-litre three-necked flask with a reflux condenser and a sealed mechanical stirrer. Dissolve 50.5 g (0.25 mol) of commercial 1-chloro-2,4-dinitrobenzene (1) in 250 ml of rectified spirit in the flask, add the hydrazine solution and reflux the mixture with stirring for an hour. Most of the reaction product separates during the first 10 minutes. Cool, filter with suction and
wash with 50 ml of warm (60°C) rectified spirit to remove unchanged chlorodinitrobenzene, and then with 50 ml of hot water. The resulting 2,4-dinitrophenylhydrazine (30 g, 60%) melts at 191–192°C (decomp.), and is pure enough for most purposes. Distil off half the alcohol from the filtrate and thus obtain a less pure second crop (about 12 g); recrystallise this from butan-1-ol (30 ml per gram). If pure 2,4-dinitrophenylhydrazine is required, recrystallise the total yield from butan-1-ol or from dioxane (10 ml per gram): this melts at 200°C (decomp.).

The following alternative method of preparation is recommended. Dissolve 50 g of purified chlorodinitrobenzene (1) in 100 ml of triethylene glycol (gentle warming may be necessary; alternatively, 125 ml of warm diethylene glycol may be used) in a 600-ml beaker and cool, with mechanical stirring, in an ice bath to 15–18°C. Place 15 ml of commercial 60–65 per cent hydrazine solution in a small separatory funnel supported over the beaker. Add the hydrazine solution to the stirred solution in the beaker at such a rate that the temperature is maintained between 15 and 20°C (20–30 minutes). When the exothermic reaction is over, digest the paste on a boiling water bath with 50 ml of methanol for 15–20 minutes. Cool the reaction mixture, filter with suction and wash with a little methanol. Dry at 100°C. The yield of 2,4-dinitrophenylhydrazine, m.p. 192–193°C (decomp.), is 46 g (93%). The product is pure enough for most purposes: the pure compound may be obtained by recrystallisation from butan-1-ol or from dioxane as described above.

Cognate preparation. 2,4-Dinitroaniline. Place a mixture of 18 g of ammonium acetate and 50 g (0.246 mol) of commercial 1-chloro-2,4-dinitrobenzene (1) in a 250-ml two-necked flask, and fit it with a reflux condenser and inlet tube (at least 2 cm diameter in order to prevent clogging) which terminates just above the surface of the reaction mixture. Half immerse the flask in an oil bath. Pass ammonia gas (from a cylinder) through a bubble counter, which contains a solution of 3 g of potassium hydroxide in 2.5 ml of water, into the mixture. Heat the oil bath to 170°C, and pass the ammonia gas at the rate of 3–4 bubbles per second for 6 hours. Allow the reaction mixture to cool, break up the solid cautiously with a glass rod, add 100 ml of water, heat to boiling and filter while hot. Dissolve the residue in 500 ml of boiling rectified (or industrial) spirit, and add water (c. 150 ml) until the solution becomes turbid; heat until the turbidity disappears and allow the clear solution to cool overnight. Filter the crystals at the pump and dry in an oven. The yield is 35 g (78%), m.p. 176–177°C. To obtain a perfectly pure product, recrystallise again from ethanol and water; use 20 ml of ethanol per gram of solid: 31.5 g of pure 2,4-dinitroaniline, m.p. 180°C, are thus obtained. The p.m.r. spectrum (Me_2CO-d_6; saturated solution, TMS) provides an excellent example of a first-order analysis from which coupling constants may be measured and interrelated: δ 3.08 (s, 2H, NH_2), 7.22 (d, 1H, C_6—H), 8.20 (d of d, 1H, C_3—H) and 8.93 (d, 1H, C_5—H).

Note. (1) It is advisable to recrystallise the commercial chlorodinitrobenzene from ethanol; m.p. 51–52°C.
Experiment 6.94  \(N,N\)-DIPHENYLPIRCRYLHYDRAZINE AND \(N,N\)-DIPHENYLPIRCRYLHYDRAZYL

\[
2\text{Ph}_2\text{N} \cdot \text{NH}_2 + \text{Cl} \cdot \text{C}_6\text{H}_2(\text{NO}_2)_3 \rightarrow \text{Ph}_2\text{N} \cdot \text{NH} \cdot \text{C}_6\text{H}_2(\text{NO}_2)_3 \cdot 2,4,6
\]

Dissolve 7.4 g (0.04 mol) of \(N,N\)-diphenylhydrazine (Expt 6.95) in 10 ml of dry dichloromethane and add a solution of 5 g (0.02 mol) of picryl chloride [1-chloro-2,4,6-trinitrobenzene, (1)] in 40 ml of dry dichloromethane. Shake the mixture, which becomes dark and warm, and set it aside for 1 hour. Cool the suspension in an ice bath, filter off the amine salt and wash it with a little dichloromethane. Concentrate the filtrate and washings to 30 ml (rotary evaporator) and treat the hot concentrate with 60 ml of boiling ethanol. Cool, collect the almost pure diphenylpicrylhydrazine which crystallises and wash it with a little cold ethanol. The yield is 6 g (76\%), m.p. 172–173 °C (decomp.). If desired, the product may be recrystallised from ethyl acetate.

**Conversion to \(N,N\)-diphenylpicrylhydrazyl.** Dissolve 3.95 g (0.01 mol) of the above hydrazine in 60 ml of dry dichloromethane, add 50 g of lead dioxide and 4 g of anhydrous sodium sulphate and shake the mixture mechanically for 1 hour. Filter, and concentrate the deep-violet filtrate on a rotary evaporator. Dilute the residual solution with two volumes of ether, and allow the product to crystallise. Filter off the large black-violet crystals of diphenylpicrylhydrazyl and wash them with ether; the yield is 3.5 g (89\%), m.p. 137–138 °C. The product may be recrystallised from a mixture of dichloromethane and ether.

**Note.** (1) To prepare picryl chloride, dissolve 5 g (0.022 mol) of picric acid in 50 ml of phosphoryl chloride and add dropwise with shaking 3.8 g (4.0 ml, 0.025 mol) of \(N,N\)-diethylaniline. Allow the resulting brown solution to remain at room temperature for 15 minutes and then pour it into 500 ml of iced water. Stir vigorously until the excess of phosphoryl chloride has hydrolysed and the product has solidified; do not allow the temperature to rise above 35–40 °C during hydrolysis, cooling the mixture when necessary in an ice–salt bath. Filter off the almost colourless solid, wash it with cold water and dry it in a desiccator over calcium chloride. The yield of almost pure picryl chloride, m.p. 82 °C, is 5.0 g (92\%).

Experiment 6.95  \(N,N\)-DIPHENYLHYDRAZINE

\[
\text{Ph}_2\text{NH} \xrightarrow{\text{NaNO}_2, \text{HCl}} \text{Ph}_2\text{N} \cdot \text{NO} \xrightarrow{4\text{HI}} \text{Zn; Me} \cdot \text{CO}_2\text{H}} \rightarrow \text{Ph}_2\text{N} \cdot \text{NH}_2
\]

**CAUTION:** *The intermediate in this reaction, as an N-nitrosoamine, is potentially carcinogenic; see Section 2.3.4, p. 49.***

**DiphenylNitrosamine.** Dissolve 17 g (0.1 mol) of pure diphenylamine in 140 ml of warm ethanol; also 8 g (0.116 mol) of sodium nitrite in 12 ml of water. Cool each solution in ice until the temperature falls to 5 °C. Add 12 ml of
concentrated hydrochloric acid slowly and with stirring to the diphenylamine solution, and immediately (otherwise diphenylamine hydrochloride may crystallise out) pour the sodium nitrite solution rapidly into the well-stirred mixture. The temperature soon rises to 20–25 °C and the diphenylnitroamine crystallises out. Cool the mixture in ice-water for 15–20 minutes, filter with suction on a Buchner funnel, wash with water to remove sodium chloride and press well with a wide glass stopper. Recrystallise from rectified spirit. The yield of pure diphenylnitrosamine (pale yellow crystals), m.p. 68 °C, is 17 g (86%).

**N,N-Diphenylhydrazine.** Dissolve 15.8 g (0.08 mol) of diphenylnitrosamine in 72 ml of ethanol in a 250-ml three-necked flask equipped with a stirrer, reflux condenser and dropping funnel. Add 36 g (0.55 mol) of zinc powder and stir vigorously. From the dropping funnel slowly add about 22 ml of glacial acetic acid; cool the flask in a bath of cold water from time to time to moderate the reaction, which is complete when the addition of acetic acid no longer causes an increase in temperature, and when a sample of the supernatant liquid no longer gives a deep blue colour when concentrated hydrochloric acid is added. Filter the warm reaction mixture, wash the residue on the filter with warm ethanol and concentrate the filtrate and washings to 40 ml on a rotary evaporator. Cool in an ice bath, and add slowly with shaking 36 ml of concentrated hydrochloric acid. Collect the blue needles of the phenylhydrazine hydrochloride by suction filtration on a sintered glass funnel, wash them with a little cold 0.5 m hydrochloric acid and suck dry. Suspend the crystals in a little water, cool in an ice bath and add slowly, with shaking and cooling, 36 ml of 25 per cent aqueous sodium hydroxide solution. Extract the liberated base with three 15 ml portions of toluene, dry the combined extracts over anhydrous potassium carbonate and remove the toluene on a rotary evaporator. Distil the residue under reduced pressure, and collect the diphenylhydrazine as a pale yellow oil of b.p. 136–137 °C/1 mmHg; the yield is 7.2 g (50%) (1). The product solidifies on cooling at 0 °C, and after crystallisation at low temperature from light petroleum (b.p. 40–60 °C) has m.p. 35 °C.

**Note.** (1) The product should not be allowed to come into contact with the skin.

### 6.8.3 ARLUREAS AND RELATED COMPOUNDS

*N-Arylureas* are obtained when salts of primary aromatic amines react with solutions of alkali metal cyanates. The process involves the rearrangement of an amine cyanate, and is analogous to Wöhlers’ classical synthesis of urea from ammonium cyanate.

\[
\text{Ar}^+\text{NH}_2\overset{\text{CNO}}{\rightarrow} \text{Ar}^+\text{NH}^+\text{CONH}_2
\]

The reaction is most conveniently carried out by warming the amine in aqueous solution with the equivalent quantity of sodium cyanate and an excess of acetic acid (Expt 6.96, *Method 1*).

In an alternative synthesis (Expt 6.96, *Method 2*), which is also convenient for the synthesis of alkylureas, the amine hydrochloride is heated in aqueous solution with urea. This reaction also probably involves the amine cyanate since in aqueous solution urea serves as a source of ammonium cyanate.
H₂N·CO·NH₂ ↔ NH₄·CNO

In the case of the synthesis of phenylurea, some sym.-diphenylurea (carbanilide) is also formed and the quantity increases with continued refluxing.

\[ \text{Ar·NH·CO·NH₂} + \text{ArNH₃Cl} \rightarrow \text{Ar·NH·CO·NH·Ar} + \text{NH₄Cl} \]

The diarylurea is very sparingly water-soluble and is therefore easily separated from the monoarylurea which is readily soluble. Diarylurea formation is less extensive when ring-substituted anilines are used.

\[ \text{sym.-Diarylthioureas} \ (3) \] (e.g. sym.-diphenylthiourea or thiocarbanilide, Expt 6.97) are prepared by heating a mixture of a primary aromatic amine and carbon disulphide in absolute ethanol. Intermediates in the reaction sequence are the aryldithiocarbamic acid (1) and the aryl isothiocyanate (2), thus:

\[ \text{Ar·NH₂} + S=C=S \rightarrow \text{Ar·NH·C·SH} \overset{\text{H₂S}}{\rightarrow} \text{Ar·N=C=S} \]

\[ \text{Ar·N=C=S} \overset{\text{H⁺, H₂O}}{\rightarrow} \text{Ar·NH·C·S·NH·Ar} \]

\[ \text{H₂NAr} \]

Upon heating the diarylthiourea with concentrated hydrochloric acid, it is partly converted into the aryl isothiocyanate (e.g. phenyl isothiocyanate or phenyl mustard oil, Expt 6.98, Method 1). A little hydrogen sulphide is evolved in a side reaction forming diphenylcarbodi-imide (4) which undergoes nucleophilic addition of aniline to yield triphenylguanidine (5), isolated from the reaction mixture as the hydrochloride.

\[ \text{Ph·N=C=N·Ph} \overset{\text{H₂S}}{\leftrightarrow} \text{Ph·NH·C·S·NH·Ph} \overset{\text{Ph·NH₂}}{\rightarrow} \text{Ph·N=C=S} \]

\[ \text{Ph·N=C=S} \overset{\text{HCl}}{\rightarrow} [\text{Ph·NH=C(NH·Ph)₂}]^+ \text{Cl⁻} \]

Phenyl isothiocyanate may be prepared in quantity (Expt 6.98, Method 2) by allowing aniline to react with carbon disulphide to form phenyldithiocarbamic acid (cf. 1), which is isolated as the ammonium salt. Treatment of the latter with lead nitrate removes the elements of hydrogen sulphide to produce phenyl isothiocyanate. As indicated in the preparation of p-bromophenyl isothiocyanate which is given as a further example, a slightly modified procedure which requires the use of rectified spirit as a reaction solvent is necessary in order to obtain good yields of isothiocyanates from substituted anilines.

**Experiment 6.96 PHENYLUREA**

**Method 1**

\[ \text{Ph·NH₂} + \text{NaCNO} + \text{Me·CO₂H} \rightarrow \text{Ph·NH·CO·NH₂} + \text{Me·CO₂Na} \]
Method 2

\[ \text{Ph} \cdot \text{H}_3 \cdot \text{Cl} + \text{NH}_2 \cdot \text{CO} \cdot \text{NH}_2 \rightarrow \text{Ph} \cdot \text{NH} \cdot \text{CO} \cdot \text{NH}_2 + \text{NH}_4 \text{Cl} \]

**Method 1.** Dissolve 9.3 g (9.1 ml, 0.1 mol) of aniline in 10 ml of glacial acetic acid diluted to 100 ml contained in a 250-ml beaker or conical flask, and add with stirring or shaking a solution of 6.5 g (0.1 mol) of sodium cyanate in 50 ml of warm water. Allow to stand for 30 minutes, then cool in ice, and allow to stand for a further 30 minutes. Filter at the pump, wash with water and dry at 100 °C. The resulting phenylurea is generally colourless and has a m.p. of 148 °C (i.e. is pure): the yield is 11 g (81%). If the colour or the m.p. of the product is not quite satisfactory, recrystallise it from boiling water (10 ml per gram) with the aid of decolourising charcoal.

**Method 2.** Dissolve 65 g (0.5 mol) of aniline hydrochloride and 120 g (2 mol) of urea in 200 ml of water contained in a 1-litre round-bottomed flask; filter the solution, if necessary. Add 4 ml of concentrated hydrochloric acid and 4 ml of glacial acetic acid. Fit a reflux condenser to the flask, introduce a few fragments of broken porcelain and boil the mixture for 30 minutes. Fine white crystals (largely sym.-diphenylurea) appear after about 15 minutes and gradually increase in amount as the refluxing is continued. Cool the flask in ice and filter with suction. Separate the mixture of phenylurea and diphenylurea (c. 42 g) by boiling with 500 ml of water and filter at the pump through a preheated Buchner funnel into a warm flask; cool the filtrate, collect the phenylurea, drain well and dry in the steam oven. The phenylurea melts at 146–147 °C and weighs 30 g (44%); recrystallisation from hot water raises the m.p. to 148 °C. The crude diphenylurea (residue from first recrystallisation after drying at 100 °C) has m.p. 241 °C and weighs 10 g (19%); recrystallisation from glacial acetic acid or ethyl acetate with the addition of a little decolourising carbon gives a colourless product, m.p. 242 °C.

**Cognate preparations.** **p-Tolylurea (Method 1).** Dissolve 10.7 g (0.1 mol) of p-toluidine in a warm mixture of 10 ml of glacial acetic acid and 50 ml of water, and then dilute with 150 ml of hot water. Introduce, with stirring or shaking, a solution of 6.5 g (0.1 mol) of sodium cyanate in 50 ml of hot water. The p-tolylurea precipitates almost immediately. Allow to stand several hours, filter at the pump, wash with water and dry. The yield of p-tolylurea, m.p. 180–180.5 °C, is 14 g (85%). Recrystallise from aqueous ethanol; the resulting p-tolylurea melts sharply at 181 °C.

**p-Bromophenylurea.** Proceed as for p-tolylurea (Method 1), but use 17.2 g (0.1 mol) of p-bromoaniline dissolved in a mixture of 50 ml of glacial acetic acid and 100 ml of water at 35 °C; add gradually a solution of 6.5 g (0.1 mol) of sodium cyanate in 50 ml of water at 35 °C. The yield of crude p-bromophenylurea is 19 g (88%); m.p. 227 °C. Recrystallise from 90 per cent aqueous ethanol; m.p. 228 °C. The m.p. depends somewhat upon the rate of heating.

**p-Methoxyphenylurea.** Proceed as for phenylurea, Method 2, but use 79 g (0.5 mol) of p-anisidine hydrochloride in place of 65 g of aniline hydrochloride; reflux the mixture for 1 hour. Cool the reaction mixture slowly to 0 °C, filter and recrystallise from boiling water. The yield of p-methoxyphenylurea, m.p. 168 °C, is 60 g (72%).
p-Ethoxyphenylurea. Proceed as for phenylurea, Method 2, but use 87 g (0.5 mol) of p-phenetidine hydrochloride; reflux the mixture for 45–90 minutes. The product commences to separate after 20–30 minutes and increases rapidly until the entire contents of the flask suddenly set to a solid mass: withdraw the source of heat immediately at this point. Cool to room temperature, add 150 ml of water, stir, filter with suction and wash with cold water. Suspend the solid in 2 litres of boiling water, add 1 g of decolourising carbon, boil for 5 minutes and filter through a hot water funnel; cool the colourless filtrate slowly to 0 °C, collect the solid which separates and dry at 100 °C. The yield of p-ethoxyphenylurea, m.p. 174 °C, is 60 g (67%).

Experiment 6.97 THIOCARBANILIDE (sym.-Diphenylthiourea)

\[
2\text{Ph}\cdot \text{NH}_2 + \text{CS}_2 \xrightarrow{\text{EtOH}} \text{S} = \text{C(} \text{NH} \cdot \text{Ph})_2 + \text{H}_2\text{S}
\]

In a 1-litre round-bottomed flask provided with an efficient double surface condenser, place 40 g (39 ml, 0.43 mol) of aniline, 50 g (40 ml, 0.66 mol) of carbon disulphide (CAUTION: flammable) (1) and 50 g (63.5 ml) of absolute ethanol (2). Set up the apparatus in the fume cupboard or attach an absorption device to the top of the condenser (see Fig. 2.61) to absorb the hydrogen sulphide which is evolved. Heat upon an electrically heated water bath or upon a steam bath for 8 hours or until the contents of the flask solidify. When the reaction is complete, arrange the condenser for downward distillation and remove the excess of carbon disulphide and alcohol (CAUTION: flammable; there must be no flame near the receiver). Shake the residue in the flask with excess of dilute hydrochloric acid (1:10) to remove any aniline present, filter at the pump, wash with water and drain well. Dry in the steam oven. The yield of crude product, which is quite satisfactory for the preparation of phenyl isothiocyanate (Expt 6.98), is 40–45 g (81–91%). Recrystallise the crude thiocarbanilide by dissolving it, under reflux, in boiling rectified spirit (filter through a hot water funnel if the solution is not clear), and add hot water until the solution just becomes cloudy and allow to cool. Pure sym.-diphenylthiourea separates in colourless needles, m.p. 154 °C.

Notes. (1) No flames may be present in the vicinity; read Section 2.3.2, p. 39.
(2) The addition of powdered potassium hydroxide (about 20 per cent of the weight of the carbon disulphide) reduces the refluxing period necessary to complete the reaction.

Experiment 6.98 PHENYL ISOTHIOCYANATE

Method 1

\[
\text{S} = \text{C(} \text{NH} \cdot \text{Ph})_2 \xrightarrow{\text{HCl}} \text{Ph} \cdot \text{N} = \text{C} = \text{S} + \text{Ph} \cdot \text{NH}_2
\]

Method 2

\[
\text{Ph} \cdot \text{NH}_2 + \text{CS}_2 \rightarrow \text{Ph} \cdot \text{NH} \cdot \text{CS} \cdot \text{SNH}_4 \xrightarrow{\text{Pb(NO}_3)_2} \text{Ph} \cdot \text{N} = \text{C} = \text{S} + \text{NH}_4\text{NO}_3 + \text{HNO}_3 + \text{PbS}
\]

Method 1. Place 25 g (0.11 mol) of crude thiocarbanilide (Expt 6.97) and 100 ml of concentrated hydrochloric acid in a 250-ml flask; fit a reflux
condenser and reflux gently in the fume cupboard for 30 minutes. Distil the mixture until the oily phenyl isothiocyanate has all passed over; the volume remaining in the flask will be 25–30 ml. Crystals of triphenylguanidine hydrochloride may appear in the distilling flask during the latter part of the distillation. Dilute the distillate with an equal volume of water, and extract the isocyanate with ether; wash the extract with a little sodium carbonate solution, and dry over anhydrous calcium chloride or magnesium sulphate. Remove the ether on a rotary evaporator and distil the residual oil, collecting the phenyl isothiocyanate at 217–220 °C (1). The yield is 10 g (67.5%).

To isolate the triphenylguanidine formed as a by-product dilute the residue in the flask with 50 ml of water, add 2–3 g of decolourising carbon, warm and filter. Cool the solution in ice, and filter off the hydrochloride at the pump. Dissolve it in the minimum volume of hot water, render the solution alkaline with sodium hydroxide and allow to cool. Filter off the free base (triphenylguanidine), and recrystallise it from ethanol; it separates in colourless crystals, m.p. 144 °C. The yield is 3 g.

Note. (1) It may also be distilled under diminished pressure, b.p. 95 °C/12 mmHg.

Method 2. Equip a 500-ml three-necked flask with a powerful mechanical stirrer and a separatory funnel; leave the third neck open or loosely stoppered. Introduce, while the flask is cooled in a freezing mixture of ice and salt, 90 ml of concentrated ammonia solution (d 0.88) and 54 g (43 ml, 0.71 mol) of pure carbon disulphide (1). Stir the mixture and run in 56 g (55 ml, 0.60 mol) of aniline from the separatory funnel during about 20 minutes; stir for a further 30 minutes, and allow to stand for another 30 minutes. A heavy precipitate of ammonium phenylthiocarbamate separates. Transfer the salt to a 5-litre round-bottomed flask by four extractions with 200 ml portions of water. Add to the resulting solution, with constant stirring, a solution of 200 g (0.605 mol) of lead nitrate in 400 ml of water; lead sulphide precipitates. Steam distil the mixture into a receiver containing 10 ml of c. 0.5 M sulphuric acid as long as organic material passes over (2–3 litres of distillate). Separate the oil, dry it over anhydrous calcium chloride or magnesium sulphate and distil under diminished pressure. Collect the phenyl isothiocyanate at 120–121 °C/35 mmHg or at 95 °C (12 mmHg). The yield is 62 g (76%).

Note. (1) CAUTION, see Expt 6.97.

Cognate preparation. p-Bromophenyl isothiocyanate (Method 2). Add 41 ml of concentrated ammonia solution (d 0.88) slowly with stirring to a solution of 45 g (0.26 mol) of p-bromoaniline (Expt 6.67), 30 g (24 ml, 0.396 mol) of carbon disulphide and 40 ml of rectified spirit at 10–15 °C. Considerable heat is evolved; cool the flask in a freezing mixture from time to time so that the temperature does not rise above 30 °C. The original milky suspension becomes clear and the intermediate dithiocarbamate soon crystallises out. Allow to stand overnight, filter the crystals, wash with a little ether, dissolve in 1500 ml of water and stir mechanically while a solution of 87 g (0.262 mol) of lead nitrate in 175 ml of water is slowly added. Continue the stirring for 20 minutes, and isolate the p-bromophenyl isothiocyanate by steam distillation into a receiver containing 5 ml of c. 0.5 M sulphuric acid; if the substance solidifies in the condenser, stop the cooling water until the solid has melted
and run into the receiver. Filter the cold solid product, wash with a little water and dry in the air upon filter paper. The yield is 15 g (50%), m.p. 61 °C.

6.9 PHENOLS AND PHENYL ETHERS

1. Methods for the introduction of a hydroxyl group into an aromatic ring by:
   (a) replacement of a sulphonic acid group (Expt 6.99); (b) replacement of a halogen (Expts 6.100 and 6.101); and (c) replacement of a diazo group (see Expt 6.69).

2. Substitution reactions of phenols: (a) nitrosation and nitration (Expts 6.102 to 6.104); (b) halogenation (Expts 6.105 and 6.106); and (c) acylation and alkylation (Expts 6.107 and 6.108).

Methods for the protection of the phenolic hydroxyl group are considered in Section 6.9.4, p. 988.

SUMMARY OF RETROSYNTHETIC STRATEGIES

C—O Disconnections (methods 1(a)–(c) and 3), e.g.

\[
\begin{align*}
\text{OH} & \iff \text{OH} \equiv \text{Ph-SO}_2\text{H}, \text{PhX}, \text{or} \text{Ph-N}_2^+ + \text{OH}/\text{H}_2\text{O} \\
& \text{(TM)}
\end{align*}
\]

\[
\begin{align*}
\text{O}^R & \iff \text{R} \equiv \text{PhOH} + \text{RX} \\
& \text{(TM)}
\end{align*}
\]

C—N, C—X, and C—C Disconnections (methods 2(a)–(c)), e.g.

\[
\begin{align*}
\text{OH} & \iff \text{NO}_2^-(\text{NO}) \equiv \text{OH} + \text{NO}_2^-(\text{HNO}_2/\text{HNO}_3) \\
& \text{(TM)}
\end{align*}
\]

\[
\begin{align*}
\text{OH} & \iff \text{X} \equiv \text{X}(\text{X}_2) \\
& \text{(TM)}
\end{align*}
\]
SPECTROSCOPIC FEATURES

Phenols, wherein the hydroxyl group is directly attached to the aromatic nucleus, exhibit in their i.r. absorption spectra strong absorption (3400–3600 cm⁻¹) arising from the O—H stretching vibrations. A full discussion of this and other characteristic absorptions due to the C—O stretching and the O—H bending vibrations, and the assignment of the substitution pattern from the absorption in the longer wavelength region is given on p. 286. The important feature of hydrogen bonding (intra- and inter-molecular) must be noted, m-cresol being an illustrative example (Fig. 3.22). The absorption frequency of the low field signal of the oxygen-bound proton in the p.m.r. spectrum of a phenol depends on the extent of hydrogen bonding, but it may be distinguished from other low-field signals since the absorption disappears after appropriate treatment of the sample with deuterium oxide (p. 348). Aromatic substitution patterns are confirmed by inspection of the appropriate region of the p.m.r. spectrum. Further descriptive accounts of structural assignments are to be found in the preparative examples below which also include an analysis of the important fragmentation patterns observed in the m.s. (see also p. 375). The presence of a hydroxyl group in an aromatic nucleus results in a bathochromic shift of the absorption of the aromatic system in the u.v.—visible; this shift becomes enhanced when a nitro group is also present p. 392).

Concerning phenyl ethers, the i.r. spectrum of anisole (Fig. 3.25), its p.m.r. spectrum (Fig. 3.46) and ¹³C-n.m.r. spectrum (Fig. 3.54) are discussed on pp. 325, and 337 respectively. Further illustrative analyses are included in some of the preparative examples below which also include a discussion of relevant m.s.
6.9.1 METHODS FOR THE INTRODUCTION OF A HYDROXYL GROUP INTO AN AROMATIC RING

REPLACEMENT OF A SULPHONIC ACID GROUP

A fairly general procedure, which has also been used on the industrial scale, involves heating the alkali metal sulphonate with either sodium or potassium hydroxide in the presence of a small amount of water to aid the fusion process. The reaction mechanism may be formulated as a bimolecular nucleophilic addition–elimination sequence.

\[
\begin{align*}
\text{SO}_3^\ominus & \quad \text{OH} \\
\text{mesomeric anion} & \quad \text{SO}_3^\ominus \quad \text{OH} \quad \text{O}^\ominus \\
\text{HSO}_3^\ominus & \quad \text{OH} \\
\end{align*}
\]

The reaction is illustrated by the synthesis of 2-naphthol (Expt 6.99).

Occasionally in the synthesis of phenols by this route oxidation products are formed. A particular example is provided by the alkali fusion of sodium anthraquinone-2-sulphonate during which a second hydroxyl group is introduced into the 1-position, forming the dyestuff alizarin (1) (cognate preparation in Expt 6.99). In the procedure described the oxidation step is promoted by the deliberate introduction of potassium chlorate as an oxidant.

REPLACEMENT OF A HALOGEN

Direct nucleophilic displacement of the halogen in an aryl halide is difficult and hydrolysis to phenols requires high temperatures and pressures; the method is therefore only suitable on the large scale. The presence of a nitro group in the ortho or para position, however, makes the halogen more labile since electron withdrawal by the nitro group in these positions stabilises the intermediate anion by electron delocalisation. \(p\)-Chloronitrobenzene, for example, is hydrolysed to \(p\)-nitrophenol when heated with 15 per cent sodium hydroxide solution at about 150°C.
When two activating nitro groups are present hydrolysis takes place readily with dilute aqueous alkali solution (e.g. 2,4-dinitrophenol, Expt 6.100).

Aryl halides of many different types, including simple unsubstituted halides, may be conveniently converted into phenols by an indirect route involving the preparation of an arylboronic acid and its subsequent oxidation with hydrogen peroxide. The arylboronic acid (3) is normally prepared by reaction of the corresponding arylmagnesium halide with a borate ester (typically tributyl borate) at between -60 and -80°C, to yield the dialkyl boronate ester (2) which is then hydrolysed to the arylboronic acid (3). The latter may be isolated, purified and then oxidised with hydrogen peroxide as described in the preparation of m-cresol (Expt 6.101). Alternatively the crude reaction mixture from the preparation of (3) may be treated directly with hydrogen peroxide.36

\[
\text{Ar} \cdot \text{MgX} \xrightarrow{\text{B(OBu})_3^{-70^\circ C}} \text{Ar} \cdot \text{B(OBu)}_2 \xrightarrow{\text{H}_2\text{O}^{\ominus}} \text{Ar} \cdot \text{B(OH)}_2 \xrightarrow{\text{H}_2\text{O}_2} \text{ArOH}
\]

A convenient purification procedure for an arylboronic acid is to convert it into the trimeric anhydride (4) by removal of water as a benzene azeotrope (see Expt 6.101, Note (3)).

\[
3\text{Ar} \cdot \text{B(OH)}_2 \rightarrow \text{O} \begin{array}{c} \text{O} \\ \text{B} \end{array} \begin{array}{c} \text{O} \\ \text{B} \end{array} \text{O} \begin{array}{c} \text{O} \\ \text{B} \end{array} + 3\text{H}_2\text{O}
\]

REPLACEMENT OF A DIAZOO GROUP

The preparation of phenols by the hydrolysis of diazonium salts with hot aqueous acid, and by a recent milder procedure suitable for diazonium salts having additional acid-sensitive groups, is discussed in Section 6.7.1, p. 922, and illustrated in Expt 6.69. Although these methods enable an aromatic hydrocarbon system to be converted in good yield into a phenol via the corresponding nitro and amino derivatives, the shorter route involving the alkaline fusion of the sulphonic acid discussed above may often be preferred.

Experiment 6.99 2-NAPHTHOL

\[
\begin{align*}
2\text{-C}_{10}\text{H}_7\cdot\text{SO}_3\text{Na} & \xrightarrow{(i) \text{ KOH}} (ii) \text{ H}^{\oplus} \xrightarrow{} 2\text{-C}_{10}\text{H}_7\text{OH}
\end{align*}
\]

CAUTION: This preparation should be carried out in a fume cupboard with the window protecting the face.

971
Support a 250-ml nickel, copper (better silver-plated copper) or iron crucible or beaker in a large circular hole in a sheet of heat resistant board resting on a tripod. Prepare a case of nickel or copper to surround a 360 °C thermometer for about two-thirds of its length; this may be done either by cutting a suitable length of nickel or copper tubing already closed at one end, or by hammering down the end of the open tube and folding over the flat part in a vice. Fit a large cork around the top of the tube; this will serve for handling the tube containing the thermometer when it is subsequently used for stirring the molten alkali. Since some splattering of the latter cannot generally be avoided, goggles, gloves and a well-fitting laboratory coat must be worn.

Place 120 g (2.15 mol) of potassium hydroxide sticks or pellets (1) together with 5 ml of water in the crucible, and heat with a Bunsen burner until it melts. When the temperature reaches about 250 °C, remove the flame, and quickly add with stirring 50 g (0.22 mol) of finely powdered sodium naphthalene-2-sulphonate (Expt 6.38). Replace the flame, stir the stiff pasty mass and continue the heating so that the temperature rises to 300 °C in 5–10 minutes. Stir the mixture continuously; there is some frothing at first and at about 300 °C the mass suddenly becomes a clear, mobile, brown oil of the potassium salt of 2-naphthol floating on a pasty mass of alkali. Raise the temperature during 5 minutes to 310 °C, remove the flame, push down the material from the side of the crucible and reheat to 310 °C for about 2 minutes, and then allow the melt to cool. Do not permit the melt to solidify completely. When it becomes pasty, ladle it out in small portions (with a nickel spatula, ‘spoon’ end) into a 1-litre beaker half-filled with crushed ice. Extract the residual material in the crucible with water and add it to the contents of the beaker. Precipitate the 2-naphthol by adding concentrated hydrochloric acid slowly and with stirring (fume cupboard: SO₂); if the 2-naphthol separates in a finely divided form, warm until the particles coagulate. Cool in ice, filter at the pump and transfer the precipitate to a beaker containing cold water. Add just sufficient 5 per cent sodium hydroxide solution to dissolve the solid and also 1 g of sodium dithionite (Na₂S₂O₄) to prevent oxidation, and filter from traces of insoluble matter. Precipitate the 2-naphthol with acetic acid, warm to produce a more readily filterable form of the precipitate, cool in ice and filter the product. Dry in the air upon filter paper. The yield is 25 g (80%), m.p. 122 °C. If the m.p. is unsatisfactory, recrystallise from water, dilute ethanol or carbon tetrachloride.

Note. (1) Sodium hydroxide may replace potassium hydroxide in this preparation; 150 g together with 15 ml of water are required. The sulphonate is stirred in when the temperature reaches 280 °C and the reaction is complete at 310–320 °C.

Cognate preparation. Alizarin. Dissolve successively in 75 ml of water 6 g (0.049 mol) of potassium chlorate, 20 g (0.065 mol) of sodium anthraquinone-2-sulphonate (Expt 6.39) and 75 g of sodium hydroxide. Transfer the mixture to a 500-ml autoclave (compare Section 2.17.2, p. 97) and heat for 20 hours at 170 °C. After cooling, scrape out the violet-coloured mass and extract it three or four times with 100 ml portions of boiling water. Acidify the filtered extract with hydrochloric acid. When cold, filter the orange precipitate of alizarin at the pump, wash it thoroughly with cold water and dry at 100 °C. The yield of alizarin is 14 g (90%). It may be purified by recrystallisation
from glacial acetic acid or by sublimation. The pure compound has m.p.
289 °C.

Experiment 6.100 2,4-DINITROPHENOL

\[ 2,4-(\text{NO}_2)\text{C}_6\text{H}_3\text{Cl} \rightarrow 2,4-(\text{NO}_2)\text{C}_6\text{H}_3\text{OH} \]

In a 1-litre round-bottomed flask equipped with a reflux condenser place a
solution of 62.5 g (0.6 mol) of anhydrous sodium carbonate in 500 ml of water
and add 50 g (0.25 mol) of commercial 1-chloro-2,4-dinitrobenzene. Reflux
the mixture for 24 hours or until the oil passes into solution. Acidify the
yellow solution with hydrochloric acid and, when cold, filter the crystalline
dinitrophenol which has separated. Dry the product upon filter paper in the
air. The yield is 42 g (91%). If the m.p. differs appreciably from 114 °C,
crystallise from ethanol or from water.

The p.m.r. spectrum (DMSO-\(d_6\), TMS) provides an excellent example for
the assignment of absorptions to specific hydrogens from the correlation of
coupling constants; the signals appear at \(\delta\) 7.29 (d, 1H, C6—H), 8.30 (d of d,
1H, C5—H), 8.63 (d, 1H, C3—H), and 12.62 (s, 1H, OH).

Experiment 6.101 \(m\)-CRESOL

\[ m-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{MgX} \xrightarrow{\text{B(OBu)}_2, \text{75 °C}} m-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{B(OBu)}_2 \xrightarrow{\text{H}_2\text{O}} m-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{B(OH)}_2 \xrightarrow{\text{H}_2\text{O}} m-\text{Me} \cdot \text{C}_6\text{H}_4\text{OH} \]

\(m\)-Tolyboronic acid. Equip a thoroughly dried 1-litre flange flask with a low
temperature reading thermometer, and an efficient sealed stirrer unit, and
attach a dropping funnel and a reflux condenser both protected with calcium
chloride guard-tubes. Mount the flask in a Cardice-acetone cooling bath and
add to the flask 40.5 g (0.17) of pure tributyl borate (1) dissolved in 150 ml of
erther (previously dried over sodium wire). Then, with fairly rapid stirring,
add slowly from the dropping funnel a solution of \(m\)-tolylimagnesium
bromide [0.175 mol; (2)] in 450 ml of dry ether. It is essential that the rate of
addition throughout the reaction should be such that the temperature of the
reaction mixture is kept between −70 and −75 °C. As the ethereal solution
of the Grignard reagent is added, a white precipitate is formed immediately
and slowly dissolves; when all of the reagent has been added (about 3 hours),
continue to stir the mixture at −75 °C for a further 2 hours. With continued
stirring, allow the reddish-orange solution to warm slowly to 0 °C, remove
the dropping funnel, condenser and stirrer, stopper the flask and place it in a
refrigerator to attain a temperature of about 5 °C over a period of 12 hours.
Slowly add the cold reaction mixture with efficient stirring to 120 ml of chilled
(0–5 °C) 10 per cent sulphuric acid. Transfer the resultant mixture to a
separating funnel, separate the layers and thoroughly extract the aqueous
phase with four 100 ml portions of ether. Concentrate the combined ether
solutions on a rotary evaporator using a water-bath temperature of 40–45 °C.
To the residual \(m\)-tolyboronic acid in butan-1-ol add 50 ml of water,
followed by 10 per cent aqueous potassium hydroxide solution until the
solution is alkaline to litmus paper. Remove the butanol as an azo trope with
water by concentrating the mixture on a rotary evaporator (water-bath
temperature 40–45 °C). Add further portions of water (25 ml) and repeat the
evaporation until no smell of butanol remains. During these evaporation stages, solid material often separates but this should not be filtered off. Render the residual solution acid to litmus by adding dilute aqueous sulphuric acid and, if necessary, make up the volume to 60 ml by the addition of distilled water. Without separating the precipitated solid, heat the mixture to boiling when the precipitate dissolves and a heavy dark brown oil appears. Decant the hot supernatant solution through a fluted filter paper and extract the oil with four 40 ml portions of boiling water. Combine the hot filtered extracts and cool. Filter off the crystalline m-tolylboronic acid and dry at room temperature by spreading upon filter papers. The yield is 5.9 g (25%) (3).

m-Cresol. In a 250-ml, two-necked round-bottomed flask fitted with an efficient stirrer and a dropping funnel, place 5.4 g (0.040 mol) of m-tolylboronic acid and 100 ml of ether. While stirring the slurry add 30 ml of 10 per cent hydrogen peroxide solution from the dropping funnel over a period of about 5 minutes. The two-phase system in the flask becomes warm as the reaction proceeds. When all the hydrogen peroxide has been added, continue stirring until the contents of the flask have cooled to room temperature (20–30 minutes) and then transfer to a separating funnel. Run off and discard the aqueous layer and wash the ether layer thoroughly with three 30 ml portions of 10 per cent iron(II) ammonium sulphate solution to remove remaining traces of hydrogen peroxide. Extract the product from the ether layer by shaking with three 30 ml portions of 10 per cent aqueous sodium hydroxide solution. Acidify the combined alkaline extracts with concentrated hydrochloric acid and extract the product with three 70 ml portions of ether. Dry the combined ether extracts with calcium sulphate, filter and evaporate on a rotary evaporator. Distil the crude product and collect the m-cresol at 198–202°C. The yield is 2.5 g (58%).

The i.r. spectrum of m-cresol is given on p. 288. The substitution pattern is confirmed from the absorptions in the 600–800 cm⁻¹ [the ortho isomer shows one band at c. 750 cm⁻¹ (5 adj. H's); the para isomer shows absorption at c. 815 cm⁻¹ (2 adj. H's)]. In the p.m.r. spectra (CDCl₃, TMS) of the three isomers the substitution pattern is only clearly defined in the case of the para isomer which shows δ 2.20 (s, 3H, Me), 6.45 (broad s, 1H, OH), 6.69 (d, 2H, ortho-H's to OH), and 6.92 (d, 2H, ortho-H's to Me). The meta and ortho isomers both show complex multiplets in the δ 6.3–7.20 region. The m.s. of all three isomers are very similar having significant fragment ions at m/z 108 (M, base peak), 107 (M – H), 79 (107 – CO), 77 (79 – H₂), and 51 (77 – C₂H₂).

Notes. (1) The tributyl borate is available commercially (Aldrich) and packaged in Sure/Seal™ bottles under nitrogen.
(2) The ethereal solution of m-tolylmagnesium bromide may be prepared by using 20 g (0.175 mol) of m-bromotoluene, 4.2 g (0.175 mol) of magnesium turnings and 450 ml of dry ether (cf. Expt 5.39). When nearly all the magnesium has reacted the solution should be quickly decanted into a dry dropping funnel and addition to the cooled tributyl borate solution begun immediately.
(3) It is not possible to obtain an analytically pure sample of arylboronic acids since, on drying, partial conversion to the trimeric anhydride occurs. A quantitative conversion to the anhydride is achieved in the case of m-tolylboronic acid by heating with forty times its weight of benzene in a flask fitted with a Dean and Stark water separator (Fig. 2.31(a)). When no further water droplets separate the benzene solution
is concentrated to one-quarter volume and cooled. \textit{m}-Tolylboronic anhydride crystallises out and has m.p. 161–162°C. The anhydride may be reconverted to the acid by dissolving it in the minimum quantity of hot water and allowing the solution to cool, whereupon the acid crystallises.

### 6.9.2 SUBSTITUTION REACTIONS OF PHENOLS

The phenolic group is activating and \textit{ortho–para} directing. The electrophilic substitution reactions in the nucleus in: (a) nitrosation and nitration; (b) halogenation and; (c) acylation and alkylation, are therefore particularly facile, and various experimental procedures need to be adopted to control the extent of substitution (cf. substitution reactions of aromatic amines and their acylated derivatives, Sections 6.6.1 and 6.6.2, pp. 906 and 916 respectively).

**NITROSATION AND NITRATION**

Phenol may be converted into a mixture of \textit{o}- and \textit{p}-nitrophenols (Expt 6.102) by reaction with dilute nitric acid; the yield of \textit{p}-nitrophenol is increased if a mixture of sodium nitrate and dilute sulphuric acid is employed. Upon steam distillation of the mixture of nitrophenols, the \textit{ortho} isomer passes over in a substantially pure form; the \textit{para} isomer remains in the distillation flask, and can be readily isolated by extraction with hot 2 per cent hydrochloric acid. The mechanism of the substitution probably involves an electrophilic attack (cf. Section 6.2.1, p. 851) by a nitrosonium ion at a position either \textit{ortho} or \textit{para} to the activating hydroxyl group, to yield a mixture of \textit{o}- and \textit{p}-nitrophenols, which are then oxidised by the nitric acid to the corresponding nitrophenols. The reaction depends upon the presence in the nitric acid of traces of nitrous acid which serve as the source of the nitrosonium ion.

\[
\begin{align*}
\text{Ph-OH} & \quad \text{\textnormal{HNO}_2} \\
\text{Ph-N=O} & \quad \text{Ph-NO} \\
\text{Ph-NO} & \quad \text{HNO}_2
\end{align*}
\]

If the phenol is allowed to react with nitrous acid (generated in an acidified solution of sodium nitrite), the nitrosophenol may be obtained in good yield. An example is provided by the nitrosation of 2-naphthol which yields 1-nitroso-2-naphthol (Expt 6.103).

By suitably introducing sulphonic acid 'blocking groups', which may subsequently be removed by heating under aqueous acidic conditions, control over the orientation of other substituents introduced into the aromatic nucleus of a phenol may be achieved. The procedure is illustrated by the synthesis of 2-nitroresorcinol (Expt 6.104). In this reaction disulphonation of the dihydric phenol can readily be achieved, the sulphonic acid groups taking up the 4- and 6-positions. When the disulphonic acid is then nitrated the nitro group enters the remaining active site, i.e. the 2-position, removal of the sulphonic acid residues then yields the required 2-nitroresorcinol. In this sequence it is essential that the experimental conditions for the nitration step are as mild as possible (i.e. below 20°C), since more vigorous conditions may result in electrophilic replacement of a sulphonic acid group by a nitro group. This is apparent in the
classical synthesis of 2,4,6-trinitrophenol (picric acid). Thus phenol is first sulphonated to yield a mixture of o- and p-phenolsulphonic acids; nitration of this product with a hot mixture of concentrated nitric acid and concentrated sulphuric acid results in the introduction of a nitro group into all the ortho and para activated positions with displacement of the sulphonic acid group. The direct nitration of phenol to the trinitro derivative in good yield is not possible since much of the starting material is oxidatively destroyed.

\[
\text{OH} \quad \text{H}_2\text{SO}_4 \rightarrow \quad \text{OH} \quad \text{SO}_3\text{H} \quad \text{OH} \quad \text{SO}_3\text{H} \quad \text{OH} \quad \text{NO}_2
\]

**HALOGENATION**

When treated with bromine water an aqueous solution of phenol gives an immediate precipitate of 2,4,6-tribromophenol (Section 9.6.6, p. 1251), owing to the powerfully activating influence of the negatively charged oxygen in the phenoxy ion.

\[
\text{OH} \quad \text{H}_2\text{O} \quad \text{Br}_2 \quad \text{OH} \quad \text{Br} \quad \text{Br} \quad \text{OH} \quad \text{Br}
\]

The monobromination of phenol can, however, be achieved by using solutions of bromine in non-polar solvents such as carbon disulphide and carbon tetrachloride at low temperature (0–5 °C). The product is almost exclusively the para isomer (Expt 6.105).

o-Bromophenol is conveniently prepared by first sulphonating phenol with excess of concentrated sulphuric acid to yield phenol-2,4-disulphonic acid, neutralising with sodium hydroxide, heating the solution of the sodium salt with 1 mol of bromine and then removing the sulphonic acid groups by treatment with aqueous sulphuric acid at 200 °C. The sequence is described and formulated in Expt 6.106.

**ACYLATION AND ALKYLATION**

The various methods for introducing a formyl group (—CO·H) into a phenolic nucleus are discussed in Section 6.10.1, p. 990. The formation of phenolic ketones (e.g. HO·C₆H₄·CO·R) by the standard Friedel–Crafts acylation procedure (i.e. the reaction of a phenol with an acid chloride in the presence of aluminium chloride) does not always give acceptable yields except in the case of polyhydroxyphenols (p. 1006). The preferred method is to convert the phenol into the phenyl ester and to subject this to rearrangement (the Fries reaction) in the presence of aluminium chloride.
Experimental procedures are given in Expt 6.107 for \( o \)- and \( p \)-hydroxypropiophenones (\( R = \text{Et} \)). The \textit{ortho–para} ratio in the product is influenced by the nature of the alkyl residue, the temperature, the solvent and the amount of aluminium chloride used: generally low temperatures favour the formation of \( p \)-hydroxyketones. It is usually possible to separate the two hydroxyketones by fractional distillation under reduced pressure through an efficient fractionating column or by steam distillation; the \textit{ortho} isomers, being chelated, are more steam volatile. It may be mentioned that Clemmensen reduction (cf. Sections 5.1.3, p. 476 and 6.1.1, p. 826) of the hydroxyketones affords an excellent route to alkyl phenols.

\[
\text{HO-}C_6H_4\cdot\text{CO-R} \xrightarrow{\text{Zn/Hg/HCl}} \text{HO-}C_6H_4\cdot\text{CH}_2\cdot\text{R}
\]

2,5-Dihydroxyacetophenone (6) (cognate preparation in Expt 6.107), which cannot be prepared by a Friedel–Crafts acetylation of hydroquinone, is obtained in good yield when hydroquinone diacetate (5) is heated in the presence of 3.3 mol of aluminium chloride.

The details of the mechanism of the Fries rearrangement are uncertain but the reaction probably involves the formation and migration of the acylium ion (7).
When phenol is treated with allyl bromide in the presence of potassium carbonate and acetone, the product is almost entirely allyl phenyl ether (Expt 6.110). This undergoes ready thermal rearrangement to give 2-allylphenol (Expt 6.108), which is an example of the Claisen rearrangement. The mechanism of this intramolecular rearrangement involves a cyclic transition state (8) as formulated below, and is designated as a [3,3] sigmatropic shift; the numbers give the location of the atoms which are joined by the new σ-bond relative to the bond undergoing fission.

A protropic shift may be induced to effect double bond migration in the side chain by heating the allyl phenyl ether with methanolic potassium hydroxide when 2-(prop-1-enyl) phenol is formed (Expt 6.108).

Experiment 6.102  o- AND p-NITROPHENOLS

PhOH $\xrightarrow{\text{dil } \text{HNO}_3}$ o- and p-$\text{O}_2\text{N-C}_6\text{H}_4\text{OH}$

Cautiously add 250 g (136 ml, c. 2.5 mol) of concentrated sulphuric acid in a thin stream and with stirring to 400 ml of water contained in a 1-litre three-necked flask, and then dissolve 150 g (1.75 mol) of sodium nitrate in the diluted acid. Cool in a bath of ice or iced water. Melt 94 g (1 mol) of phenol (CAUTION) with 20 ml of water, and add this dropwise from a separatory funnel to the vigorously stirred mixture in the flask; maintain the temperature at about 20 °C. Continue the stirring for a further 2 hours after all the phenol has been added. Pour off the mother-liquor from the resinous mixture of nitro compounds. Melt the residue with 500 ml of water, shake and allow the contents of the flask to settle. Pour off the wash liquor and repeat the washing at least two or three times to ensure the complete removal of any residual acid. Steam distil the mixture (Fig. 2.102) until no more o-nitrophenol passes over; if the latter tends to solidify in the condenser, turn
off the cooling water temporarily. Collect the distillate in cold water, filter at the pump and drain thoroughly. Dry upon filter paper in the air. The yield of o-nitrophenol, m.p. 46°C (1), is 50 g (36%).

Allow the residue in the flask to cool during 2 hours and then cool in ice for 15–30 minutes. Filter off the crude p-nitrophenol and boil it with 1 litre of 2 per cent hydrochloric acid (2) together with about 5 g of decolourising charcoal for at least 10 minutes. Filter through a hot water funnel (or through a preheated Buchner funnel): allow the filtrate to crystallise overnight. Filter off the almost colourless needles and dry them upon filter paper. The yield of p-nitrophenol, m.p. 112°C, is 35 g (25%). Further small quantities may be obtained by concentrating the mother-liquor and also by repeating the extraction of the residue with 2 per cent hydrochloric acid.

The p.m.r. spectra of the two isomers confirm their substitution patterns. In the case of p-nitrophenol (Me₂CO, TMS) signals are observed at δ 7.06 (d, 2H, ortho-H's to OH), 8.15 (d, 2H, ortho-H's to NO₂) and 9.32 (broad s, 1H, OH); with o-nitrophenol the four dissimilar aromatic protons give rise to complex coupling leading to signals at δ 6.8–7.2 (m, 2H, C₅,₆—H), 7.51 (m, 1H, C₄—H), 8.00 (d of d, 1H, C₃—H), and 10.46 (s, 1H, OH).

Notes. (1) If the m.p. is not quite satisfactory, dissolve the o-nitrophenol in hot ethanol (or industrial spirit) under reflux, add hot water drop by drop until a cloudiness just appears and allow to cool spontaneously. Filter off the bright yellow crystals and dry between filter paper.
(2) It is not advisable to treat the crude p-nitrophenol with sodium hydroxide solution in order to convert it into the sodium derivative: alkali causes extensive resinification.

**Experiment 6.103 1-NITROSO-2-NAPHTHOL**

\[
\text{H}_2\text{NNO}_2 + \text{HNO}_2 \rightarrow \text{H}_2\text{NNO}_2 + \text{CO}_2
\]

Dissolve 100 g (0.7 mol) of 2-naphthol (Expt 6.99) in a warm solution of 28 g (0.7 mol) of sodium hydroxide in 1200 ml of water contained in a 2.5-litre round-bottomed flask fitted with a mechanical stirrer. Cool the solution to 0°C in a bath of ice and salt, and add 50 g (0.725 mol) of powdered sodium nitrite. Start the stirrer and add, by means of a separatory funnel supported above the flask, 220 g (166.5 ml) of 5.6 M sulphuric acid at such a rate that the whole is added during 90 minutes and the temperature is kept at 0°C; add crushed ice (about 200 g in all) from time to time in order to maintain the temperature at 0°C. The solution should react acid to Congo red paper after all the sulphuric acid has been introduced. Stir the mixture for an additional hour; keep the temperature at 0°C. Filter off the 1-nitroso-2-naphthol at the pump and wash it thoroughly with water. Dry the pale yellow product upon filter paper in the air for four days; the colour changes to dark brown and the 1-nitroso-2-naphthol, m.p. 97°C, weighs 130 g. It contains about 10 per cent of its weight of moisture, but is otherwise almost pure. The moisture may be removed by leaving the air-dried compound in a desiccator for 24 hours; the yield is 115 g (96%), m.p. 106°C.

If 1-nitroso-2-naphthol is required in the crystalline condition, recrystal-
lise it from light petroleum (b.p. 60–80°C, 7.5 ml per gram); the recovery is almost quantitative, m.p. 106°C.

**Experiment 6.104 2-NITRORESORCINOL**

Carefully add 25 ml of concentrated sulphuric acid (98%) to 5.5 g (0.05 mol) of resorcinol contained in a 150-ml beaker while stirring the mixture continuously with a glass rod; then warm the mixture to 60–65°C on a water bath and allow to stand for 15 minutes. Cool the slurry of the 4,6-disulphonic acid which is obtained to 0–10°C and add carefully from a well-supported dropping funnel a cooled mixture of 4 ml of concentrated nitric acid (72%) and 5.6 ml of concentrated sulphuric acid. It is essential that the temperature of the reaction mixture should not be allowed to exceed 20°C. When the addition is complete, allow the mixture to stand for a further 15 minutes, and then cautiously add 15 g of crushed ice. External cooling may be also necessary to keep the temperature below 20°C.

Transfer the resulting yellow-brown solution to a 250-ml round-bottomed flask and steam distil (Fig. 2.102); collect about 250 ml of distillate, cool and filter off the precipitated yellow-orange 2-nitroresorcinol. A further quantity of crude material may be obtained by extracting the filtered steam distillate with ether. The yield of crude material is 2.2 g (28%) of m.p. 76°C; the m.p. may be raised to 85°C by recrystallisation from aqueous ethanol. The p.m.r. spectrum (polysol-d) should be recorded and the signals assigned to the aromatic protons.

**Experiment 6.105 p-BROMOPHENOL**

\[
\text{C}_6\text{H}_5\text{OH} \xrightarrow{\text{Br}_2, \text{CS}_2} (\alpha) + p-\text{Br} \cdot \text{C}_6\text{H}_4\text{OH}
\]

**CAUTION:** This preparation should be conducted in an efficient fume cupboard.

Equip a 500-ml three-necked flask with a reflux condenser, a mechanical stirrer and a separatory funnel. Attach to the top of the condenser a calcium chloride guard-tube leading by means of a glass tube to a funnel just immersed in a beaker holding about 150 ml of water for absorption of hydrogen bromide (compare Fig. 2.61(a)) (1). Place 94 g (1 mol) of phenol dissolved in 100 ml of dry carbon disulphide (CAUTION: flammable) in the flask, set the stirrer in motion and cool the flask in a mixture of ice and salt. When the temperature falls below 5°C, add slowly (during about 2 hours) from the separatory funnel a solution of 160 g (51 ml, 1 mol) of bromine (CAUTION) in 50 ml of carbon disulphide. Then arrange the flask for distillation under reduced pressure by inserting a Claisen still-head which incorporates a short fractionating side-arm (compare Fig. 2.108) into the central socket of the three-necked flask; stopper the remaining sockets. Connect a condenser set for downward distillation to the still-head and
attach the device for absorbing the hydrogen bromide evolved to the sidearm of the receiver adapter. Distil off the carbon disulphide at atmospheric pressure on a water bath held at 60 °C. (CAUTION: very low flash point, see Section 2.3.2, p. 40.) Remove the absorption device, insert a capillary leak and a thermometer into the Claisen still-head sockets and continue distillation under reduced pressure (oil bath). Collect two fractions: (a) b.p. below 145 °C/25–30 mmHg which is an inseparable mixture of o- and p-bromophenols (24–33 g), and; (b) b.p. 145–150 °C/25–30 mmHg, which is fairly pure p-bromophenol. The residue in the flask contains some higher boiling 2,4-dibromophenol. The p-bromophenol solidifies on cooling to a solid white mass, which usually contains traces of an oil; this may be removed by spreading on a porous tile or by centrifuging. The dry crystals have m.p. 63 °C; the yield is 140–145 g (81–84%).

The p.m.r. spectrum (CDCl₃, TMS) is characteristic of para substitution showing signals at δ 5.20 (s, 1H, OH), 6.69 (d, 2H, ortho-H's to OH), and 7.30 (d, 2H, ortho-H's to Br); with o-bromophenol (Expt 6.106) the p.m.r. spectrum (CDCl₃, TMS) shows a complex multiplet at δ 6.74–7.43 for the four dissimilar aromatic protons. The m.s. of p-bromophenol shows significant fragment ions at m/z 174, 172 (M, ⁸¹Br, ⁷⁹Br), 93 (M − Br), 65 (93 − CO), and 39 (65 − C₂H₂).

Note. (1) A considerable quantity of constant boiling point hydrobromic acid may be obtained by distilling these solutions.

Experiment 6.106 o-BROMOPHENOL

\[
\text{PhOH} \xrightarrow{\text{H}_2\text{SO}_4, \text{excess}} \text{Br}_2, \text{Na salt} \xrightarrow{\text{Br}_2} \text{PhSO}_3\text{H} \xrightarrow{\text{H}_2\text{SO}_4/\text{H}_2\text{O}, 200 ^\circ\text{C}} 2\text{-Br·C}_6\text{H}_4\text{OH}
\]

In a 1-litre flask, equipped as in the preceding experiment, but omitting the gas absorption device, place a mixture of 31 g (0.33 mol) of phenol (CAUTION) and 116 g (63 ml) of concentrated sulphuric acid, and heat in a boiling water bath for 3 hours with mechanical stirring. Cool to room temperature or below by immersing the flask in ice-water, and then add slowly a solution of 95 g of sodium hydroxide in 235 ml of water: a solid salt may separate, but this will dissolve at a later stage. Replace the separatory funnel by a thermometer, which dips well into the liquid, and support a small dropping funnel over the top of the condenser. Cool the alkaline solution to room temperature, and add 53 g (17 ml) of bromine (CAUTION) from the dropping funnel down the condenser during 20–30 minutes while stirring constantly; permit the temperature to rise to 40–50 °C. Continue the stirring for 30 minutes after the bromine has been introduced: the reaction mixture should still be alkaline and contain only a small amount of suspended matter. The solution must now be evaporated. Arrange the flask assembly so that a rapid stream of air can be passed through the stirred reaction mixture, i.e. replace the thermometer by a wide air leak, connect the condenser for downward distillation using a knee bend and fit a receiver adapter with the
take-off arm connected to the water pump. Heat the flask in an oil bath at 150–155 °C while maintaining a brisk current of air until a thick pasty mass remains (30–40 minutes). Allow to cool and then add 270 ml of concentrated sulphuric acid (fume cupboard: much hydrogen bromide is evolved). Heat the flask in an oil bath at 195–205 °C and pass a current of steam into the mixture (compare Fig. 2.102); this results in the hydrolysis of the sulphonate groups and the bromophenol distils over as a heavy, colourless (or pale yellow) oil. When the distillate is clear, extract it with ether. Dry the ethereal extract with a little magnesium sulphate, remove the ether on a water bath (Fig. 2.101) and distil the residue as rapidly as possible since the bromophenol is somewhat unstable and decomposes appreciably at the high temperature. Collect the fraction, b.p. 195–200 °C (a colourless liquid with a characteristic odour), which is practically pure o-bromophenol. The yield is 25 g (43%). The compound is somewhat unstable and decomposes on standing, becoming brown or red in colour. The p.m.r. spectrum is noted above in comparison with that of p-bromophenol.

**Experiment 6.107 \( o- \) AND \( p- \) HYDROXIPROPIOPHENONES**

\[
\text{Ph} \cdot \text{O} \cdot \text{CO} \cdot \text{Et} \xrightarrow{\text{AKCh}} \text{o-} \text{and} \text{p-HO} \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{Et}
\]

**CAUTION:** *This preparation should be carried out in an efficient fume cupboard.*

Equip a 1-litre three-necked flask with a dropping funnel, a sturdy mechanical stirrer and an efficient double surface reflux condenser, and place 187 g (1.4 mol) of anhydrous aluminium chloride and 200 ml of carbon disulphide in it (CAUTION: see Section 2.3.2, p. 40); attach a gas absorption trap (Fig. 2.61) to the top of the condenser. Stir the suspension and add 188 g (179 ml, 1.25 mol) of phenyl propanoate (Expt 5.149) slowly and at such a rate that the solvent boils vigorously (about 90 minutes). Much hydrogen chloride is evolved and is absorbed by the trap. When all the phenyl propanoate has been introduced, gently reflux the reaction mixture on a water bath until the evolution of hydrogen chloride ceases (about 2 hours). Turn the reflux condenser downwards (compare Fig. 2.98) and distil off the solvent from the water bath (CAUTION: carbon disulphide). Then replace the latter by an oil bath maintained at 140–150 °C and heat, with stirring, for 3 hours. During this period more hydrogen chloride is evolved, the mixture thickens and finally becomes a brown resinous mass; continue the stirring as long as possible. Allow the reaction mixture to cool and decompose the aluminium chloride complex by slowly adding first 150 ml of dilute hydrochloric acid (1 : 1) and then 250 ml of water; much heat is evolved and a dark oil collects on the surface. Allow to stand overnight, when most of the p-hydroxypropiophenone in the upper layer solidifies. Filter this off at the pump, and recrystallise it from 200 ml of methanol; 74 g (39%) of \( p \)-hydroxypropiophenone (a pale yellow solid), m.p. 147 °C, are obtained.

Remove the methanol from the mother-liquors using a rotary evaporator and combine the residue with that obtained by extracting the original filtrate with ether and similarly evaporating. Dissolve the combined residues in 250 ml of 10 per cent sodium hydroxide solution, and extract with two 50 ml portions of ether to remove non-phenolic products. Acidify the alkaline
solution with hydrochloric acid, separate the oily layer, dry it over magnesium sulphate and distil under diminished pressure, preferably from a flask with fractionating side arm (Fig. 2.108). Collect the o-hydroxypropiophenone (65 g, 35%) at 110–115°C/6 mmHg and a further quantity (20 g, 11%) of crude p-hydroxypropiophenone at 140–150°C/11 mmHg.

Record the i.r. spectrum of each isomer and note the absorptions due to the OH and CO stretching vibrations (in particular the effect of hydrogen bonding in the case of the ortho isomer). Each spectrum shows absorptions in the 700–800 cm⁻¹ region which confirms the respective state of substitution. The p.m.r. spectra are easily differentiated: the ortho isomer (CDCl₃, TMS) has signals at δ 1.19 (t, 3H, Me), 2.93 (q, 2H, CH₂), 6.60–7.75 (m, 5H, C₆H₅—H), and 12.13 (s, 1H, OH); the para isomer (DMSO-d₆, TMS) has signals at δ 1.10 (t, 3H, Me), 2.92 (q, 2H, CH₂), 6.90 (d, 2H, ortho-H’s to COEt) and 7.88 (d, 2H, ortho-H’s to OH). In the latter case the hydroxyl proton is not observed.

Cognate preparation. 2,5-Dihydroxyacetophenone. Finely powder a mixture of 40 g (0.2 mol) of dry hydroquinone diacetate (1) and 87 g (0.65 mol) of anhydrous aluminium chloride in a glass mortar and introduce it into a 500-ml round-bottomed flask, fitted with an air condenser protected by a calcium chloride tube and connected to a gas absorption trap (Fig. 2.61). Immerse the flask in an oil bath and heat slowly so that the temperature reaches 110–120°C at the end of about 30 minutes: the evolution of hydrogen chloride then begins. Raise the temperature slowly to 160–165°C and maintain this temperature for 3 hours. Remove the flask from the oil bath and allow to cool. Add 280 g of crushed ice followed by 20 ml of concentrated hydrochloric acid in order to decompose the excess of aluminium chloride. Filter the resulting solid with suction and wash it with two 80 ml portions of cold water. Recrystallise the crude product from 200 ml of 95 per cent ethanol. The yield of pure 2,5-dihydroxyacetophenone, m.p. 202–203°C, is 23 g (58%). Record the p.m.r. spectrum (DMSO-d₆, TMS) and by careful inspection of the magnitude of the coupling constants confirm the following assignment of signals at δ 2.59 (s, 3H, Me), 6.80 (d, 1H, C₃—H, measure J₃,₄ and note that J₃,₆ is negligible), 7.06 (d of d, 1H, measure J₃,₄ and J₄,₆), 7.24 (d, 1H, measure J₄,₆), 9.14 (s, 1H, C₅—OH), and 11.40 (s, 1H, C₆—OH, hydrogen-bonded). Interpret the m.s. which shows significant ions at m/z 152, 137, 123, 109 and 43.

Note. (1) Hydroquinone diacetate may be prepared as follows. Add 1 drop of concentrated sulphuric acid to a mixture of 55 g (0.5 mol) of hydroquinone and 102 g (95 ml, 1 mol) of acetic anhydride in a 500-ml conical flask. Stir the mixture gently by hand; it warms up rapidly and the hydroquinone dissolves. After 5 minutes, pour the clear solution on to 400 ml of crushed ice, filter with suction and wash with 500 ml of water. Recrystallise the solid from 50 per cent aqueous ethanol (c. 400 ml are required). The yield of pure hydroquinone diacetate, m.p. 122°C, is 89 g (91%).
Experiment 6.108 2-ALLYLPHENOL AND 2-(PROP-1-ENYL)PHENOL

2-Allylphenol. Boil 50 g of allyl phenyl ether (Expt 6.110) gently in a round-bottomed flask fitted with an air reflux condenser. Determine the refractive index of the mixture at intervals; the rearrangement is complete and the boiling is stopped when the refractive index ($n_D^{25}$) has risen to 1.55 (about 6 hours are required). Dissolve the product in 100 ml of 5 M sodium hydroxide solution and extract with two 30 ml portions of light petroleum (b.p. 40-60 °C) which removes the small amount of 2-methylidihydrobenzofuran formed as by-product and which is neutral. Carefully acidify the alkaline solution with 5 M hydrochloric acid with cooling and extract the mixture with one 50 ml portion and two 25 ml portions of ether. Dry the extract over anhydrous sodium sulphate and remove the ether with a rotary evaporator. Distil the residue under reduced pressure to give 2-allylphenol, b.p. 103-106 °C/19 mmHg or b.p. 96 °C/13 mmHg; $n_D^{25}$ 1.5440. The yield is 35 g (70%).

Rearrangement to 2-(prop-1-enyl)phenol. Prepare a saturated solution (about 50% w/v) of potassium hydroxide in 60 ml of methanol. Place this solution together with 20 g of 2-allylphenol in a round-bottomed flask fitted with a still-head and condenser set for downward distillation. Arrange a thermometer so that the bulb dips into the mixture and distil the latter slowly until the temperature reaches 110 °C. Remove the still-head, attach an air condenser to the flask and boil the reaction mixture gently under reflux for 6 hours. Cool the mixture, cautiously acidify with concentrated hydrochloric acid and extract the product with three 30-ml portions of ether. Dry the extract, remove the ether and distil the residue under reduced pressure. Collect the 2-(prop-1-enyl)phenol as a fraction, b.p. 110-115 °C/15 mmHg; it crystallises on cooling in an ice bath, yield 15 g (75%). Recrystallisation from dry light petroleum (b.p. 60-80 °C) gives shining needles, m.p. 37 °C. The i.r. and p.m.r. spectra of allyl phenyl ether, 2-allylphenol and 2-(prop-1-enyl)phenol should be recorded and critically compared.

6.9.3 FORMATION OF PHENYL ETHERS

Examples of the preparation of alkyl benzyl ethers by the Williamson synthesis are included in Section 5.6.2, p. 583. An example of an alkyl phenyl ether is provided by the synthesis of phenacetin (Expt 6.109) where p-aminophenol is first converted into its N-acetyl derivative by reaction with slightly more than one equivalent of acetic anhydride. Treatment of the product with ethanolic sodium ethoxide solution followed by ethyl iodide then yields the ethyl ether of N-acetyl-p-phenetidine (phenacetin). This compound is biologically active and has been widely employed for example as an antipyretic and analgesic; however, owing to undesirable side reactions, its use is now restricted.

The initial preparation of the sodium derivative of the phenol by treatment with sodium ethoxide may be avoided in a number of instances by heating
directly the phenol, the alkyl halide and anhydrous potassium carbonate in acetone solution. Examples are provided by the preparation of allyl phenyl ether and butyl 2-nitrophenyl ether (Expt 6.110). A further cognate preparation, that of 2,4-dichlorophenoxyacetic acid, is of interest since the product is an important plant growth hormone and selective weed-killer. The conversion of phenols into phenoxyacetic acids by this route is of value in that these crystalline derivatives are useful for the characterisation of the phenolic compounds (Section 9.6.6, p. 1248).

Conversion of phenols into their methyl or ethyl ethers by reaction with the corresponding alkyl sulphates in the presence of aqueous sodium hydroxide affords a method which avoids the use of the more expensive alkyl halides (e.g. the synthesis of methyl 2-naphthyl ether and veratraldehyde, Expt 6.111). Also included in Expt 6.111 is a general procedure for the alkylation of phenols under PTC conditions.38,39 The method is suitable for 2,6-dialkylphenols, naphthols and various functionally substituted phenols. The alkylating agents include dimethyl sulphate, diethyl sulphate, methyl iodide, allyl bromide, epichlorohydrin, butyl bromide and benzyl chloride.

**Experiment 6.109 PHENACETIN**

\[
\text{p-HO-C}_6\text{H}_4\text{.NH}_2 \xrightarrow{\text{Me-CO}} \text{p-HO-C}_6\text{H}_4\text{.NH.CO.Me} \xrightarrow{\text{EtI}} \text{p-EtO-C}_6\text{H}_4\text{.NH.CO.Me}
\]

Suspend 11 g (0.1 mol) of p-aminophenol in 30 ml of water contained in a 250-ml beaker or conical flask and add 12 ml (0.127 mol) of acetic anhydride. Stir (or shake) the mixture vigorously and warm on a water bath. The solid dissolves. After 10 minutes, cool, filter the solid acetyl derivative at the pump and wash with a little cold water. Recrystallise from hot water (about 75 ml) and dry upon filter paper in the air. The yield of p-hydroxyacetanilide, m.p. 169 °C (1), is 14 g (93%).

Place 1.55 g (0.0675 mol) of clean sodium in a 250-ml round-bottomed flask equipped with a reflux condenser. Add 40 ml of absolute alcohol (or rectified spirit). If all the sodium has not disappeared after the vigorous reaction has subsided, warm the flask on a water bath until solution is complete. Cool the mixture and add 10 g (0.066 mol) of p-hydroxyacetanilide. Introduce 15 g (8 ml, 0.1 mol) of ethyl iodide slowly through the condenser and reflux the mixture for 45–60 minutes. Pour 100 ml of water through the condenser at such a rate that the crystalline product does not separate; if crystals do separate, reflux the mixture until they dissolve. Then cool the flask in an ice bath: collect the crude phenacetin with suction and wash with a little cold water. Dissolve the crude product in 80 ml of rectified spirit; if the solution is coloured, add 2 g of decolourising carbon, boil and filter. Treat the clear solution with 125 ml of hot water and allow to cool. Collect the pure phenacetin at the pump and dry in the air. The yield is 9.5 g (80%), m.p. 137 °C.

The p.m.r. spectrum (DMSO-\(d_6\), TMS) shows signals at \(\delta\) 1.30 (t, 3H, Me), 2.0 (s, 3H, COMe), 3.92 (q, 2H, CH\(_2\)), 6.80 (d, 2H, ortho-H’s to OEt), 7.42 (d, 2H, ortho-H’s to NH) and 9.68 (s broad, 1H, NH).

**Note.** (1) If the m.p. is unsatisfactory, dissolve the product in dilute alkali in the cold...
and then reprecipitate it by the addition of acid to the neutralisation point. This procedure will eliminate traces of the diacetate of p-aminophenol which may be present; the acetyl group attached to nitrogen is not affected by cold dilute alkali, but that attached to oxygen is readily hydrolysed by the reagent.

**Experiment 6.110 ALLYL PHENYL ETHER**

\[
\text{PhOH} + \text{Br} \xrightarrow{\text{K}_2\text{CO}_3} \text{PhCH} = \text{CH}_2
\]

Place 47 g (0.5 mol) of phenol, 60.5 g (0.5 mol) of allyl bromide (Expt 5.54), 69.1 g (0.5 mol) of anhydrous potassium carbonate and 100 ml of acetone in a 250-ml, two-necked round-bottomed flask fitted with a reflux condenser and sealed stirrer unit, and boil on a steam bath for 8 hours with stirring. Pour the reaction mixture into 500 ml of water, separate the organic layer and extract the aqueous layer with three 20 ml portions of ether. Wash the combined organic layer and ether extracts with 2 M sodium hydroxide solution, and dry over anhydrous potassium carbonate. Remove the ether with a rotary evaporator and distil the residue under reduced pressure. Collect the allyl phenyl ether, b.p. 85 °C/19 mmHg; the yield is 57 g (85%).

**Cognate preparations. Butyl 2-nitrophenyl ether** (o-Butoxynitrobenzene). Place a mixture of 28 g (0.2 mol) of o-nitrophenol (Expt 6.102), 28 g (0.2 mol) of anhydrous potassium carbonate, 30 g (23.5 ml, 0.22 mol) of butyl bromide and 200 ml of dry acetone in a 1-litre round-bottomed flask fitted with an efficient reflux condenser, and reflux on a steam bath for 48 hours. Distil off the acetone, add 200 ml of water and extract the product with two 100 ml portions of benzene (CAUTION). Wash the combined benzene extracts with three 90 ml portions of 10 per cent sodium hydroxide solution, remove the benzene by distillation at atmospheric pressure and distil the residue under reduced pressure. Collect the o-butoxynitrobenzene at 171–172 °C/19 mmHg (or at 127–129 °C/2 mmHg); the yield is 30 g (77%).

**2,4-Dichlorophenoxyacetic acid.**

\[
2,4\text{-Cl}_2\text{C}_6\text{H}_3\text{OH} + \text{Cl} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H} \xrightarrow{\text{OH}} 2,4\text{-Cl}_2\text{C}_6\text{H}_3\cdot \text{O} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H}
\]

Place 8.1 g (0.05 mol) of 2,4-dichlorophenol and 4.7 g (0.05 mol) of chloroacetic acid (CAUTION: causes skin blisters) in a 400-ml beaker; add slowly, with stirring, a solution of 4.5 (0.112 mol) of sodium hydroxide in 25 ml of water. Considerable heat is developed during the reaction. Heat the reaction mixture on a wire gauze until most of the liquid has evaporated: treat the residue with 150 ml of water, cool and filter if necessary. Acidify the clear solution with dilute hydrochloric acid (litmus). Extract the dense oil which separates with two 25 ml portions of ether, wash the combined extracts with 10–15 ml of water, dry with 1 g of magnesium sulphate, filter through a fluted filter paper and distil off the ether on a rotary evaporator. Recrystallise the residue of crude, 2,4-dichlorophenoxyacetic acid from about 35 ml of benzene (fume cupboard). The yield of pure acid, m.p. 138 °C, is 6.0 g (54%). The p.m.r. spectrum (DMSO-\text{d}_6, TMS) provides a good example for assignment of signals on the basis of measurement of coupling constants; the signals appear at \(\delta 4.75\) (s, 2H, OCH\text{_2}), 7.00 (d, 1H, C\text{_6}—H, measure \(J_{5,6}\) and note that \(J_{3,6}\) is negligible), 7.26 (d of d, 1H, C\text{_5}—H, measure \(J_{5,6}\) and \(J_{3,5}\), 7.41 (d, 1H,
C₃—H, only J₃,5 observed) and 11.90 (broad s, 1H, CO₂H). Note some overlapping of the signals arising from the protons at C₃ and C₅.

**Experiment 6.111 METHYL 2-NAPHTHYL ETHER (Nerolin)**

\[ 2\text{-C}_{10}\text{H}_7\text{OH} + \text{NaOH} + \text{Me}_2\text{SO}_4 \rightarrow 2\text{-C}_{10}\text{H}_7\text{O}\cdot\text{Me} + \text{Na(Me)}\text{SO}_4 + \text{H}_2\text{O} \]

**CAUTION:** This preparation should be carried out in an efficient fume cupboard.

Equip a 500-ml three-necked flask with a separatory funnel, a sealed mechanical stirrer and a reflux condenser. Place 36 g (0.25 mol) of 2-naphthol in the flask, add a solution of 10.5 g of sodium hydroxide in 150 ml of water and stir the mixture; cool the warm mixture to about 10°C by immersing the flask in an ice bath. Place 31.5 g (23.5 ml, 0.25 mol) of dimethyl sulphate (CAUTION: see Section 4.2.24, p. 430) in the separatory funnel and add dropwise, during 1 hour, while stirring the mixture vigorously. Warm for 1 hour at 70–80°C with stirring in order to complete the methylation. Allow to cool and filter off the methyl 2-naphthyl ether at the pump, wash with 10 per cent sodium hydroxide solution, then liberally with water and drain thoroughly. Recrystallise from industrial spirit. The yield is 33 g (84%), m.p. 72°C.

**Cognate preparations.** Veratraldehyde (3,4-dimethoxybenzaldehyde). Place 152 g (1 mol) of a good sample of commercial vanillin, m.p. 81–82°C, in a 1-litre three-necked flask equipped with a reflux condenser, a mechanical stirrer and two separatory funnels (one of which is supported over the top of the reflux condenser). Melt the vanillin by warming on a water bath and stir vigorously. Charge one funnel with a solution of 82 g of pure potassium hydroxide in 120 ml of water and the other funnel with 160 g (120 ml, 1.04 mol) of purified dimethyl sulphate (CAUTION). Run in the potassium hydroxide solution at the rate of two drops a second, and 20 seconds after this has started add the dimethyl sulphate at the same rate. Stop the external heating after a few minutes; the mixture continues to reflux gently from the heat of the reaction. The reaction mixture should be pale reddish-brown since this colour indicates that it is alkaline; should the colour change to green, an acid reaction is indicated and this condition should be corrected by slightly increasing the rate of addition of the alkali. When half to three-quarters of the reagents have been added, the reaction mixture becomes turbid and separates into two layers. As soon as all the reagents have been run in (about 20 minutes), pour the yellow reaction mixture into a large porcelain basin and allow to cool without disturbance, preferably overnight. Filter the hard crystalline mass of veratraldehyde, grind it in a glass mortar with 300 ml of ice-cold water, filter at the pump and dry in a vacuum desiccator. The yield of veratraldehyde, m.p. 43–44°C, is 160 g (96%). This product is sufficiently pure for most purposes; it can be purified without appreciable loss by distillation under reduced pressure, b.p. 158°C/8 mmHg; m.p. 46°C. The aldehyde is easily oxidised in the air and should therefore be kept in a tightly stoppered bottle.

**Butyl phenyl ether.** Weigh out 11.5 g (0.5 mol) of clean sodium into a dry, 1-litre round-bottomed flask provided with a double surface condenser, and
PRACTICAL

6.9

add 250 ml of absolute ethanol. If the reaction becomes so vigorous that the alcohol cannot be held back by the condenser, direct a stream of cold water or place a wet towel on the outside of the flask until it is again under control: do not cool the alcohol unduly otherwise the last traces of sodium will take a considerable time to dissolve. Add a solution of 47 g (0.5 mol) of pure phenol (CAUTION) in 50 ml of absolute ethanol and shake. Into a small separatory funnel supported in the top of the condenser, place 133 g (82.5 ml, 0.72 mol) of butyl iodide (Expt 5.59) or an equivalent quantity of butyl bromide (Expt 5.54) and add it, with shaking, during 15 minutes. Boil the solution gently for 3 hours, arrange the apparatus for downward distillation and distil off as much as possible of the alcohol on a water bath; this process is facilitated by wrapping the exposed part of the flask in a cloth. Add water to the residue in the flask, separate the organic layer and wash it twice with 25 ml portions of 10 per cent sodium hydroxide solution, then successively with water, dilute sulphuric acid and water: dry with magnesium sulphate. Distil and collect the butyl phenyl ether at 207–208°C. The yield is 60 g (80%).

General procedure for the preparation of phenolic ethers under PTC conditions. A mixture of dichloromethane (50 ml), water (50 ml), the phenol (10 mmol), sodium hydroxide (15 mmol), the alkylating agent (20–30 mmol) and benzyltributylammonium chloride, bromide or iodide (0.1–1.0 mmol) is agitated with a vibromix (Section 2.14), at room temperature for 2–12 hours. The organic layer is then separated and the aqueous layer extracted twice with dichloromethane (20 ml). The combined extracts are evaporated, the residue mixed with water and the mixture extracted with ether or pentane. The organic extract is washed twice with 2 M ammonia solution to remove dimethyl sulphate if necessary (methanolic ammonia in the case of diethyl sulphate), then 2 M sodium hydroxide solution (ethanolic sodium hydroxide in the case of hindered phenols) and finally with saturated sodium chloride solution. After drying with sodium sulphate, the solvent is evaporated and the residual phenolic ether purified by distillation or crystallisation.

When methyl iodide is used as the alkylating agent it is found that the reaction proceeds most satisfactorily when a stoichiometric amount of quaternary ammonium salt is used. Use of less than one equivalent of catalyst results in slow and incomplete reaction due to the inhibition of the catalytic effect by iodide. Reactions with benzyl chloride are carried out similarly.

6.9.4 SOME METHODS FOR THE PROTECTION OF THE PHENOLIC HYDROXYL GROUP

The important methods for the protection of phenols are very similar to those used for the alcoholic hydroxyl group (Section 5.4.6, p. 550), namely (a) ether formation, and (b) ester formation.

ETHERS

Section 6.9.3 provides experimental details for the formation of alkyl, allyl and benzyl ethers under a range of conditions, including PTC procedures.

Deprotection of aryl methyl ethers may be effected under strongly acidic conditions (e.g. hydriodic acid, Section 9.6.11, p. 1253), but the milder methods employing either iodotrimethylsilane in chloroform solution at 20–50°C for several hours, or boron tribromide at room temperature may be preferable.
General procedure for deprotection of mono- and polymethyl-aryl ethers with boron tribromide. To a 10-ml flask fitted with a septum and magnetic stirrer bar are added reactant (3.6 mmol) and 5 ml of dichloromethane. An inert atmosphere is established and maintained. This mixture is cooled in a dry ice/propan-2-ol bath and boron tribromide [0.13 ml, 1.32 mmol (for mono- methyl ethers), or 0.38 ml, 4 mmol (for dimethyl ethers)] is added through the septum by use of a syringe. The cold bath is removed and the mixture stirred for 30 minutes, poured into ice water, stirred for 30 minutes, saturated with salt and extracted with dichloromethane. The extract is dried and concentrated. The purity of the product is established by h.p.l.c. analysis on a Waters Associates 6000A model using both refractive index and u.v. absorbance detectors with a Waters 3.9 mm i.d. × 30 cm µ-Bondapack C18 reverse phase column.

Deprotection of allyl aryl ethers is accomplished by protonolysis with palladium on activated charcoal in methanol solution in the presence of toluene- p-sulphonic acid, or by reduction with sodium bis(2-methoxyethoxy)aluminium hydride in toluene solution (Aldrich). This latter reagent also cleaves aryl benzyl ethers.

Catechol and other o-dihydroxy aromatic systems may be protected by the formation of the methylenedioxy compound, most conveniently achieved by the following PTC procedure. A mixture of water (20 ml), dibromomethane (0.15 mol) and Adogen 464 (1 mmol), is vigorously stirred and heated to reflux. The air in the system is displaced by nitrogen. A solution of the appropriate o- dihydroxybenzene (0.1 mol) and sodium hydroxide (0.25 mol) in water (50 ml) is added at such a rate that addition is complete after 2 hours. After addition is complete, the reaction mixture is stirred and refluxed for a further hour. The product is isolated by standard work-up procedures.

ESTERS
The general procedures for the formation of acetates, benzoates and toluene-p-sulphonates are described in Section 9.6.6, p. 1248. Toluene-p-sulphonates are stable to the presence of lithium aluminium hydride, to the acidic conditions used in aromatic nitrations and to the high temperatures that might be necessary in an Ullmann reaction.

The most convenient procedure for deprotection of these esters is aqueous alkaline hydrolysis; a general procedure for this operation, including possible variations in technique which might be required in certain instances, is discussed in Section 9.6.17, p. 1266.

6.10 AROMATIC ALDEHYDES
Aromatic aldehydes may be prepared by the following general procedures.
2. Reactions involving modification of aromatic ring substituents (Expts 6.117 to 6.120).

Methods for the protection of the carbonyl group are considered in Section 6.12.8, p. 1056.
SUMMARY OF RETROSYNTHETIC STRATEGIES

Disconnection (method 1), e.g.

\[
\begin{align*}
\text{H} & \quad \text{O} \\
\text{R} & \quad \text{(TM)} \\
\end{align*}
\]

\[
\begin{align*}
\text{CHO} & \quad \text{=} \\
\text{R} \cdot \text{C}_6\text{H}_5 + \text{CO/HCl} \\
\end{align*}
\]

\[
\begin{align*}
\text{Z} & \quad \text{(TM)} \\
\end{align*}
\]

\[
\begin{align*}
\text{CHO} & \quad \text{=} \\
\text{Z} \cdot \text{C}_6\text{H}_5 + \text{formaldehyde equivalents} \\
\end{align*}
\]

Functional group removal/interconversion (FGR/FGI) (method 2), e.g.

\[
\begin{align*}
\text{Cl} & \quad \text{O} \\
\text{Z} & \quad \text{(TM)} \\
\end{align*}
\]

\[
\begin{align*}
\text{OH} & \quad \text{or} \\
\text{Z} & \quad \text{(TM)} \\
\end{align*}
\]

[SPECTROSCOPIC FEATURES]

The electron-withdrawing mesomeric interaction of the carbonyl group with the aromatic system results in the i.r. absorption frequency of its stretching vibration being lower than that exhibited in aliphatic aldehydes (p. 299). The absorption arising from the stretching vibration of the H—CO bond is also clearly observed (Fig. 3.30; anisaldehyde). This hydrogen may also be readily assigned in the p.m.r. spectrum of aromatic aldehydes and distinguished from other low field signals arising from acidic or phenolic protons, since the signal is unaffected by treatment of the sample with deuterium oxide. Aromatic substitution patterns are frequently assignable by inspection of both i.r. and p.m.r. spectra. The fragmentation patterns observed in the m.s. of aromatic aldehydes is illustrated and discussed in the case of benzaldehyde on p. 378. Further descriptive accounts of structural assignments are to be found in the preparative examples below.

6.10.1 AROMATIC FORMYLATION REACTIONS

Aromatic aldehydes may be obtained by passing a mixture of carbon monoxide and hydrogen chloride into the aromatic hydrocarbon in the presence of a mixture of copper(i) chloride and aluminium chloride which acts as a catalyst (Gatterman-Koch reaction). It is probable that the electrophilic species is the formyl cation [H—C=O] formed from the mixture of gases in the presence of
the Lewis acid. The preparation of \( p \)-tolualdehyde by this method has been described.\(^{45} \)

\[
\text{ArH} + [\text{H-} \overset{\text{O}}{\text{C}=\text{O}}] \xrightarrow{\text{CuCl}} \text{Ar} \cdot \text{CHO} + \text{H}^+ 
\]

The Gatterman–Koch formylation is unsuitable for the preparation of aldehydes from phenols and phenolic ethers owing to the formation of complexes with the Lewis acid.

A convenient method for the introduction of a formyl group, specifically in the ortho position of a phenol, involves reaction with tin(iv) chloride in the presence of tributylamine followed by treatment with paraformaldehyde.\(^{46} \) It is applicable to phenols with other electron-donating or -withdrawing substituents, and is illustrated by the conversion of \( p \)-cresol into 5-methyl-2-hydroxybenzaldehyde (Expt 6.112). The reaction is thought to proceed via two successive six-membered coordinated tin complexes.

\[
\begin{align*}
\text{X} \cdot \text{C}_6\text{H}_4 \cdot \text{OH} + \text{SnCl}_4 & \xrightarrow{\text{Br}_3\text{N}} \xrightarrow{\text{HCl}} \text{X} \cdot \text{C}_6\text{H}_4 \cdot \text{O} \cdot \text{SnCl}_3 \\
\end{align*}
\]

\[
\begin{align*}
\text{X} \cdot \text{C}_6\text{H}_4 \cdot \text{OH} + \text{MeO} \cdot \text{SnCl}_3 \\
\end{align*}
\]

Other methods which are variously suitable for the formylation of aromatic hydrocarbons, phenols, phenolic ethers and heterocyclic systems, employ a range of alternative \textit{formaldehyde equivalents}. These latter include the species \( \overset{\text{O}}{\text{H}} \overset{\text{C}=\text{NH}}{\text{}} \) (from hydrogen cyanide/aluminium chloride, \textit{Gatterman aldehyde synthesis}), \( \overset{\text{O}}{\text{Me}_2\text{N}=\text{CHCl}} \) (from dimethylformamide/phosphorus oxychloride, \textit{Vilsmeier reaction}), \( \overset{\text{O}}{\text{ClICHOMe}} \) (from dichloromethyl methyl ether/titanium(iv) chloride), \( \overset{\text{O}}{\text{CICH}_2} \) (from chloroform/sodium hydroxide, \textit{Reimer–Tiemann reaction}), and 1,3-dithiane.

The Gatterman aldehyde synthesis employs hydrogen cyanide and unlike the Gatterman–Koch procedure, this method is successful in the case of phenols and phenolic ethers, although only the more reactive hydrocarbons are formylated in good yield. The mechanism probably involves the species \( [\text{H-} \overset{\text{O}}{\text{C}=\text{NH}}] \) as the effective electrophile.

\[
\begin{align*}
\text{ArH} + [\text{H-} \overset{\text{O}}{\text{C}=\text{NH}}] \xrightarrow{\text{AlCl}_3} [\text{Ar-CH=NH}] \xrightarrow{\text{H}_2\text{O}} \text{Ar} \cdot \text{CHO} \\
\end{align*}
\]
One alternative which avoids the use of the hazardous hydrogen cyanide is passing dry hydrogen chloride either into a mixture of zinc cyanide, aluminium chloride, the hydrocarbon or phenolic ether and a solvent (such as tetrachloroethylene or benzene), or into a mixture of zinc cyanide, the phenol and anhydrous ether or benzene. The zinc cyanide is converted by the hydrogen chloride into hydrogen cyanide (which reacts in situ), and zinc chloride which is known to be an effective catalyst in this reaction. A second alternative, which is applicable to hydrocarbons only, is to use acetone cyanohydrin as an in situ source of hydrogen cyanide. The preparation of 2,4,6-trimethylbenzaldehyde (mesitaldehyde) from mesitylene and the related cognate preparations (Expt 6.113) provides a varied range of examples.

Certain reactive aromatic hydrocarbons are formylated by dimethylformamide in the presence of phosphorus oxychloride (the Vilsmeier reaction, e.g. 9-formylantracene, Expt 6.114). This method can also be used with advantage for the formylation of π-excessive heteroaromatic systems (e.g. 2-formylthiophene, cognate preparation in Expt 6.114).

\[
\begin{align*}
\text{Me}_2\text{N} & \quad \text{Cl}_3\text{P} = \text{O} \\
\text{Me}_2\text{N} & \quad \text{Cl}_3\text{P} = \text{Cl} \\
\text{Me}_2\text{N} & \quad \text{O} - \text{P} = \text{O} \\
\text{Me}_2\text{N} & \quad \text{O} - \text{P} = \text{Cl} \\
\text{Ar} - \text{C} & \quad \text{NMe}_2 \quad \longrightarrow \quad \text{Ar} \cdot \text{CH} = \text{NMe}_2 \text{Cl} \quad \text{H}_2\text{O} \quad \longrightarrow \quad \text{Ar} \cdot \text{CHO}
\end{align*}
\]

A generally applicable method of formylation involves the reaction of an aromatic hydrocarbon and dichloromethyl methyl ether under Friedel–Crafts conditions (cf. Section 6.11.1, p. 1006). The intermediate chloroacetal (1) thus formed is readily hydrolysed to the corresponding aldehyde (e.g. p-t-butylbenzaldehyde, Expt 6.115).

\[
\begin{align*}
\text{ArH} + \text{Cl}_2\text{CHOME} & \quad \xrightarrow{\text{TiCl}_4/\text{HCl}} \quad \text{Ar} \cdot \text{CH(OMe)Cl} \\
& \quad \xrightarrow{\text{H}_2\text{O}} \quad \text{Ar} \cdot \text{CHO} + \text{MeOH}
\end{align*}
\]

The procedure is of value for the formylation of polycyclic aromatic and heteroaromatic systems, phenols and phenolic ethers.

Phenols are smoothly converted into phenolic aldehydes by reaction with chloroform in the presence of base (the Reimer–Tiemann reaction). This overall formylation reaction is of interest in that it involves the generation from chloroform and alkali of the reactive intermediate, dichlorocarbene (2). This effects electrophilic substitution in the reactive phenolate ions giving the benzylidene dichloride (3) which is hydrolysed by the alkaline medium to the corresponding hydroxylaldehyde. The phenolic aldehyde is isolated from the reaction medium after acidification.
In the case of phenol the main product is o-hydroxybenzaldehyde (salicylaldehyde, Expt 6.116), but some of the para isomer is also formed. The isomers are separated by steam distillation in which only the ortho isomer is steam volatile owing to intramolecular hydrogen bonding. In the cognate preparation (2-hydroxy-1-naphthaldehyde) the preferential reaction at the 1-position should be noted.

Finally, it should be noted that a specific ortho formylation process which uses 1,3-dithiane as a formaldehyde equivalent has been described. The reaction process appears to be of wide applicability and is similar to the ortho formylation of primary aromatic amines which has been described by the same authors (see p. 909).

Experiment 6.112 5-METHYL-2-HYDROXYBENZALDEHYDE

To a four-necked round-bottomed flask (2.5 litres) equipped with a reflux condenser, mechanical stirrer, thermometer and nitrogen supply, are added anhydrous toluene (200 ml), p-cresol (108 g, 1.0 mol), tin(iv) chloride (26 g, 0.1 mol) (1) and tributylamine (74 g, 0.4 mol). The mixture is stirred for 20 minutes at room temperature, then paraformaldehyde (66 g) is added. The resulting yellowish solution is heated at 100 ± 0.5°C for 8 hours. After cooling, the reaction mixture is poured into water (5 litres), acidified to pH 2 with 2 M hydrochloric acid and extracted with ether. The ether extract is washed with saturated sodium chloride solution, dried over anhydrous sodium sulphate and concentrated to leave the crude product, which is subjected to steam distillation. The final product is obtained in 86 per cent yield, m.p. 55–56°C.

Note. (1) The commercially available anhydrous reagent should be used.
Experiment 6.113 2,4,6-TRIMETHYLBENZALDEHYDE (Mesitaldehyde)

\[ 1,3,5-C_6H_3Me_3 + \text{Zn(CN)}_2^2- + 3\text{HCl} \rightarrow 2,4,6-\text{Me}_3C_6H_2\cdot\text{CH} = \text{NH}_2\}^{\oplus} + \text{H}_2\text{O}^{\oplus} \]

\[ 2,4,6-\text{Me}_3C_6H_2\cdot\text{CHO} \]

Method A (use of zinc cyanide). CAUTION: The entire preparation should be conducted in an efficient fume cupboard. Tetrachloroethane is a potent poison and hydrogen cyanide is liberated during the reaction.

Equip a 500-ml multi-necked flange flask with a reflux condenser, an efficient stirrer, a gas-inlet tube and a thermometer; the thermometer should be so sited that during the subsequent reaction the bulb is well immersed in the liquid, but the gas inlet tube need extend only just below the surface. Place 51 g (59 ml, 0.425 mol) of redistilled mesitylene (b.p. 163–166°C), 73.5 g (0.625 mol) of zinc cyanide (Section 4.2.81, p. 467) and 200 ml of 1,1,2,2-tetrachloroethane in the flask, and stir the mixture while a rapid stream of dry hydrogen chloride (Section 4.2.38, p. 438) is passed through it until the zinc cyanide is decomposed (about 3 hours). Immerse the flask in a bath of crushed ice, remove the inlet tube and replace it by means of the arrangement depicted in Fig. 2.57, having previously charged the conical flask with 197 g of finely ground, anhydrous aluminium chloride. Stir the mixture very vigorously and add the aluminium chloride over a period of 10 minutes. Remove the ice bath, and resume the passage of hydrogen chloride gas for 3.5 hours; the heat of reaction will raise the temperature to about 70°C at the end of an hour. Maintain the temperature at 67–72°C for the remainder of the reaction period. Cool, and pour the reaction mixture, with hand stirring, into a 2-litre beaker about half-full of crushed ice to which 50 ml of concentrated hydrochloric acid has been added. Allow to stand overnight, transfer to a 1.5-litre round-bottomed flask, fit a condenser and reflux for 3 hours. Allow to cool, separate the organic layer and extract the aqueous layer once with 25 ml of tetrachloroethane. Wash the combined tetrachloroethane solutions with 75 ml of 10 per cent sodium carbonate solution, and steam distil (Fig. 2.102).

Set the first 400–450 ml of distillate aside for the recovery of the solvent (1), and collect the second portion (about 4.5 litres) as long as oily drops pass over. Extract the distillate with 250 ml of toluene, dry the extract with a little magnesium sulphate and remove the solvent on an oil bath or a rotary evaporator. Distil the residue from a 150-ml flask with a fractionating side-arm (compare Fig. 2.108), and collect the mesitaldehyde at 118–121°C/16 mmHg; the yield is 50 g (79%) (2).

The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 2.30 (s, 3H, C₄—Me), 2.59 (s, 6H, C₂—Me and C₆—Me), 6.85 (s, 2H, C₃—H, and C₅—H), and 10.50 (s, 1H, CHO). The m.s. gives significant fragment ions at m/z 148 (M), 147 (M — H, base peak), 119 (147 — CO), 105 (119 — CH₂), 91 (105 — CH₂), and 77 (91 — CH₂).

Notes. (1) The first portion of the steam distillate consists almost entirely of tetrachloroethane and water. The solvent is recovered by separating the organic layer, drying with anhydrous calcium chloride or magnesium sulphate and distilling.

(2) The following procedure is more convenient and less time-consuming, but the yield is lower (about 40 g). Mix the powdered aluminium chloride and zinc cyanide by shaking, add the mesitylene and immerse the flask in an oil bath at 100°C. Stir the mixture and pass in a fairly rapid stream of dry hydrogen chloride for 4 hours; continue
the heating and stirring for a further 2 hours, but discontinue the passage of the gas. Decompose the reaction mixture, and complete the preparation as above.

Method B (use of acetone cyanohydrin). A mixture of mesitylene (6 g, 0.05 mol) and acetone cyanohydrin (4.2, 0.05 mol) (Expt 5.168) in 1,2-dichloroethane (20 ml) is cooled to 0 °C. Aluminium chloride (13.3 g, 0.1 mol) is slowly added to the stirred mixture which is then allowed to warm to room temperature. After refluxing for 24 hours the mixture is hydrolysed and extracted with 1,2-dichloroethane. The organic layer is washed, neutralised and dried over magnesium sulphate. The solvent is evaporated and the crude product distilled to yield 3.5 g (48%) of 2,4,6-trimethylbenzaldehyde, b.p. 71 °C/9 mmHg.

Cognate preparations. Method A 2,4-Dihydroxybenzaldehyde (β-resorcyraldehyde). Equip a 500-ml three-necked flask with a reflux condenser, an efficient sealed stirrer and a wide inlet tube (to prevent clogging by the precipitate) extending nearly to the bottom of the vessel. Attach the inlet tube to an empty (safety) wash bottle and to this a generator producing hydrogen chloride (Section 4.2.38, p. 438); connect the top of the condenser by means of a tube to a wash bottle containing concentrated sulphuric acid, then to an empty bottle, and finally to the surface of sodium hydroxide solution (Fig. 2.61(a)). Place 20 g (0.18 mol) of resorcinol, 175 ml of sodium-dried ether and 40 g (0.34 mol) of powdered anhydrous zinc cyanide in the flask, start the stirrer and pass in a rapid stream of hydrogen chloride. The zinc cyanide gradually disappears with the formation of a cloudy solution; further passage of hydrogen chloride results in the separation of the imine hydrochloride condensation product as a thick oil which solidifies after 10–30 minutes. When the ether is saturated with hydrogen chloride (after about 1.5 hours), pass the gas more slowly and continue the stirring for a further half an hour to ensure the completeness of the reaction. Decant the ether from the solid material, add 100 ml of water to the latter, heat to the boiling point, filter the hot solution through a hot water funnel and allow the filtrate to cool. Filter the resorcyraldehyde (12 g) which separates as soon as the mixture is cold; allow the filtrate to stand for 15 hours when a further 11.5 g of the aldehyde is obtained (total yield 94%). The β-resorcyraldehyde, after drying, has m.p. 135–136 °C and is very faintly coloured. The colour may be removed by recrystallisation from hot water with the addition of a little decolourising carbon.

2-Hydroxy-1-naphthaldehyde. Proceed as for β-resorcyraldehyde except that 20 g (0.138 mol) of 2-naphthol replaces the resorcinol. Recrystallise the crude product (20 g, 83%) from water with the addition of a little decolourising carbon; the pure aldehyde has m.p. 80–81 °C.

Anisaldehyde (p-methoxybenzaldehyde). Use the apparatus described for β-resorcyraldehyde. Place 30 g (30 ml, 0.28 mol) of anisole, 75 ml of sodium-dried benzene (CAUTION) and 52 g (0.44 mol) of powdered zinc cyanide in the flask. Cool the mixture in a bath of cold water, start the stirrer and pass in a rapid stream of hydrogen chloride for 1 hour. Remove the gas inlet tube, and without stopping the stirrer, add 45 g of finely powdered anhydrous aluminium chloride slowly. Replace the gas inlet and pass in a slow steam of hydrogen chloride while heating the mixture at 40–45 °C for 3–4 hours. Allow
to cool somewhat and pour the reaction mixture with stirring into excess of dilute hydrochloric acid; the imine hydrochloride separates as a heavy precipitate. Reflux the mixture for half an hour in order to decompose the imine hydrochloride and steam distil. Separate the organic layer in the distillate, dry with a little anhydrous magnesium sulphate and distil off the benzene. Continue distillation with an air bath and collect the anisaldehyde as a fraction which has a b.p. 246–248 °C; the yield is 35 g (92%). If required the product may be redistilled under reduced pressure, b.p. 134–135 °C/12 mmHg. The i.r. spectrum is given on p. 301; the p.m.r. spectrum should be recorded and interpreted.

Experiment 6.114 9-FORMYLANTHRACENE (9-Anthraldehyde)

\[ \text{Anthracene} + \text{Me}_2\text{N} \cdot \text{CHO} + \text{POCl}_3 \xrightarrow{-\text{HCl}} \text{Me}_2\text{N} \cdot \text{CH} \cdot \text{O} \cdot \text{POCl}_2 \]

\[ \text{Me}_2\text{N} \cdot \text{CH} \cdot \text{O} \cdot \text{POCl}_2 \xrightarrow{\text{H}_2\text{O}} \text{CHO} \]

\[ \xrightarrow{-4\text{H}^+(\text{CH}_3\text{CO}_2^-)} + \text{Me}_2\text{NH} + \text{H}_2\text{PO}_4^- + 3\text{Cl}^- \]

Equip a 500-ml three-necked flask with a sealed stirrer unit, a reflux condenser and a dropping funnel. Assemble the apparatus on a water bath in a fume cupboard. Place in the flask a mixture of 17.8 g (0.1 mol) of anthracene (1), 19 g (20 ml, 0.26 mol) of dimethylformamide and 20 ml of o-dichlorobenzene (2), and charge the dropping funnel with 27 g (16 ml, 0.175 mol) of phosphorus oxychloride; close the condenser and dropping funnel with calcium chloride guard-tubes. Start the stirrer, run in the phosphorus oxychloride steadily and then heat on a boiling water bath for 2 hours. Cool the reaction flask in an ice-salt bath and neutralise the contents to Congo red by running in aqueous sodium acetate solution (about 100 g of the trihydrate in 175 ml of water are required). Dilute with more water to about 2 litres and allow the mixture to stand at 0 °C for 2 hours. Filter off the yellow crystalline product and recrystallise it from aqueous acetic acid; the yield of 9-formylanthracene is 12 g (58%), m.p. 104 °C.

Notes. (1) Good quality material should be used; commercial fluorescent grade of m.p. c. 215 °C is suitable.
(2) The use of o-dichlorobenzene as a solvent is recommended. If the reaction is carried out in excess dimethylformamide alone, the product is contaminated with unreacted anthracene. It is then best to extract the crude material with cold methanol, remove the anthracene by filtration and recover the product by dilution with water.

Cognate preparation. 2-Formylthiophene (thiophene-2-aldehyde). Use 21 g (19.3 ml, 0.25 mol) of thiophene, 23 g (24 ml, 0.315 mol) of dimethylformamide and 80 ml of 1,2-dichloroethane as solvent. Cool to 0 °C, add 48 g (29 ml, 0.313 mol) of phosphorus oxychloride slowly with stirring, and then heat, carefully at first, and then under reflux for 2 hours. Cool, pour on to crushed ice, neutralise with sodium acetate (c. 200 g of the hydrate), separate the
organic phase and extract the aqueous phase with ether. Wash the combined organic phases with aqueous sodium hydrogen carbonate, dry over magnesium sulphate and remove the solvent on a rotary evaporator. Distil the residue under reduced pressure and collect the 2-formylthiophene as a fraction of b.p. 85–86 °C/16 mmHg; yield 20 g (71%). Record the p.m.r. spectrum (CCl₄, TMS) and assign the signals which appear at δ 7.12 (t, 1H), 7.67 (d, 2H), and 9.86 (s, 1H), bearing in mind that the protons on C₃ and C₅ appear equivalent (cf. furan-2-aldehyde, cognate preparation in Expt 6.133).

**Experiment 6.115 p-t-BUTYLBENZALDEHYDE**

\[
\text{Ph-CMe}_3 + \text{ClCH-O-Me} \xrightarrow{\text{TiCl}_4} \text{p-Me}_3\text{C-}C_6\text{H}_4\cdot\text{CHO}
\]

Equip a 250-ml three-necked flask with a thermometer, reflux condenser, dropping funnel (protected with a calcium chloride guard-tube) and magnetic stirrer, and attach a gas absorption trap to the top of the condenser; assemble the apparatus in the fume cupboard. Place 15.1 g (0.12 mol) of t-butylbenzene (Expt 6.5) and 60 ml of dry dichloromethane (Section 4.1.5, p. 399) in the flask and cool to 0–5 °C in an ice–salt bath. To the stirred solution add 38 g (22 ml, 0.2 mol) of titanium (iv) chloride rapidly from the dropping funnel (2 to 3 minutes); the mixture becomes orange. Then add 11.5 g (0.1 mol) of dichloromethyl methyl ether (Expt 5.71) (CAUTION) during 20 minutes to the stirred and cooled solution. Hydrogen chloride is evolved after the first few drops of the ether are added. Stir the mixture for 5 minutes after completion of the addition, remove the cooling bath, allow the mixture to warm to room temperature (about half an hour) and then heat at 35 °C for 15 minutes. Pour the mixture into a separating funnel containing 100 g of ice and shake thoroughly. Separate the lower organic layer and extract the aqueous layer with three 25 ml portions of dichloromethane. Wash the combined dichloromethane extracts with three 25 ml portions of water, add a crystal of hydroquinone to prevent oxidation of the aldehyde and dry over magnesium sulphate. Filter the solution, remove the solvent by flash distillation and distil the residue under reduced pressure through a short fractionating column. The fraction which distils at 52 °C/4 mmHg is t-butylbenzene; collect the p-t-butylbenzaldehyde as a fraction of b.p. 98 °C/4 mmHg; the yield is 10.8 g (67%).

**Experiment 6.116 SALICYLALDEHYDE**

\[
\text{PhOH} \xrightarrow{\text{CHCl}_3} \text{o- and p-HO-C}_6\text{H}_4\cdot\text{CHO}
\]

Equip a 1-litre three-necked flask with an efficient double surface reflux condenser, a mechanical stirrer and a thermometer, the bulb of which is within 2 cm of the bottom of the flask. Place a warm solution of 80 g of sodium hydroxide in 80 ml of water in the flask, add a solution of 25 g (0.266 mol) of phenol (CAUTION) in 25 ml of water and stir. Adjust the temperature inside the flask to 60–65 °C (by warming on a water bath or by cooling, as may be found necessary); do not allow the crystalline sodium phenoxide to separate out. Introduce 60 g (40.5 ml, 0.5 mol) of chloroform (CAUTION) in three portions at intervals of 15 minutes down the condenser.
Maintain the temperature of the well-stirred mixture at 65–70 °C during the addition by immersing the flask in hot or cold water as may be required. Finally heat on a boiling water bath for 1 hour to complete the reaction. Remove the excess of chloroform from the alkaline solution by steam distillation (Fig. 2.102). Allow to cool, acidify the orange-coloured liquid cautiously with dilute sulphuric acid and again steam distil the almost colourless liquid until no more oily drops are collected. Set aside the residue in the flask for the isolation of \( p \)-hydroxybenzaldehyde. Extract the distillate at once with ether, remove most of the ether from the extract by distillation on a water bath using a rotary evaporator. Transfer the residue, which contains phenol as well as salicylaldehyde, to a small glass-stoppered flask, add about twice the volume of saturated sodium metabisulphite solution, and shake vigorously (preferably mechanically) for at least half an hour, and allow to stand for 1 hour. Filter the paste of bisulphite compound at the pump, wash it with a little alcohol, and finally with a little ether (to remove the phenol). Decompose the bisulphite compound by warming in a round-bottomed flask on a water bath with dilute sulphuric acid, allow to cool, extract the salicylaldehyde with ether and dry the extract with anhydrous magnesium sulphate. Remove the ether by flash distillation and distil the residue collecting the salicylaldehyde (a colourless liquid) at 195–197 °C. The yield is 12 g (37%).

To isolate the \( p \)-hydroxybenzaldehyde, filter the residue from the steam distillation while hot through a fluted filter paper in order to remove resinous matter, and extract the cold filtrate with ether. Distill off the ether, and recrystallise the yellow solid from hot water to which some aqueous sulphurous acid is added. The yield of \( p \)-hydroxybenzaldehyde (colourless crystals), m.p. 116 °C, is 2–3 g (6–9%).

Record the i.r. spectrum of both isomers and assign the OH and CHO bands. The substitution patterns may be confirmed by comparison of their p.m.r. spectra (\( \text{Me}_2\text{CO-d}_6 \), TMS); for the \textit{para} isomer the signals appear at \( \delta \) 7.04 (d, 2H, ortho-H’s to OH), 7.86 (d, 2H, ortho-H’s to CHO), 8.73 (s, 1H, OH), and 8.73 (s, 1H, CHO); for the \textit{ortho} isomer, wherein hydrogen bonding exists, the two signals at \( \delta \) 9.80 and 10.98 may be assigned to either the OH or CHO groups, and the aromatic protons appear as two groups of complex multiplets at \( \delta \) 6.7–7.1 and 7.3–7.7. The m.s., which shows the following principal fragment ions for either isomer, should be interpreted; \( m/z \) 122, 121, 104, 93, 65, and 39.

**Cognate preparation. 2-Hydroxy-1-naphthaldehyde.** Equip a 1-litre three-necked flask with a separatory funnel, a sealed mechanical stirrer and a double surface-reflux condenser. Place 50 g of 2-naphthol and 150 ml of rectified spirit in the flask, start the stirrer and rapidly add a solution of 100 g of sodium hydroxide in 210 ml of water. Heat the resulting solution to 70–80 °C on a water bath, and place 62 g (42 ml) of pure chloroform (CAUTION) in the separatory funnel. Introduce the chloroform dropwise until reaction commences (indicated by the formation of a deep blue colour), remove the water bath and continue the addition of the chloroform at such a rate that the mixture refluxes gently (about 1.5 hours). The sodium salt of the phenolic aldehyde separates near the end of the addition. Continue the stirring for a further 1 hour. Set the condenser for downward distillation (but
retaining the stirrer) and distil off the excess chloroform and alcohol. Treat the residue, with stirring, dropwise with concentrated hydrochloric acid until the contents of the flask are acid to Congo red paper (about 88 ml are required); a dark oil, accompanied by a considerable amount of sodium chloride, separates. Add sufficient water to dissolve the salt, extract the oil with ether, wash the ethereal solution with water, dry with anhydrous magnesium sulphate and remove the solvent. Distil the residue under reduced pressure and collect the slightly coloured aldehyde at 177–180°C/20 mmHg; it solidifies on cooling. Recrystallise the solid from about 40 ml of ethanol. The yield of 2-hydroxy-1-naphthaldehyde, m.p. 80°C, is 28 g (47%).

6.10.2 REACTIONS INVOLVING MODIFICATIONS OF AROMATIC RING SUBSTITUENTS

Several procedures for the synthesis of aromatic aldehydes are available which involve the selective oxidation of a methyl group attached to an aromatic ring. A useful general reagent is a solution of chromium trioxide in acetic anhydride and acetic acid. The aldehyde is converted into the gem-diacetate as it is formed and is thus protected from further oxidation. The aldehyde is liberated from the diacetate by hydrolysis under acid conditions; the yields, however, are frequently only moderate (e.g. p-nitrobenzaldehyde, Expt 6.117).

\[
\text{Ar} \cdot \text{Me} \xrightarrow{\text{CrO}_3 \ (\text{Me} \cdot \text{CO})_2 \text{O}} \text{Ar} \cdot \text{CH(O\cdot CO\cdot Me)}_2 \xrightarrow{\text{H}_2\text{O}^\circ} \text{Ar} \cdot \text{CHO}
\]

Aldehydes may also be obtained by the hydrolysis of gem-dihalogen compounds obtained by the side-chain halogenation of a methylarene.

\[
\text{Ar} \cdot \text{Me} \xrightarrow{2\text{Br}_2} \text{Ar} \cdot \text{CHBr}_2 \xrightarrow{\text{H}_2\text{O}} \text{Ar} \cdot \text{CHO}
\]

Side-chain bromination occurs under the influence of light (cf. Expt 6.28) and the extent of bromination is controlled by ensuring that the bromine (used in the theoretical amount) is added no faster than the rate at which it is consumed. The halogen in the benzylidene halide is reactive and hydrolysis occurs readily under mild conditions. In the example cited (p-bromobenzaldehyde, Expt 6.118) the use of a boiling aqueous suspension of calcium carbonate gives good results.

Aromatic and heteroaromatic aldehydes can alternatively be prepared from the corresponding methyl compound by subjecting the chloromethyl or bromomethyl derivative to the Sommelet reaction. This procedure involves an initial reaction between the halomethyl compound and hexamethylenetetramine (hexamine), and hydrolysing the resulting quaternary hexamine salt (4) with hot aqueous acetic acid.

\[
\text{Ar} \cdot \text{Me} \xrightarrow{X_2} \text{Ar} \cdot \text{CH}_2X \xrightarrow{(\text{CH}_2)_8\text{N}_4} \text{Ar} \cdot \text{CH}_2\text{N(\text{CH}_2)_6\text{N}_3})X \xrightarrow{\text{H}_2\text{O}} \text{Ar} \cdot \text{CHO}
\]

The mechanism of the reaction is not certain but hydrolysis of the salt may yield the primary amine (5), formaldehyde and ammonia. A hydride ion transfer then probably occurs between the benzylamine and the protonated aldimine (6), derived from formaldehyde and ammonia. Hydrolysis of the resulting aromatic aldimine (7) then yields the required aldehyde.
\[
\text{Ar}\cdot\text{CH}_2\text{N}((\text{CH}_2)_6\text{N}_3)^{\ominus} \xrightarrow{\text{H}_2\text{O}} \text{Ar}\cdot\text{CH}_2\text{NH}_2 + 4\text{H}\cdot\text{CHO} + 3\text{NH}_3
\]

(5)

\[
\text{Ar}\cdot\text{CH} \xrightarrow{\text{H}_2\text{O}} \text{Ar}\cdot\text{CHO} + \text{NH}_3
\]

A typical procedure is that described in Expt 6.119 for the synthesis of 1-naphthaldehyde. The synthesis of \(p\)-nitrobenzaldehyde provides an example in which the intermediate crystalline hexamine salt is isolated prior to hydrolysis. 2-Naphthaldehyde is prepared from the bromomethyl compound, the preparation of which illustrates the use of \(N\)-bromosuccinimide for effecting benzylic bromination of 2-methylnaphthalene.

Acid chlorides can be selectively hydrogenated in the presence of a catalyst (palladium deposited on a carrier, which is usually barium sulphate but is occasionally charcoal). The reaction, which involves the hydrogenolysis of the carbon–halogen bond, is known as the Rosenmund reduction and has been widely used for the synthesis of aromatic and heterocyclic aldehydes.

\[
\text{Ar}\cdot\text{COCl} + \text{H}_2 \xrightarrow{\text{catalyst}} \text{Ar}\cdot\text{CHO} + \text{HCl}
\]

The procedure is to pass purified hydrogen through a hot solution of the pure acid chloride in toluene or xylene in the presence of a catalyst; the exit gases are bubbled through water to absorb the hydrogen chloride, and the solution is titrated with standard alkali from time to time so that the reduction may be stopped when the theoretical quantity of hydrogen chloride has been evolved. Further reduction of the aldehyde, leading to the corresponding alcohol and thence to the methylarene, can usually be prevented by using the appropriate catalyst poison or regulator, which inactivates the catalyst towards reduction of the aldehyde but not the acid chloride. The regulator usually contains sulphur, e.g. quinoline-sulphur or thiourea; its use is not always necessary, however, and it has been stated that the decisive factors are to keep the reaction mixture at the lowest temperature at which hydrogen chloride is liberated and to arrest the reaction as soon as 1 mol of hydrogen chloride is evolved. The reduction is illustrated by the synthesis of 2-naphthaldehyde (Expt 6.120).

An alternative procedure\(^{49}\) for effecting the conversion of acid chlorides into aldehydes is chemical reduction with bis(triphenylphosphine)copper(I) tetrahydroborate (see also Section 5.7.4, p. 594). The procedure is illustrated by the synthesis of 3,4-dimethoxybenzaldehyde which is isolated as the 2,4-dinitrophenylhydrazine derivative\(^{50}\) (cognate preparation in Expt 6.120).

**Experiment 6.117 \(p\)-NITROBENZALDEHYDE**

\[
p\cdot\text{O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{Me} \xrightarrow{\text{CrO}_3\left(\text{Me}\cdot\text{CO}_2\text{O}\right)} \text{p}\cdot\text{O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CH(OCO Me)}_2 \xrightarrow{\text{H}_2\text{O}} \text{p}\cdot\text{O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}
\]

 Equip a 1-litre three-necked flask with a mechanical stirrer, a dropping funnel and a thermometer, and immerse the flask in a bath of ice and salt. Place
200 g (185 ml, 2 mol) of acetic anhydride and 25 g (0.18 mol) of p-nitrotoluene in the flask, and add slowly, with stirring, 40 ml of concentrated sulphuric acid. When the temperature has fallen to 0°C introduce slowly, with stirring, a solution of 50 g (0.5 mol) of chromium trioxide in 225 ml of acetic anhydride (1), at such a rate that the temperature does not exceed 10°C; continue stirring for 2 hours after all the chromium trioxide solution has been added. Pour the contents of the flask into a 3-litre beaker one-third filled with crushed ice and almost fill the beaker with cold water. Filter the solid at the pump and wash it with cold water until the washings are colourless. Suspend the product in 150 ml of cold 2 per cent sodium carbonate solution and stir mechanically for about 10–15 minutes; filter, wash with cold water, and finally with 10 ml of ethanol. Dry in a vacuum desiccator; the yield of crude p-nitrobenzylidene diacetate is 30 g (65%) (2).

Reflux the crude p-nitrobenzylidene diacetate with a mixture of 70 ml of ethanol, 70 ml of water and 7 ml of concentrated sulphuric acid for 30 minutes, filter through a fluted filter paper and cool the filtrate in ice. Collect the crystals by suction filtration, wash with cold water and dry in a vacuum desiccator. The yield of p-nitrobenzaldehyde, m.p. 106°C, is 15 g (55% overall). The spectroscopic characteristics are discussed with those of the ortho isomer, cognate preparation below.

Notes. (1) The solution is prepared by adding the chromium trioxide portionwise to the well-cooled acetic anhydride. Addition of the anhydride to the oxide in bulk may lead to explosive decomposition.

(2) The pure diacetate may be isolated by dissolving in 100 ml of hot ethanol, filtering from any insoluble impurities and allowing to cool: 28 g (61%), m.p. 125–126°C, are obtained.

Cognate preparations. o-Nitrobenzaldehyde. Use 25 g (0.18 mol) of o-nitrotoluene and proceed as for p-nitrobenzaldehyde, but allow a period of 3 hours stirring at 5–10°C after the addition of the chromium trioxide solution. In the work-up, omit the final ethanol washing; to remove unchanged o-nitrotoluene boil the crude product under reflux for 30 minutes with 120 ml of light petroleum (b.p. 60–80°C). The yield of o-nitrobenzylidene diacetate of m.p. 82–84°C is 16 g (36%).

Suspend 16 g of the diacetate in a mixture of 85 ml of concentrated hydrochloric acid, 140 ml of water and 25 ml of ethanol and boil under reflux for 45 minutes. Cool the mixture to 0°C, filter the solid with suction and wash with water. Purify the crude aldehyde by rapid steam distillation; collect about 1 litre of distillate during 15 minutes, cool, filter and dry in a vacuum desiccator over calcium chloride. The yield of pure o-nitrobenzaldehyde, m.p. 44–45°C, is 7.5 g (28% overall). The crude solid may also be purified after drying either by distillation under reduced pressure (the distillate of rather wide b.p. range, e.g. 120–144°C/3–6 mmHg, is quite pure) or by dissolution in toluene (2–2.5 ml per gram) and precipitation with light petroleum, b.p. 40–60°C (7 ml per ml of solution). The substitution pattern of the ortho and para isomers is confirmed by their p.m.r. spectra (CDCl₃, TMS) which should be compared with that of the meta isomer (p. 856). For the para isomer signals appear at δ 8.09 (d, 2H, ortho-H’s to CHO), 8.39 (d, 2H, ortho-H’s to NO₂), and 10.19 (s, 1H, CHO); for the ortho isomer signals appear at δ 7.63–8.2 (m, 4H, C_AR—H), and 10.31 (s, 1H, CHO).
Experiment 6.118  p-BROMOBENZALDEHYDE

\[
p-\text{Br-C}_6\text{H}_4\cdot\text{Me} \xrightarrow{\text{Br}_2} p-\text{Br-C}_6\text{H}_4\cdot\text{CHBr}_2 \xrightarrow{\text{H}_2\text{O}} p-\text{Br-C}_6\text{H}_4\cdot\text{CHO}
\]

**CAUTION:** This preparation should be carried out in the fume cupboard.

Equip a 1-litre multi-necked flange flask with a reflux condenser, a mechanical stirrer, a dropping funnel and a thermometer which reaches nearly to the bottom of the flask; connect the upper end of the condenser to an absorption trap (Fig. 2.61). Place 100 g (65 ml, 0.58 mol) of \(p\)-bromotoluene (Expt 6.72) in the flask and immerse the latter in an oil bath (colourless oil in a large beaker). Heat the bath until the temperature of the stirred \(p\)-bromotoluene reaches 105 °C. Illuminate the liquid with an unfrosted 150-watt tungsten lamp, and add 200 g (1.25 mol) of bromine (CAUTION) slowly from the dropping funnel: do not allow a large excess of bromine to accumulate in the reaction mixture. Add about one half of the bromine during 1 hour while the temperature is kept at 105–110 °C, and add the remainder during 2 hours while the temperature is slowly raised to 135 °C. Raise the temperature slowly to 150 °C when all the bromine has been introduced. Transfer the crude \(p\)-bromobenzylidene dibromide (1) to a 2-litre flask, mix it intimately with 200 g of precipitated calcium carbonate and then add about 300 ml of water. Attach a reflux condenser to the flask, heat the mixture first on a water bath and then on a wire gauze over a free flame with continuous shaking until the liquid boils (2); reflux the mixture for 15 hours to complete the hydrolysis. Steam distil the reaction mixture rapidly (3); collect the first 1 litre of distillate separately, filter off the product and dry in a vacuum desiccator; 60 g (56%) of pure \(p\)-bromobenzaldehyde, m.p. 56–57 °C, are thus obtained. Collect a further 2 litres of distillate (4); this yields about 15 g of a less pure product, m.p. 52–56 °C. Purify this by trituration with saturated sodium bisulphite solution (2 ml per gram) and, after about 3 hours, filter off the pasty mixture at the pump, wash it with alcohol and then with ether. Transfer the bisulphite compound to a flask fitted for steam distillation (Fig. 2.102), add excess of sodium carbonate solution and isolate the aldehyde by steam distillation; 13 g (12%) of \(p\)-bromobenzaldehyde, m.p. 56–57 °C, are thus collected. The p.m.r. spectrum should be recorded and interpreted.

**Notes.** (1) This compound is lachrymatory and also produces a burning sensation on the skin; the latter is relieved by washing the affected parts with alcohol.
(2) This gradual heating reduces the risk of breaking the flask.
(3) The best results are obtained by conducting the steam distillation in a large three-necked flask provided with a sealed stirrer unit in the central aperture; the aldehyde distils slowly unless the mixture is well stirred.
(4) If the solution in the flask is acidified with hydrochloric acid, about 8 g of crude \(p\)-bromobenzoic acid may be isolated.

Experiment 6.119  1-NAPHTHALDEHYDE

\[
1\text{-C}_{10}\text{H}_7\cdot\text{CH}_2\text{Cl} \xrightarrow{\text{(CH}_3)_2\text{N}_2} \text{Me-}\text{CO}_2\text{H} 1\text{-C}_{10}\text{H}_7\cdot\text{CH}_2\cdot\text{C}_6\text{H}_{12}^\ominus\text{N}_4^\ominus\text{Cl}^\ominus \rightarrow 1\text{-C}_{10}\text{H}_7\cdot\text{CHO}
\]

In a 500-ml flask, fitted with a reflux condenser, place 53 g (0.3 mol) of 1-(chloromethyl)naphthalene, 84 g (0.6 mol) of hexamethylenetetramine and
250 ml of 50 per cent aqueous acetic acid. [CAUTION: 1-(Chloromethyl)naphthalene and, to a lesser degree, 1-naphthaldehyde have lachrymatory and vesicant properties; adequate precautions should therefore be taken to avoid contact with these substances.] Heat the mixture under reflux for 2 hours; it becomes homogeneous after about 15 minutes and then an oil commences to separate. Add 100 ml of concentrated hydrochloric acid and reflux for a further 15 minutes; this will hydrolyse any Schiff's bases which may be formed from amine and aldehyde present and will also convert any amines into the ether-insoluble hydrochlorides. Cool, and extract the mixture with 150 ml of ether. Wash the ether layer with three 50 ml portions of water, then cautiously with 50 ml of 10 per cent sodium carbonate solution, followed by 50 ml of water. Dry the ethereal solution with anhydrous magnesium sulphate, remove the ether by distillation on a steam bath and distil the residue under reduced pressure. Collect the 1-naphthaldehyde at 160–162°C/18 mmHg; the yield is 38 g (81%).

Cognate preparations. p-Nitrobenzaldehyde. This preparation is an example of the Sommelet reaction in which the hexaminium salt is isolated. Dissolve 11 g (0.13 mol) of hexamethylenetetramine in 70 ml of chloroform (CAUTION) and add 11.4 g (0.067 mol) of p-nitrobenzyl chloride or 14.4 g of p-nitrobenzyl bromide (Expt 6.28). Heat the mixture under reflux on a steam bath for 4 hours; a precipitate gradually separates. Replace the reflux condenser by a condenser set for distillation and distil off about 35 ml of solvent. Add 35 ml of acetone, cool in ice, collect the precipitate by suction filtration and dry it in the air. Heat the hexaminium salt thus obtained under reflux for 1 hour with 100 ml of 50 per cent acetic acid; then add 100 ml of water and 25 ml of concentrated hydrochloric acid and continue the refluxing for 5–10 minutes. Cool the solution in ice, collect the crystals of p-nitrobenzaldehyde and dry them in a vacuum desiccator. The yield is 6.4 g (63%), m.p. 106°C. The p.m.r. spectrum is noted in Expt 6.117.

2-Naphthaldehyde.

\[ 2\text{-C}_{10}\text{H}_7\cdot\text{CH}_3 \xrightarrow{\text{NBS}} 2\text{-C}_{10}\text{H}_7\cdot\text{CH}_2\text{Br} \xrightarrow{\text{(i) (CH}_2)_2\text{N}_4} \xrightarrow{\text{(ii) H}_2\text{O}^\circ} 2\text{-C}_{10}\text{H}_7\cdot\text{CHO} \]

Dissolve 71 g of 2-methylnaphthalene in 450 g (283 ml) of carbon tetrachloride and place the solution in a 1-litre three-necked flask equipped with a mechanical stirrer and reflux condenser. Introduce 89 g of N-bromosuccinimide (Section 4.2.10, p. 422) through the third neck, close the latter with a stopper and reflux the mixture with stirring for 16 hours. Filter off the succinimide and remove the solvent under reduced pressure on a water bath. Dissolve the residual brown oil (largely 2-(bromomethyl)naphthalene) in 300 ml of chloroform, and add it to a rapidly stirred solution of 84 g of hexamethylenetetramine in 150 ml of chloroform contained in a 2-litre three-necked flask, fitted with a reflux condenser, mechanical stirrer and dropping funnel: maintain the rate of addition so that the mixture refluxes vigorously. A white solid separates almost immediately. Heat the mixture to reflux for 30 minutes, cool and filter. Wash the crystalline hexaminium bromide with two 100 ml portions of light petroleum, b.p. 40–60°C, and dry; the yield of solid, m.p. 175–176°C, is 147 g. Reflux the hexaminium salt for 2 hours with 750 ml of 50 per cent acetic acid, add 150 ml of concentrated hydrochloric acid,
continue the refluxing for 5 minutes more and cool. Extract the aldehyde from the solution with ether, evaporate the ether and recrystallise the residue from hot hexane. The yield of 2-naphthaldehyde, m.p. 59–60 °C, is 50 g (64% overall).

Experiment 6.120 2-NAPHTHALDEHYDE

\[
2\text{C}_{10}\text{H}_7\cdot\text{COCl} \xrightarrow{\text{H}_2/\text{Pd-BaSO}_4} 2\text{C}_{10}\text{H}_7\cdot\text{CHO}
\]

Fit a 250-ml three-necked flask with a reflux condenser, a high-speed sealed stirrer (1) and a gas inlet tube extending to a point just above the bottom of the stirrer. Place 28.5 g (0.15 mol) of 2-naphthoyl chloride (Expt 6.161), 100 ml of sodium-dried xylene, 3 g of palladium–barium sulphate catalyst and 0.3 ml of the stock poison solution (Section 4.2.54, p. 452) in the flask. Connect the top of the condenser by a rubber tube to a 6-mm glass tube extending to the bottom of a 250-ml conical flask containing 200 ml of distilled water and a few drops of phenolphthalein indicator; arrange a burette charged with c. 1 M sodium hydroxide solution (prepared from the pure solid) for delivery into the flask. The apparatus must be sited in the fume cupboard.

Displace the air in the reaction flask with hydrogen from a cylinder of the gas, heat the flask in an oil bath at 140–150 °C, and stir the mixture vigorously. Continue to pass hydrogen at such a rate that 1–2 bubbles per second emerge in the conical flask. Follow the course of the reaction by the rate of hydrogen chloride evolution. The first 25 ml of alkali should be neutralised in 12–15 minutes, and the reaction should be complete in about 2 hours. About 92 per cent of the theoretical amount of hydrogen chloride (ċ 142.5 ml of 1 M NaOH solution) is recovered; the end of the reaction is indicated by a rather abrupt cessation of hydrogen chloride evolution. Cool the flask add 1 g of decolourising carbon with stirring and filter the solution with suction through a hardened filter paper and keep the spent catalyst for recovery. Remove the xylene by flash distillation using a 50–75 ml flask with fractionating side-arm and then distil under reduced pressure with the aid of an oil bath: a small fraction, consisting largely of naphthalene, passes over first, followed by 2-naphthaldehyde at 147–149 °C/11 mmHg (temperature of bath, 170–180 °C). This (19 g, 81%) solidifies on cooling to a white solid, m.p. 59–60 °C.

Note. (1) Rapid stirring is desirable in order to obtain the maximum reaction rate; absorption of hydrogen occurs chiefly at the rapidly agitated surface.

Cognate preparation. 3,4-Dimethoxybenzaldehyde 2,4-dinitrophenylhydrazone (use of bis(triphenylphosphine)copper(i) tetrahydroborate)\(^\text{50}\)

3,4-Dimethoxybenzoyl chloride (1.14 g, 5.7 mmol) in acetone (100 ml) is treated with triphenylphosphine (3.04 g, 11.6 mmol). To this solution at room temperature, bis(triphenylphosphine)copper(i) tetrahydroborate (3.47 g, 5.8 mmol) (Section 4.2.49, p. 449) is added and the reaction mixture stirred for 45 minutes. The white precipitate of triphenylphosphine copper chloride (4.9 g, 5.5 mmol) is removed by filtration and the filtrate evaporated to dryness. The residue is extracted with ether (the ether-insoluble residue is shown to be triphenylphosphine borane). The ether is removed, the residue
redissolved in chloroform (60 ml) and the resulting solution stirred over copper(1) chloride (1 g) to remove the remaining triphenylphosphine. The reaction mixture is filtered, the chloroform evaporated and the residue extracted with methanol (1). The methanol extract is treated with a solution of 2,4-dinitrophenylhydrazine sulphate to give 1.66 g (86%) of 3,4-dimethoxy-benzaldehyde 2,4-dinitrophenylhydrazone, m.p. 269–271 °C.

Note. (1) Triphenylphosphine may be removed from a mixture of triphenylphosphine and organic compounds by stirring a chloroform solution over copper(1) chloride, the reaction mixture is filtered, the chloroform removed and the organic compound dissolved in ether or methanol. A 1:1 Ph₃P:CuCl complex is formed which is soluble in chloroform but insoluble in ether or methanol.

6.11 AROMATIC KETONES AND QUINONES

Methods for the protection of the carbonyl group are considered in Section 6.12.8, p. 1056.

SUMMARY OF RETROSYNTHETIC STRATEGIES FOR AROMATIC KETONES

Disconnection (methods 1 and 2), e.g.

\]

SPECTROSCOPIC FEATURES
The spectroscopic characteristics exhibited by acetophenone (Ph·CO·Me) are fully discussed on p. 268 (i.r. spectrum, Fig. 3.9), p. 329 (p.m.r. spectrum, Fig. 3.48), and p. 378 (m.s., Fig. 3.83(b)) and may be regarded as being typical of
aromatic ketones. Further substitution in the aromatic nucleus, or the presence of other alkyl or aralkyl groups, or of other aromatic residues attached to the carbonyl carbon gives rise to predictable changes in these spectral features. Descriptive assignments are given in some of the preparative examples below.

6.11.1 FRIEDEL–CRAFTS-TYPE ACRYLATION PROCESSES

The reaction of a carboxylic acid chloride or anhydride with an aromatic hydrocarbon in the presence of anhydrous aluminium chloride generally gives a good yield of the aromatic ketone:

\[
\text{ArH} + \text{R} \cdot \text{COCl} \xrightarrow{\text{AlCl}_3} \text{Ar} \cdot \text{CO} \cdot \text{R} + \text{HCl}
\]

\[
\text{Ar}^1 \text{H} + \text{Ar}^2 \cdot \text{COCl} \xrightarrow{\text{AlCl}_3} \text{Ar}^1 \cdot \text{CO} \cdot \text{Ar}^2 + \text{HCl}
\]

\[
\text{ArH} + (\text{R} \cdot \text{CO})_2 \text{O} \xrightarrow{\text{AlCl}_3} \text{Ar} \cdot \text{CO} \cdot \text{R} + \text{R} \cdot \text{CO}_2 \text{H}
\]

It should be noted that Friedel–Crafts acylation differs from Friedel–Crafts alkylation (see Section 6.1.1, p. 826) in one important respect in that the alkylation process requires relatively small (catalytic) quantities of aluminium chloride. With acylations, however, at least one molar equivalent of aluminium chloride is necessary for each carbonyl group present in the acylating agent. This is because aluminium chloride is capable of forming rather stable complexes with the carbonyl group (see formulation below). This complex formation therefore requires an equivalent quantity of metal halide, and hence a slight excess over this amount is employed in order to ensure that the free reagent may be present to act as the catalyst: thus 1.2 and 2.2 molar equivalents of aluminium chloride are generally employed for acid chlorides and acid anhydrides respectively. Excess of benzene or of toluene may be used as a solvent (when either of these substances constitutes one of the reactants), otherwise carbon disulphide or nitrobenzene is usually employed. Friedel–Crafts acylation is free of two features which complicate the alkylation reaction, namely, (i) polysubstitution and (ii) rearrangements. There is usually no difficulty in arresting the acylation with the introduction of a single acyl group into the aromatic nucleus as the acyl group deactivates the nucleus to further electrophilic attack. In the case of benzene homologues which may show a tendency to isomerise or disproportionate under the influence of aluminium chloride (see Section 6.1.1, p. 826) preliminary mixing of the acyl and aluminium halides is recommended.

The mechanism of the Friedel–Crafts acylation reaction, formulated below for reactions using acid chlorides, probably involves the acylium ion (2) as the reactive electrophilic species, although an electrophilic complex (1) between the acid chloride and aluminium chloride may also be involved.
The use of aliphatic carboxylic acid anhydrides in place of the corresponding acid chlorides offers many advantages; these include:

(a) the greater ease of obtaining the anhydrides in a state of purity, and their availability as commercial products (acetic, propanoic, butanoic and succinic anhydrides);

(b) the handling of disagreeable acid chlorides is avoided;

(c) the absence of any appreciable quantities of by-products and of resinous substances;

(d) the reaction is smooth and the yield is generally good.

The preparations of butyrophenone, propiophenone, benzophenone and methyl 2-naphthyl ketone, given in Expt 6.121, provide examples of acylation reactions carried out under standard Friedel–Crafts conditions using the appropriate acid chloride as the acylating reagent. In the case of the acetylation of naphthalene, two isomeric acetyl derivatives are possible and the composition of the product is dependent upon the reaction conditions (cf. the sulphonation of naphthalene, Section 6.4.1, p. 873). With nitrobenzene as the solvent the product is largely the thermodynamically more stable 2-acetonaphthalene, whereas in carbon tetrachloride the 1-isomer is formed as the kinetically controlled product. Also included in the cognate preparations are several acylation reactions of phloroglucinol which, unlike simple phenols, proceed with acceptable yields, together with a convenient alternative preparation of benzophenone from benzene and excess carbon tetrachloride; this latter reaction involves the intermediate formation of dichlorodiphenylmethane which is hydrolysed to the ketone.

The use of acetic anhydride as the acylating reagent is described in the preparation of p-methylacetophenone (Expt 6.122), and in a range of cognate preparations in which the substrates are benzene derivatives possessing electron-releasing groups (Br, Cl, OMe, Ph). In these cases the product is largely the para isomer. The presence of deactivating groups (CHO, CN, NO₂) renders the aromatic ring inactive towards acylation under Friedel–Crafts conditions, which therefore permits the use of nitrobenzene as a reaction solvent in suitable cases. Also included here is the acetylation of thiophene and of ferrocene. Electrophilic substitution in these cases proceeds with great ease and the catalyst is a small amount of phosphoric acid. With thiophene the most reactive site is the 2-position, and 2-acetylthiophene is the predominant isomer formed; ferrocene gives a unique mono-acetyl derivative.

Reaction of succinic anhydride with benzene in the presence of anhydrous aluminium chloride (slightly over two equivalents; see above) yields 3-benzoylpropanoic acid. This may be reduced by the Clemmensen method in the presence of a solvent (toluene) immiscible with the hydrochloric acid to 4-phenylbutanoic acid. Cyclisation to α-tetralone (Expt 6.123) is then effected smoothly by treatment with hot polyphosphoric acid. This reaction sequence represents the first stages in the Haworth procedure for the synthesis of polycyclic aromatic hydrocarbons (see Section 6.1.4, p. 839).

Aroylation of an aromatic system by reaction with phthalic anhydride under Friedel–Crafts conditions yields the o-aroylbenzoic acid. These readily available compounds have characteristic melting points which make them useful as derivatives in the characterisation of aromatic hydrocarbons and of aryl halides (Section 9.6.3, p. 1238).
With benzene the product is o-benzoylbenzoic acid (Expt 6.124), and with toluene, o-(p-toluoyl)benzoic acid (Expt 6.132). The aroylbenzoic acids are important starting materials for the synthesis of quinones (Section 6.11.3, p. 1022), into which they are cyclised using polyphosphoric acid (Expt 6.132).

Phenolic ketones may be prepared by the Hoesch acylation reaction, which may be regarded as an extension of the Gattermann aldehyde synthesis (Section 6.10.1, p. 990). The procedure involves reaction of a nitrile with a phenol (or phenolic ether) in the presence of zinc chloride and hydrogen chloride; best results are usually obtained with polyhydric phenols or their ethers, as for example in the preparation of phloroacetophenone (Expt 6.125). The formation of phenolic ketones by means of the Fries rearrangement of phenolic esters with aluminium chloride is discussed on p. 976.

**Experiment 6.121 BUTYROPHENONE** *(Phenyl propyl ketone-use of the acyl chloride)*

\[
\text{PhH} + \text{Me} \xrightarrow{\text{AlCl}_3} \text{Ph} - \text{Me} + \text{HCl}
\]

**CAUTION:** *All operations should be conducted in an efficient fume cupboard.*

Equip a 500-ml three-necked flask with a double surface reflux condenser, a sealed stirrer unit and a dropping funnel protected by a calcium chloride guard-tube. Connect the top of the condenser to a trap for absorbing the hydrogen chloride evolved (Fig. 2.61). Place 60 g (0.45 mol) of anhydrous, finely powdered aluminium chloride (see Section 4.2.4, p. 416) and 88 g (100 ml) of dry benzene (CAUTION) in the flask. Start the stirrer, and add 39.5 g (38 ml, 0.37 mol) of butanoyl chloride (Expt 5.138) slowly during about half-an-hour. In the early stages it may be necessary to warm the flask gently to initiate the reaction (hydrogen chloride is evolved) which should then proceed without further heating while the remainder of the acid chloride is added. Finally, heat the flask in a water bath at about 50°C for 1 hour in order to complete the reaction. Cool and pour the reaction mixture into about 250 ml of water and a little crushed ice contained in a 750-ml flask; decomposition occurs with the evolution of heat and a dark oil (largely a solution of butyrophenone in benzene) separates on the surface. Stopper the flask and shake to complete the decomposition; if any solid remains undissolved, add a little concentrated hydrochloric acid to dissolve it. Pour the mixture into a separatory funnel, run off and discard the lower layer, wash the benzene with water, then with dilute sodium hydroxide solution (to remove the hydrogen chloride), again with water, and finally dry over magnesium sulphate or calcium chloride. Remove excess benzene by flash distillation from a boiling water bath; use the apparatus shown in Fig. 2.101 (100-ml distilling flask). When most of the benzene has been removed,
replace the dropping funnel by a 360°C thermometer and the water condenser by a short air condenser. Continue the distillation by careful heating over a gauze or, better, in an air bath – (CAUTION): there may be some benzene in the residual oil – and collect the butyrophenone at 227–230°C or at 110°C/10 mmHg. The yield is 25 g (51%).

The i.r. spectrum should be recorded and the absorptions assigned using the spectrum of acetophenone (p. 268) as a guide. The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 0.95 (t, 3H, Me), 1.92 (m, 2H, CH₂Me), 2.82 (t, 2H, CO-CH₂), 7.12–7.55 (m, 3H, C₃, 4, 5–H), and 7.80–8.1 (m, 2H, C₂, 6–H). The multiplet at δ 1.92 provides a good example of the (N + 1) (M + 1) rule (p. 341) for the multiplicity of protons when coupled to N and M non-equivalent adjacent protons.

**Cognate preparations. Propiophenone (ethyl phenyl ketone).** Proceed as above but use 34.5 g (32 ml, 0.37 mol) of propanoyl chloride. The yield of propiophenone, b.p. 214–217°C, is 30 g (60%). An improved yield is obtained by the following process. Add a mixture of 75 g (70.5 ml, 0.81 mol) of propanoyl chloride and 90 g (103 ml, 1.15 mol) of sodium-dried benzene (CAUTION) to a vigorously stirred suspension of 75 g (0.56 mol) of finely powdered anhydrous aluminium chloride in 100 ml of dry carbon disulphide (CAUTION: see Sections 2.3.2, p. 40 and 4.2.32, p. 411). Then introduce more of the aluminium chloride (about 35 g) until no further evolution of hydrogen chloride occurs. The yield of propiophenone, b.p. 123°C/25 mmHg, is about 90 g (90%).

**Benzophenone.** A. Into a 500-ml round bottomed flask place 120 ml (105 g, 1.35 mol) of dry benzene (CAUTION) and 35 g (29 ml, 0.25 mol) of redistilled benzoyl chloride. Weigh out 37 g (0.275 mol) of finely powdered, anhydrous aluminium chloride into a dry stoppered conical flask, and add the solid, with frequent shaking, during 10 minutes to the contents of the flask. Fit a reflux condenser with a gas absorption trap attachment to the flask, and heat on a water bath for 3 hours or until hydrogen chloride is no longer evolved. Pour the contents of the flask while still warm into a mixture of 200 g of crushed ice and 100 ml of concentrated hydrochloric acid. Separate the upper benzene layer (filter first, if necessary), wash it with 50 ml of 5 per cent aqueous sodium hydroxide solution, then with water, and dry with magnesium sulphate. Remove the benzene after filtration by flash distillation and distil the residue under diminished pressure through a short fractionating side-arm (Fig. 2.108). Collect the benzophenone at 187–190°C/15 mmHg; it solidifies to a white solid on cooling, m.p. 47–48°C. The yield is 30 g (66%).

B.

\[
_{2}{\text{PhH}} + _{2}{\text{CCl}}_{4} \xrightarrow{2{\text{HCl}}} _{2}{\text{PhCCl}}_{2}{\text{Ph}} \xrightarrow{2{\text{H}_{2}O}} _{2}{\text{PhCOPh}}
\]

Use a four-necked 1-litre flange flask fitted with a double surface condenser, a sealed stirrer unit, a thermometer and a dropping funnel protected by a calcium chloride guard-tube. Attach a gas absorption trap to the reflux condenser outlet. Place 91 g (0.68 mol) of powdered anhydrous aluminium chloride and 200 ml (319 g, 2.07 mol) of dry carbon tetrachloride (CAUTION, p. 399) in the flask, surround the latter with an ice bath and, when the temperature has fallen to 10–15°C, introduce 10 ml (9 g) of sodium-dried benzene (CAUTION). The reaction commences immediately (hydro-
gen chloride is evolved and the temperature rises); add salt to the ice bath to get more efficient cooling. When the temperature commences to fall after the reaction has once started, add a mixture of 100 ml (97 g) of dry benzene (total 1.37 mol) and 110 ml (1.14 mol) of dry carbon tetrachloride at such a rate that the temperature is maintained between 5 and 10 °C (1). The addition usually requires 1–2 hours; continue the stirring for a further 3 hours while maintaining the temperature at 10 °C, and then allow to stand overnight.

Immerse the flask in ice, start the stirrer and add about 500 ml of water through the separatory funnel; the excess carbon tetrachloride usually refluxes during the addition. Distil off as much as possible of the carbon tetrachloride on a water bath, and then distil the mixture with steam (Fig. 2.102) during 30 minutes to remove the residual carbon tetrachloride (2) and to hydrolyse the dichlorodiphenylmethane to benzophenone. Separate the benzophenone layer and extract the aqueous layer with 40 ml of benzene. Dry the combined benzene extract and benzophenone with magnesium sulphate. Remove the benzene by flash distillation and isolate the pure benzophenone, m.p. 47–48 °C, as described in A above. The yield is 105 g (85%).

Notes. (1) Below 5 °C, the reaction is too slow; above 10 °C, appreciable amounts of tarry matter are formed.
(2) About 200 ml of carbon tetrachloride are recovered; this contains some benzene, but may be used after drying and redistillation, in another run.

**Methyl 2-naphthyl ketone** (2-acetynaphthalene). Equip a 1-litre three-necked flask with a sealed mechanical stirrer unit and a pressure-equalising dropping funnel fitted with a calcium chloride guard-tube; stopper the third neck. Place 64 g (0.5 mol) of resublimed naphthalene and 350 g (291 ml) of pure nitrobenzene in the flask and stir until dissolved. To the homogeneous solution add 43.5 g (38.5 ml, 0.55 mol) of redistilled acetyl chloride from the dropping funnel. Cool to −5 °C in a freezing mixture of ice and salt and introduce, while stirring vigorously, 73.5 g (0.55 mol) of finely powdered anhydrous aluminium chloride in small portions during 90 minutes; do not allow the temperature to rise above 0 °C. The aluminium chloride dissolves and a deep green solution results. Remove the stirrer and stopper the central neck; into the side-necks of the flask fit respectively a drawn-out capillary tube and a tube leading through a filter flask trap to a water filter pump. Reduce the pressure to 15–20 mmHg; hydrogen chloride is copiously evolved and a vigorous ebullition occurs in the mixture. When no more gas is evolved, add an excess of crushed ice and separate the nitrobenzene layer. Wash the latter successively with two 100 ml portions of dilute hydrochloric acid and 100 ml of 5 per cent sodium carbonate solution. Use either of the following methods for isolating the pure 2-acetynaphthalene from the accompanying 1-isomer (about 10%) (1).

1. Steam distil from a 1.5-litre flask until the odour of nitrobenzene is no longer perceptible in the distillate (6–12 hours). Extract the cold residue with three 100 ml portions of ether, dry the combined extracts with magnesium sulphate and distil off the ether. The residue solidifies and consists of almost pure methyl 2-naphthyl ketone, m.p. 52 °C; the yield is 30 g (35%). Upon recrystallisation from glacial acetic acid, the m.p. is raised to 54 °C.

2. Distil the dried (magnesium sulphate) nitrobenzene solution under reduced pressure. Nitrobenzene passes over at 95–100 °C/16 mmHg and the
temperature rises rapidly to 170 °C/15 mmHg; collect the fraction of b.p. 170–180 °C/15 mmHg. Transfer while still liquid to a porcelain basin; it solidifies on cooling. Spread it on a porous tile to absorb the small proportion of liquid methyl 1-naphthyl ketone which is present: the resulting yield of crude methyl 2-naphthyl ketone, m.p. 40–42 °C, is 50 g (59%). Two recrystallisations from glacial acetic acid (or from glacial acetic acid–water) give the almost pure 2-isomer, m.p. 53 °C.

**Notes.** (1) Acetylation in carbon tetrachloride solution gives the 1-isomer as the major component. Add 70 g (0.52 mol) of powdered dry aluminium chloride to a vigorously stirred mixture of 41.9 g (38 ml, 0.53 mol) of acetyl chloride and 100 ml of carbon tetrachloride. The mixture becomes warm; cool to 20 °C and then run in slowly a solution of 32 g (0.25 mol) of naphthalene in 100 ml of carbon tetrachloride. Complete the reaction by warming to 30 °C for 30 minutes. Decompose the reaction mixture and work up the product, distilling the final product under reduced pressure, b.p. 165 °C/15 mmHg. The yield is 38.5 g (90%).

**2,4,6-Trihydroxyisobutyrophenone (Phloroisobutyrophenone).** Stir a mixture of 15 g (0.12 mol) of anhydrous phloroglucinol (1), 48 g (0.56 mol) anhydrous powdered aluminium chloride and 60 ml carbon disulphide (CAUTION) for 30 minutes in a three-necked flask fitted with a mechanical stirrer, a dropping funnel and a double surface condenser protected by a calcium chloride guard-tube. Add 45 ml of nitrobenzene, stir the reaction mixture for a further 30 minutes and then surround the flask with a water bath maintained at 60 °C. Add a solution of 13 g (0.12 mol) of 2-methylpropanoyl chloride (Expt 5.138) in 5 ml of nitrobenzene from the dropping funnel over a period of 30 minutes keeping the temperature of the water bath at 60 °C (2). After further 30 minutes of stirring at this temperature pour the viscous residue on to crushed ice, add 425 g (1.5 mol) of Rochelle salt (sodium potassium tartrate) and neutralise the solution with approximately 40 per cent aqueous sodium hydroxide solution (3). Remove the nitrobenzene and carbon disulphide within a period of 20 minutes by vigorous steam distillation without allowing the volume of residual liquor to increase above about 700 ml (4). Filter off the crystals which separate from the residual solution on cooling and standing (usually overnight) and recrystallise twice from water to give 9.3 g (40%) of pure phloroisobutyrophenone hydrate, m.p. 78–80 °C; the anhydrous product, m.p. 138–140 °C, may be obtained by allowing the hydrate to stand in a vacuum desiccator over phosphorus pentoxide for a few days.

**Notes.** (1) Phloroglucinol contains two molecules of water of crystallisation; these are removed by heating for 12 hours at 120 °C.

(2) When carried out on a larger scale the volume of hydrogen chloride gas which is evolved justifies the attachment of a gas adsorption trap (Fig. 2.61) to the outlet of the calcium chloride guard-tube. On the scale suggested in this experiment, the apparatus should be sited within an efficient fume cupboard and the vapours led via a tube to a drain to prevent corrosion of the stirrer motor.

(3) Phloroisobutyrophenone is unstable when heated in the presence of acid; the addition of Rochelle salt prevents the precipitation of aluminium hydroxide when the free acid is neutralised with sodium hydroxide. If any precipitate does appear more Rochelle salt should be added; the exact amount of aqueous sodium hydroxide will vary with each experimental sequence; the point of neutrality is ascertained with universal indicator paper.

(4) If a bench supply of steam is not available, a large steam-can heated with three
large Bunsen burners, or with the large flame of an air–gas blow lamp may be employed. Two efficient double surface water condensers connected in series will be required to cope with the volume of steam and vapour produced and great care must be exercised to ensure that the outlet to the receiver vessel is suitably trapped to prevent the escape of the highly flammable carbon disulphide vapour.

2.4.6-Trihydroxyvalerophenone. Use 15 g (0.12 mol) of phloroglucinol, 48 g (0.56 mol) of anhydrous powdered aluminium chloride and 14.4 g (0.12 mol) of valeryl chloride (Expt 5.138) with the same volumes of nitrobenzene and carbon disulphide and under the conditions described for phloroisobutyrophenone. The yield of hydrated product, m.p. 88–90°C (m.p. 152–154°C, anhydrous), is 11.5 g (42%).

2',4',6'-Trihydroxy-2-methylbutanophenone. Use 15 g (0.12 mol) of phloroglucinol, 48 g (0.56 mol) of anhydrous powdered aluminium chloride and 14.4 g (0.12 mol) of 2-methylbutanoyl chloride (Expt 5.138) under the conditions specified above. The yield of hydrated product, m.p. 61–63°C, is 14.3 g (52%). The anhydrous product is hygroscopic.

Experiment 6.122 p-METHYLCETOPHENONE (Acetylation with acetic anhydride)

\[
\text{Ph·Me} + (\text{Me·CO})_2\text{O} \xrightarrow{\text{AlCl}_3} p-\text{Me·C}_6\text{H}_4·\text{CO·Me} + \text{Me·CO}_2\text{H}
\]

Equip a 500-ml three-necked flask with a double surface condenser, a sealed stirrer unit and a dropping funnel protected with a calcium chloride guard-tube. Connect the top of the condenser to a trap for absorbing the hydrogen chloride evolved (Fig. 2.61). Place 75 g (0.56 mol) of anhydrous, finely powdered aluminium chloride (see Section 4.2.4, p. 416) and 120 g (140 ml, 1.30 mol) of pure dry toluene (Section 4.1.3, p. 398) in the flask and cool the latter in a bath of ice-water. Add 26 g (24 ml, 0.25 mol) of redistilled acetic anhydride during half an hour while the contents of the flask are thoroughly stirred; much heat is evolved in the reaction. Heat on a boiling water bath for about 30 minutes (or until the evolution of hydrogen chloride almost ceases) to complete the reaction, cool and pour the contents of the flask into a mixture of 150 g of crushed ice and 150 ml of concentrated hydrochloric acid contained in a beaker or flask. Stir or shake until all the aluminium salts are dissolved. Transfer the mixture to a separatory funnel, add 25–30 ml of ether, shake and separate the upper (largely toluene) layer. Extract the aqueous layer with 25 ml of ether and add this to the toluene solution. Wash the combined toluene and ether extracts with 50 ml of 10 per cent sodium hydroxide solution (or until the washings remain alkaline), then with water, separate the organic layer and dry it with magnesium sulphate or anhydrous calcium chloride. Remove the ether and toluene by distillation under atmospheric pressure and isolate the p-methylacetophenone by distillation at reduced pressure through a short fractionating column. The product (29 g, 86%) has b.p. 93–94°C/7 mmHg. The i.r. and p.m.r. spectra of p-methylacetophenone and the compounds of the following cognate preparations should be recorded and interpreted using the spectra of acetophenone as a guide (pp. 268 and 329).

Cognate preparations. p-Bromoacetophenone. In a 1-litre three-necked flask,
equipped as above, place 78.5 g (52.5 ml, 0.5 mol) of dry bromobenzene (Expt 6.23), 200 ml of dry carbon disulphide (CAUTION: see Section 2.3.2, p. 40) and 150 g of finely powdered anhydrous aluminium chloride. Stir the mixture and heat on a water bath until gentle refluxing commences; add 51 g (47.5 ml, 0.5 mol) of redistilled acetic anhydride slowly through the dropping funnel (30–60 minutes). Maintain gentle refluxing during the addition of the acetic anhydride and for 1 hour afterwards. Distil off most of the carbon disulphide on a water bath, allow the reaction mixture to cool somewhat and while still warm pour it slowly with stirring into a mixture of 500 g of crushed ice and 300 ml of concentrated hydrochloric acid. Decompose any residue in the flask and add it to the main product. Extract with 150 and 100 ml portions of ether, wash the combined extracts twice with water, once with 10 per cent sodium hydroxide solution and twice with water. Dry the extract with magnesium sulphate or anhydrous calcium chloride, remove the ether and distil the residue under reduced pressure. The p-bromoacetophenone boils at 130 °C/15 mmHg or at 117 °C/7 mmHg and a 3 °C fraction should be collected; it crystallises as a white solid, m.p. 50 °C. The yield is 75 g (75%). The b.p. under atmospheric pressure has been given as 255.5 °C/736 mmHg.

**p-Chloroacetophenone.** Use 56 g (51 ml, 0.5 mol) of chlorobenzene and proceed as for p-bromoacetophenone. The yield of product, b.p. 124–126 °C/24 mmHg, m.p. 20–21 °C, is 60 g (78%). The b.p. under atmospheric pressure is 237 °C.

**p-Methoxyacetophenone.** Use 54 g (54.5 ml, 0.5 mol) of anisole and proceed as for p-bromoacetophenone. The yield of p-methoxyacetophenone, b.p. 139 °C/15 mmHg, is 70 g (93%). The b.p. under atmospheric pressure is 265 °C.

**p-Phenylacetophenone.** In a 1-litre three-necked flask provided with a dropping funnel, a mechanical stirrer and a reflux condenser, place 77 g (0.5 mol) of biphenyl, 150 g (1.125 mol) of finely powdered anhydrous aluminium chloride and 350 ml of anhydrous carbon disulphide (CAUTION). Charge the dropping funnel with 51 g (47.5 ml, 0.5 mol) of pure acetic anhydride and close the mouth of the funnel with a calcium chloride guard-tube. Heat the mixture on a water bath until gentle refluxing commences, and add the acetic anhydride during 1 hour; the addition product makes its appearance as a curdy mass when about three-quarters of the anhydride has been added. Reflux the reaction mixture gently for a further hour. Allow to cool and pour the reaction product slowly and with stirring on to crushed ice to which hydrochloric acid has been added. Filter the precipitated p-phenylacetophenone on a Buchner funnel, wash repeatedly with water until free from acid, dry, and distil under reduced pressure. There is usually a small fraction of low boiling point; the main product passes over at 196–210 °C/18 mmHg and solidifies on cooling. The yield of crude p-phenylacetophenone, m.p. 118 °C, is 85 g (86%). Upon recrystallisation from rectified spirit, the m.p. is raised to 120–121 °C; the recovery is about 80 per cent.
2-Acetylthiophene

\[
\text{S} + (\text{Me-CO})_2\text{O} \rightarrow \text{S-CO-Me}
\]

Place 84 g (79 ml, 1 mol) of thiophene and 51 g (47.5 ml, 0.5 mol) of acetic anhydride in a 500-ml three-necked flask, fitted with a thermometer, mechanical stirrer and reflux condenser. Heat the stirred solution to 70–75 °C, remove the source of heat and add 5 g (4 ml) of 85–89 per cent orthophosphoric acid. An exothermic reaction occurs after 2–3 minutes and the temperature may rise to 90 °C; immerse the flask in a bath of cold water to control the reaction. When the boiling subsides (c. 5 minutes), reflux the mixture for 2 hours. Add 125 ml of water, stir for 5 minutes, transfer the cold reaction mixture to a separatory funnel, remove the water layer, wash with two 50 ml portions of 5 per cent sodium carbonate solution and dry over magnesium sulphate. Distil the orange-red liquid through a short fractionating column (Fig. 2.108) at atmospheric pressure and thus recover 38 g of unchanged thiophene at 83–84 °C. Distil the residue under reduced pressure and collect the 2-acetylthiophene at 89–90 °C/10 mmHg; this solidifies on cooling in ice, m.p. 10 °C. The yield is 44 g (70%).

*Acetylferrrocene* [acetylcyclopentadienyl(cyclopentadienyl)iron(II)]. Using a Pasteur pipette add 85 per cent phosphoric acid (1 ml) to a mixture of ferrocene (Expt 6.15) (1.5 g) and acetic anhydride (5 ml) contained in a small round-bottomed flask with constant shaking. Protect the mixture by the attachment of a calcium chloride drying tube, and heat it on a water bath for 10 minutes. Pour the mixture on to ice (20 g) contained in a 500 ml beaker. Add water to melt the remaining ice, and then neutralise the mixture by adding solid sodium hydrogen carbonate until carbon dioxide is no longer evolved. Cool the mixture in an ice bath for 15 minutes and filter on a No. 2 or No. 3 sintered glass crucible. Wash the collected solid with water to remove any white inorganic salts. Dry the orange-brown product by drawing air through it for at least 15 minutes. The product consists mainly of the acetyl derivative and unreacted ferrocene.

**Purification by column chromatography.** Push a small wad of glass wool to the bottom of a dry 50 ml burette with the aid of a glass rod; pour in enough acid-washed sand to give a 5 mm layer. Prepare a solvent mixture of ethyl acetate (20 ml) and light petroleum (180 ml, b.p. 60–80 °C). Make a slurry of column grade silica gel with a little of the prepared solvent and transfer to the burette. Repeat this operation until the silica gel level reaches the 20 ml mark, and then drain the solvent to *just* coincide with this level. Mix the above crude acetyl derivative (0.4 g) with a little silica gel and slurry with a small portion of solvent mixture. Transfer the slurry to the burette using a *small* amount of additional solvent, and again lower the solvent level to the silica gel layer. Add another 5 mm-layer of sand. Fill the burette with solvent taking care not to disturb the upper sand layer. Elute the products at the rate of 1–2 drops per second when the difference in colour of ferrocene and its acetyl derivative will enable them to be collected as separate fractions. Evaporate each collected fraction to dryness and confirm their identity by melting point.
determinations, and by recording their i.r. spectra in chloroform solution, and their p.m.r. spectra. The p.m.r. spectrum of ferrocene exhibits a single absorption peak, $\delta = 4.09$; that of the acetyl derivative (CDCl$_3$, TMS) has absorptions at $\delta = 2.39$ (s, 3H, Me), 4.19 (s, 5H, unsubstituted ring H’s), 4.48 (m, 2H, C$_3$,=—H), and 4.77 (m, 2H, C$_1$,=—H).

**Experiment 6.123 $\alpha$-TETRALONE**

\[
\begin{align*}
\text{PhH} + \text{O} & \xrightarrow{\text{AlCl}_3} \text{Ph} - \text{C} - \text{C} - \text{COOH} \xrightarrow{\text{Zn/Hg/}HCl} \text{Ph} - \text{C} - \text{C} - \text{COOH} \\
\text{CO}_2\text{H} & \xrightarrow{\text{PPA}} \text{Ph} - \text{C} - \text{C} - \text{CO}
\end{align*}
\]

**3-Benzoylpropanoic acid.** Place 175 g (2.25 mol) of sodium-dried benzene (CAUTION) and 34 g (0.34 mol) of succinic anhydride (Expt 5.141) in a 1-litre three-necked flask equipped with a sealed stirrer unit and two efficient reflux condensers, the tops of which are connected through a Y-junction to a single efficient gas absorption device (Fig. 2.61). Stir the mixture and add 100 g (0.75 mol) of powdered, anhydrous aluminium chloride all at once. The reaction usually starts immediately — hydrogen chloride is evolved and the mixture becomes hot; if there is no apparent reaction, warm gently. Heat in an oil bath to gentle refluxing, with continued stirring, for half an hour. Allow to cool, immerse the flask in a bath of cold water and slowly add 150 ml of water from a separatory funnel inserted into the top of one of the condensers. Introduce 50 ml of concentrated hydrochloric acid and separate the benzene by steam distillation (Fig. 2.102). Transfer the hot mixture to a 600-ml beaker; the 3-benzoylepropanoic acid separates as a colourless oil, which soon solidifies. Cool in ice, filter off the acid at the pump and wash with 100 ml of cold dilute hydrochloric acid (1:3 by volume) and then with 100 ml of cold water. Dissolve the crude acid in a solution of 40 g of anhydrous sodium carbonate in 250 ml of water by boiling for 10–15 minutes; filter the solution with suction to remove the small amount of aluminium hydroxide and wash with two 25 ml portions of hot water. Treat the hot filtrate with 2 g of decolourising carbon, stir for 5 minutes and filter at the pump through a preheated Buchner funnel. Transfer the hot filtrate to a 1-litre beaker, cool to about 50°C and cautiously acidify with 65–70 ml of concentrated hydrochloric acid. Cool to 0°C in a freezing mixture of ice and salt, filter, wash thoroughly with cold water, dry for 12 hours upon filter papers, and then to constant weight at 45–50°C. The yield of practically pure 3-benzoylepropanoic acid, m.p. 115°C, is 57 g.

**4-Phenylbutanoic acid.** Prepare amalgamated zinc from 120 g of zinc wool contained in a 1-litre round-bottomed flask (Section 4.2.80, p. 467), decant the liquid as completely as possible and add in the following order 75 ml of water, 180 ml of concentrated hydrochloric acid, 100 ml of pure toluene and 50 g (0.28 mol) of 3-benzoylepropanoic acid. Fit the flask with a reflux
condenser connected to a gas absorption device (Fig. 2.61), and boil the reaction mixture vigorously for 30 hours; add three or four 50 ml portions of concentrated hydrochloric acid at approximately six-hour intervals during the refluxing period in order to maintain the concentration of the acid. Allow to cool to room temperature and separate the two layers. Dilute the aqueous portion with about 200 ml of water and extract with three 75 ml portions of ether. Combine the toluene layer with the ether extracts, wash with water and dry over anhydrous magnesium or calcium sulphate. Remove the solvents by distillation under diminished pressure using a rotary evaporator and distil the residue under reduced pressure (Fig. 2.108). Collect the 4-phenylbutanoic acid at 178–181 °C/19 mmHg; this solidifies on cooling to a colourless solid (40 g, 89%) and melts at 47–48 °C.

\( \alpha \)-Tetralone. Heat 120 g of polyphosphoric acid (Section 4.2.58, p. 458) to 90 °C in a 1-litre beaker on a steam bath. Liquefy 33 g (0.20 mol) of 4-phenylbutanoic acid by heating to 70 °C and add this in one portion to the polyphosphoric acid with manual stirring. Remove the beaker from the steam bath and continue stirring for 3 minutes; the temperature should remain at about 90 °C. Then add 100 g more of polyphosphoric acid and warm on a steam bath with vigorous stirring for 4 minutes. Cool to 60 °C, add 300 g of crushed ice and stir until the polyphosphoric acid is completely hydrolysed and a yellow oil has separated. Extract the mixture with three 150 ml portions of ether and wash the combined extracts with water, with 5 per cent aqueous sodium hydroxide solution and then with water until the washings are neutral. Dry the ethereal solution over magnesium sulphate and remove the ether on a rotary evaporator. Distil the residue under reduced pressure through a short fractionating column and collect the \( \alpha \)-tetralone at 105–107 °C/2 mmHg or 135–137 °C/15 mmHg. The yield is 23 g (79%).

**Experiment 6.124 \( o \)-BENZOYLBENZOIC ACID**

![Chemical structure](image)

Equip a 750-ml three-necked flask with a sealed mechanical stirrer and a reflux condenser connected with a gas absorption trap (Fig. 2.61); insert a stopper in the third neck. Place 25 g (0.17 mol) of pure phthalic anhydride [see Expt 5.220, Note (1)] and 100 ml (1.16 mol) of sodium-dried benzene (CAUTION) in the flask; start the stirrer and add 50 g (0.375 mol) of powdered anhydrous aluminium chloride from a stoppered test tube in four portions or, alternatively, use the device shown in Fig. 2.57. If the reaction does not commence after the addition of the first 12 g of aluminium chloride, warm for a few seconds on a water bath. When all the aluminium chloride has been added and the evolution of hydrogen chloride slackens, warm on a water bath and ultimately reflux the mixture until the evolution of gas practically ceases. Cool the flask, add crushed ice slowly until the dark mass is completely decomposed and then run in concentrated hydrochloric acid (35–40 ml) until the solution clears. Steam distil (Fig. 2.102) to remove the excess
of benzene; the residue in the flask, when cooled in ice, largely solidifies and consists of crude o-benzoylbenzoic acid. Filter off the solid product and wash it well with 74 ml of cold water; dissolve the solid in 150 ml of warm 10 per cent sodium carbonate solution. Treat the solution of the sodium salt with 2 g of decolourising charcoal, boil for 2 minutes and filter through a preheated Buchner funnel. Place the filtrate in a 1-litre beaker, cool in ice and cautiously acidify with concentrated hydrochloric acid while stirring well (c. 20 ml are required). The acid separates as an oil but it soon crystallises on stirring and cooling. Filter when ice cold, and wash with a little water. Dry in the air upon filter paper; the product, which is somewhat efflorescent, consists largely of the monohydrate, m.p. 94 °C.

To prepare pure anhydrous o-benzoylbenzoic acid, dissolve the air-dried (or the moist) product in about 175 ml of toluene contained in a 500-ml round-bottomed flask fitted with a reflux condenser and heat on a water bath. Transfer the toluene solution to a separatory funnel, run off any water present and dry with magnesium sulphate. Concentrate the toluene solution to about half its volume and add light petroleum (b.p. 60–80 °C) to the hot solution until a slight turbidity is produced. Allow to cool spontaneously to room temperature, then cool in ice to about 5 °C, collect the crystals and dry. The yield of pure, anhydrous o-benzoylbenzoic acid, m.p. 128 °C, is 32 g (84%).

**Experiment 6.125 2,4,6-TRIHYDROXYACETOPHENONE**
*(Phloroacetophenone)*

Place 25.2 g (0.2 mol) of dry phloroglucinol (1), 16.4 g (20.9 ml, 0.4 mol) of anhydrous acetonitrile (2), 100 ml of sodium-dried ether and 5 g of finely powdered, fused zinc chloride in a 500-ml Buchner flask fitted with a wide gas inlet tube. Protect the side-arm of the flask with a calcium chloride guard-tube. Cool the flask in an ice–salt mixture in the fume cupboard and pass a rapid stream of dry hydrogen chloride (Section 4.2.38, p. 438) through the solution for 2 hours with occasional shaking. Allow the flask to stand in an ice chest for 24 hours, and again pass dry hydrogen chloride into the pale orange mixture for a further 2 hours. Stopper the flask and leave it in an ice chest (or refrigerator) for 3 days. A bulky orange-yellow precipitate of the ketimine hydrochloride is formed. Decant the ether and wash the solid with two 25 ml portions of anhydrous ether. Transfer the solid with the aid of about 1 litre of hot water to a 2-litre round-bottomed flask provided with a reflux condenser. Boil the yellow solution vigorously for 2 hours, allow to cool somewhat, add 4–5 g of decolourising carbon, boil the solution for 5 minutes longer and filter the hot solution with suction through a preheated Buchner funnel. Extract the decolourising carbon with two 100 ml portions of boiling water and add the filtrate to the main product. Allow to stand overnight, and filter the pale yellow or colourless needles of phloroaceto-
phenone at the pump, dry at 120 °C to remove the molecule of water of crystallisation and preserve in a tightly stoppered bottle. The yield is 29 g (85%), m.p. 217–219 °C. This product is pure enough for many purposes, but may be obtained absolutely pure by recrystallisation from hot water (35 ml per gram) and drying at 120 °C; m.p. 218–219 °C.

Notes. (1) See acetylation of phloroglycinol, Expt 6.121, cognate preparation, Note (1).
(2) The acetonitrile may be dried over anhydrous calcium sulphate or by distilling from phosphorus pentoxide.

6.11.2 SYNTHESIS OF AROMATIC KETONES FROM CARBOXYLIC ACID DERIVATES

Grignard reagents derived from aryl bromides are readily prepared and may be converted into organocadmium compounds by treatment with cadmium chloride (cf. Section 5.8.4, p. 616). Reaction of an organocadmium with a carboxylic acid chloride constitutes a convenient synthesis of aryl alkyl ketones.

\[
2\text{ArBr} + 2\text{Mg} \rightarrow 2\text{ArMgBr} \xrightarrow{\text{CdCl}_2} \text{Ar}_2\text{Cd} + 2\text{MgClBr}
\]

\[
\text{Ar}_2\text{Cd} + 2\text{R} \cdot \text{COCl} \rightarrow 2\text{Ar} \cdot \text{CO} \cdot \text{R} + \text{CdCl}_2
\]

The reaction is illustrated by the formation of propiophenone from diphenylcadmium and propanoyl chloride (Expt 6.126). Better yields are obtained by carrying out the synthesis in this manner rather than attempting the alternative combination of diethylcadmium with benzoyl chloride. Alternatively an alkyl-lithium 'cuprate' could be used with an aromatic acid chloride (p. 616).

Several examples of the synthesis of aryl alkyl ketones by the thermal decarboxylation of mixtures of carboxylic acids over heated metal salts are included under the preparation of aliphatic ketones (Expt 5.93). In this section the preparation of dibenzyl ketone (Expt 6.127) by the pyrolysis of the barium salt of phenylacetic acid, which proceeds in good yield, is included as a further example of this general type of synthesis.

Experiment 6.126 PROPIOPHENONE (Ethyl phenyl ketone)

\[
\text{Ph}_2\text{Cd} + 2\text{Et} \cdot \text{COCl} \rightarrow 2\text{Ph} \cdot \text{CO} \cdot \text{Et} + \text{CdCl}_2
\]

**CAUTION:** All operations should be conducted in an efficient fume cupboard.

Prepare a solution of diphenylcadmium in 110 ml of dry benzene (CAUTION) using 4.9 g (0.2 mol) of magnesium, 31.4 g (0.2 mol) of bromobenzene and 19.5 g (0.106 mol) of anhydrous cadmium chloride following the experimental procedure given for the preparation of dibutylcadmium (Expt 5.94). Cool the solution to 10 °C, and add during 3 minutes a solution of 14.8 g (0.16 mol) of propanoyl chloride (b.p. 78–79 °C) in 30 ml of dry benzene (CAUTION); use external cooling with an ice bath to prevent the temperature rising above 40 °C. Stir the mixture for 2 hours at 25–35 °C. Add crushed ice (c. 200 g) and sufficient dilute (1 M) sulphuric acid to give a clear aqueous layer. Separate the benzene from the aqueous layer and extract the latter with two 20 ml portions of benzene. Wash the combined extracts successively with 50 ml portions of water, 5 per cent sodium carbonate solution, water and saturated sodium chloride solution. Dry over anhydrous sodium sulphate, remove the benzene by flash distillation and distil the residue under reduced
pressure. The yield of propiophenone, b.p. 100–102 °C/16 mmHg, is 17.5 g (82%).

Experiment 6.127 DIBENZYL KETONE

\[(\text{Ph} \cdot \text{CH}_2 \cdot \text{CO}_2 \cdot \text{Ba}) \xrightarrow{\text{heat}} (\text{Ph} \cdot \text{CH}_2)_2 \text{CO} + \text{BaCO}_3\]

Place 40 g (0.127 mol) of barium hydroxide octahydrate with 60 ml of water in a 250-ml round-bottomed flask and add 34 g (0.25 mol) of phenylacetic acid (Expt 5.128) slowly with swirling; warm the mixture until a clear solution is obtained. Evaporate the solution on a water bath under reduced pressure using a rotary evaporator, to yield a pasty mass of moist barium phenylacetate. Fit the flask with a Claisen still-head carrying a gas inlet tube for nitrogen extending well into the flask and a 360 °C thermometer, and attach an air condenser with a receiver flask connected by means of an adapter with side arm. Lag the Claisen head with suitable insulating tape. Pass a slow stream of nitrogen into the flask and heat the latter gently in an air bath. When the residual water has been expelled, change the receiver. Now heat more strongly; dibenzyl ketone passes over at 320–325 °C as a pale yellow oil (24 g) which solidifies on standing. Redistil under reduced pressure and collect pure dibenzyl ketone at 210 °C/35 mmHg as a colourless oil (21 g, 80%); this completely crystallises on standing and has m.p. 33–34 °C.

6.11.3 QUINONES

The simplest quinones are o- and p-benzoquinone [(3) and (4) respectively]. This quinonoid structural feature is widespread in naturally occurring compounds isolated from moulds, fungi, lichens, plants and insects, which include not only substituted benzoquinones but also substituted polycyclic quinones [i.e. the substituted analogues of, for example, 1,2-naphthoquinone (5), 9,10-anthraquinone (6), and 9,10-phenanthraquinone (7)].

![Structures](image)

These quinonoid systems play a vital role in biosynthetic routes, are found as structural units in antibiotics and pigments, and are found in compounds having antihaemorrhagic activity (e.g. the Vitamin K group). In the laboratory substituted quinones are used as oxidising agents, and as starting materials for
the synthesis of polycyclic compounds by virtue of their dienophilic reactivity in
the Diels–Alder reaction (Section 7.6).
An excellent survey of the various methods of synthesis is available; this
section includes some of the illustrative methods of synthesis of the simpler
analogues. These methods may be considered under the following headings: (a)
the oxidation of hydrocarbons; (b) the oxidation of phenols and the oxidative
coupling of phenols; (c) the oxidation of dihydric phenols and aminophenols;
and (d) the cyclisation of aroylbenzoic acids.

OXIDATION OF HYDROCARBONS
Quinones of the more reactive, polycyclic, aromatic systems can usually be
obtained by direct oxidation, which is best carried out with chromium(vi)
compounds under acidic conditions. In this way 1,4-naphthoquinone, 9,10-
anthraquinone and 9,10-phenanthraquinone are prepared from naphthalene,
anthracene and phenanthrene respectively (Expt 6.128). Also included in this
section is the reduction of anthraquinone with tin and acid to give anthrone,
probably by the sequence of steps formulated below.

OXIDATION OF PHENOLS AND THE OXIDATIVE COUPLING OF
PHENOLS
The classical and the most useful laboratory method for the preparation of
quinones is the oxidation of monohydric phenols with the radical reagent,
potassium nitrosodisulphonate [(K03S)2NO] (Fremy’s salt) (the Teuber
reaction). Details for the conversion of 3,4-dimethylphenol into 3,4-dimethyl-
1,2-benzoquinone may be regarded as typical; the probable mechanistic
pathway is formulated below.
The ortho coupling of phenoxy radicals is noted in the formation of 1,1'-bi-2-naphthol from 2-naphthol by oxidation with iron(III) chloride (Expt 6.10). In the case of hindered 2,6-dialkylphenols, a very wide range of oxidants have been found to be variously successful in effecting para coupling; further oxidation then occurs to give an extended quinone.

Oxidation of hindered phenols bearing additionally a para methyl group leads to substituted stilbenequinones. These may be reduced in the presence of zinc and acid to the corresponding dihydroxystilbenes.

The reagents which have been used here to illustrate these interesting reactions are periodic acid for the oxidation of 2,6-di-t-butylphenol,\(^5\) and a Celite-supported silver carbonate reagent for the oxidation of 2,6-dimethyl phenol, and 2,4,6-trimethylphenol\(^5\) (Expt 6.129).

**OXIDATION OF DIHYDRIC PHENOLS AND AMINOPHENOLS**

\(p\)-Benzoquinone is conveniently prepared in the laboratory by the oxidation of hydroquinone (Expt 6.130) with either chromium trioxide in acetic acid or with sodium chlorate in the presence of vanadium pentoxide as a catalyst.

\(p\)-Benzoquinone and hydroquinone form a well-defined molecular complex known as quinhydrone. This complex, in the form of dark green crystals having a glistening metallic lustre, is conveniently prepared (Expt 6.130) by the partial oxidation of hydroquinone with a solution of iron alum.

The behaviour of \(p\)-benzoquinone on reaction with acetic anhydride in the presence of sulphuric acid is of interest. The eventual product is 1,2,4-triacetoxybenzene (the Thiele acetylation), which is formed by the following
reaction sequence, initiated by a 1,4-addition of acetic anhydride across an \( \alpha,\beta \)-unsaturated carbonyl system.

\[
\begin{align*}
\text{MeCO}_2 & \quad \xrightleftharpoons{} \quad \text{Me} \cdot \text{CO} \cdot \text{O} \\
\end{align*}
\]

The formation of \( o \)-quinones by the above oxidative methods is less reliable since the \emph{ortho} quinonoid system is more susceptible to attack by electrophilic and nucleophilic species; mild conditions are therefore essential. The use of the silver carbonate/Celite reagent noted above for phenol coupling reactions is particularly suitable; the conditions are those described in Expt 6.129, and they have been applied to the oxidation of catechol, 4-methylcatechol, 4-t-butylcatechol, and 3,5-di-t-butylcatechol to yield the corresponding \( o \)-quinones in almost quantitative yield.

A fairly general procedure for the synthesis of \( o \)- and \( p \)-quinones consists in coupling a phenol with a diazonium salt and reducing the resulting azo compound to an aminophenol with sodium dithionite. Mild oxidation with, for example, iron(III) chloride results in the formation of the corresponding quinone (e.g. the preparation of 1,2-naphthoquinone described and formulated in Expt 6.131).

**CYCLISATION OF AROYL BENZOIC ACIDS**

The aroylation of an aromatic system by reaction with phthalic anhydride under Friedel–Crafts conditions is described in Section 6.11.1, p. 1006. The cyclisation of the derived \( o \)-aryloxybenzoic acid with polyphosphoric acid is a convenient route to substituted anthraquinones. The reaction is illustrated by the formation of 2-methylanthraquinone from \( o \)-(p-toluoyl)benzoic acid (Expt 6.132).

**Experiment 6.128 1,4-NAPHTHOQUINONE**

\[
\begin{align*}
\text{CrO}_3 & \quad \xrightarrow{\text{CH}_3\cdot\text{CO}_2\text{H}} \quad \text{O} \\
\end{align*}
\]

Place a solution of 120 g (1.2 mol) of pure chromium trioxide in 150 ml of 80 per cent aqueous acetic acid in a 2-litre three-necked flask, fitted with a
thermometer, mechanical stirrer and 1-litre dropping funnel. Surround the flask by a mixture of ice and salt and, when the temperature has fallen to 0°C, add a solution of 64 g (0.5 mol) of pure naphthalene in 600 ml of glacial acetic acid, with constant stirring, over a period of 2–3 hours while maintaining the internal temperature at 10–15°C. Continue the stirring overnight, during which time the reaction mixture and bath attain room temperature. Allow the dark green solution to stand for 3 days and stir occasionally. Pour the reaction mixture into 5–6 litres of water, collect the crude naphthoquinone by suction filtration, wash with 200 ml of water and dry in a desiccator. Recrystallise from 500 ml of petroleum ether (b.p. 80–100°C). The yield of pure 1,4-naphthoquinone, m.p. 124–125°C, is 17 g (22%).

Cognate preparations. 9,10-Anthraquinone. Place 5.0 g of powdered anthracene and 50 ml of glacial acetic acid in a 250-ml, two-necked round-bottomed flask with a reflux condenser and a dropping funnel. Mix the flask contents thoroughly by a swirling action and heat the mixture to reflux when most of the anthracene dissolves. Dissolve 10.0 g of chromium trioxide in 7–8 ml of water, add 25 ml of glacial acetic acid and pour the well-stirred mixture into the dropping funnel. Remove the heat source from the flask and add slowly the oxidising reagent at such a rate that the mixture continues to reflux (7–10 minutes); then reflux for a further 10 minutes when all the anthracene will have reacted completely. Cool the solution and pour into 250 ml of cold water. Stir the mixture vigorously, filter off the precipitated anthraquinone under gentle suction, wash it thoroughly on the filter with hot water, then with 50 ml of hot 1 M sodium hydroxide solution and finally with much cold water; drain well. Dry the anthraquinone by pressing it between several sheets of filter paper and leave it overnight in a desiccator over calcium chloride. The yield is 5.5 g (94%).

Purify the anthraquinone by either of the following methods:

1. Recrystallise the crude product from boiling glacial acetic acid with the aid of decolourising charcoal, wash the resulting crystals on the Buchner funnel with a little cold rectified spirit and dry in the air.
2. Sublime the dry solid using the procedure described in Section 2.21. The purified anthraquinone is obtained as yellow crystals having m.p. 273°C.

Reduction of anthraquinone to anthrone. Place 52 g (0.25 mol) of anthraquinone, 50 g (0.42 mol) of granulated tin and 375 ml of glacial acetic acid in a 1-litre round-bottomed flask fitted with a reflux condenser. Heat the contents of the flask to boiling and slowly run in 125 ml of concentrated hydrochloric acid from a dropping funnel down the condenser over a period of 2 hours. By this time all the anthraquinone should have passed into solution; if not, add more tin and hydrochloric acid. Filter the liquid with suction through a sintered glass funnel, and add 50 ml of water. Cool the solution to about 10°C when the anthrone will crystallise out. Filter the crystals at the pump on a Buchner funnel and wash with water. Dry upon filter-paper or upon a porous tile: the yield of crude anthrone, m.p. about 153°C, is 40 g (82%). Recrystallise from a 3:1 mixture of benzene and light petroleum, b.p. 60–80°C (10–12 ml per gram); this gives 30 g (61%) of pure anthrone, m.p. 155°C.

Phenanthraquinone. Add 20 ml of concentrated sulphuric acid cautiously and with stirring to 40 ml of water contained in a 250-ml beaker. Heat to 90–95°C
on a water bath (it may be necessary to place the beaker in the boiling water bath), add 2.0 g (0.011 mol) of purified phenanthrene, and then 12.0 g of potassium dichromate in 0.5 g quantities until a vigorous reaction sets in: the latter usually occurs by the time about half of the oxidising agent has been added. Remove the beaker from the water bath – the temperature of the mixture will be 110–115 °C – and continue adding the potassium dichromate in small portions to maintain the reaction. Do not allow the temperature to fall below 85 °C as the reaction will cease: if necessary, heat on a water bath. When the addition is completed, heat on a boiling water bath for a further 30 minutes.

Cool the beaker in a bath of cold water and add 150 ml of cold water. Filter off the crude phenanthraquinone with suction and wash it with water until free from chromium salts. Suspend the solid in 20 ml of rectified spirit and add, with stirring, 20 ml of saturated sodium metabisulphite solution. Break up the lumps of the addition product with a glass rod and allow to stand, with frequent stirring, for 10 minutes. Add 150 ml of water to dissolve the addition product and filter with suction. Reject the precipitate which consists of the impurities present in the phenanthrene. Add saturated sodium carbonate solution to the filtrate until the bisulphite addition product is completely decomposed: allow the precipitate to settle for 1 minute, then add a few drops of sodium carbonate solution and note whether any further precipitation occurs. Stir the precipitate for 2–3 minutes, filter with suction, wash with three 20 ml portions of water and drain well. Dry the product between filter papers and then in a desiccator over calcium chloride. The yield of phenanthraquinone, m.p. 206 °C, is 1.4 g (60%). The product may be recrystallised from glacial acetic acid (about 20 ml), but the m.p. is unaffected.

Experiment 6.129 3,3',5,5'-TETRA-t-BUTYLDIPHENOQUINONE

\[
\begin{align*}
2 \text{Bu}^t \text{C}_6\text{H}_4\text{OH} & \overset{\text{H}_2\text{O}_2}{\rightarrow} \text{Bu}^t \text{C}_6\text{H}_4\text{O}_2\text{C}_6\text{H}_4\text{Bu}^t \\
2,6\text{-Di-t-butylphenol} (2.06 \text{ g}, 10 \text{ mmol}) & \text{dissolved in dimethylformamide (10 ml), an aqueous solution of 4 M periodic acid (3.5 g, 4 ml) added, and the solution stirred at 85–95 °C (hot water bath) for 4–5 minutes. The coloured product partially crystallises out by this time. After 5–10 minutes at room temperature, the reaction mixture is diluted with 50 per cent aqueous methanol (8–10 ml), and the product isolated by filtration and washed with cold methanol. The resultant is recrystallised from aqueous acetone to give the product (94%) as brown-red needles, m.p. 245–247 °C.}
\end{align*}
\]

Cognate preparation. General procedure using Celite-supported silver carbonate. Preparation of reagent. The Celite is purified by washing it successively with methanol containing 10 per cent concentrated hydrochloric acid and then with distilled water until neutral; it is finally dried at 120 °C. Purified Celite (30 g) is added to a mechanically stirred solution of silver nitrate (34 g, 200 mmol) in distilled water (200 ml). A solution of sodium carbonate decahydrate (30 g, 105 mmol) (or 21 g, 210 mmol of potassium
hydrogen carbonate) in distilled water (300 ml) is then added slowly to the resulting homogeneous suspension. When the addition is complete, stirring is continued for a further 10 minutes. The yellow-green precipitate which is formed is then filtered off and finally dried in a rotary evaporator over a period of several hours. The silver carbonate/Celite reagent contains about 1 mmol of silver carbonate in 0.57 g.

**Oxidation procedure.** The reagent is freed from residual water by azeotropic distillation with benzene (CAUTION). The compound to be oxidised is then added and refluxed in benzene (c. 200 ml for 0.5-2.0 g of compound). At the end of the reaction (determined by t.l.c. monitoring), the solid phase is filtered off and the solvent evaporated. The product is usually highly pure and recrystallisation is unnecessary. With 2,6-dimethylphenol the molar ratio of phenol to silver carbonate is 1:4.4, and the reaction time is half an hour; in this case 3,3′,5,5′-tetramethyldiphenoquinone is obtained in 98 per cent yield and has m.p. 217–218 °C. With 2,4,6-trimethylphenol, using the same molar ratio of phenol to oxidant, and a reaction time of 2 hours, 3,3′,5,5′-tetramethylstilbenequinone is obtained in 93 per cent yield and having m.p. 227–228 °C.

**Reduction of a stilbenequinone.** A solution of 3,3′,5,5′-tetramethylstilbenequinone (0.05 g) in acetic acid (100 ml) is shaken with zinc dust (4 g) for about 1 hour. The colourless mixture is filtered and the filtrate neutralised with sodium hydrogen carbonate. Extraction with ether and evaporation of solvent gives 3,3′,5,5′-tetramethyl-4,4′-dihydroxystilbene as yellow crystals, m.p. 237–240 °C; p.m.r. (Me₂CO-d₆, TMS) δ 2.24 (s, 12H), 3.00 (s, 2H), 6.87 (s, 2H), and 7.12 (s, 4H).

**Experiment 6.130 p-BENZOQUINONE**

![Chemical structure of p-Benzoquinone]

**Method 1.** Cool a solution of 33 g (0.33 mol) of hydroquinone in 150 ml of 60 per cent acetic acid contained in a 600-ml beaker to below 5 °C in an ice bath. Dissolve 42 g (0.42 mol) of chromium trioxide in 70 ml of water, and add 30 ml of glacial acetic acid. By means of a separatory funnel with bent stem and supported over the beaker, add the chromium trioxide solution to the mechanically stirred hydroquinone solution at such a rate that the temperature does not rise above 10 °C; the addition takes about 2 hours. Filter the mixture at once and wash the quinone several times with 10 ml portions of ice-cold water. Spread the material upon filter paper until dry, but no longer or the quinone will be lost through sublimation. The yield of quinone (a bright yellow crystalline solid), m.p. 115 °C, is 21 g (66%); it darkens when exposed to light.

Impure quinone may be purified by placing it in a distilling flask attached to a condenser and passing a rapid current of steam into the flask: the quinone sublimes and collects in the receiver. It is separated from the water by filtration and dried; the m.p. is 116 °C. The vapour has a penetrating odour and attacks the eyes.
Method 2. In a 1-litre round-bottomed flask, provided with a mechanical stirrer, place 0.5 g of vanadium pentoxide (catalyst), 500 ml of 2 per cent sulphuric acid, 55 g (0.5 mol) of hydroquinone and 30 g of sodium chlorate. Stir the mixture vigorously for about 4 hours. Greenish-black quinhydrone is first formed and this is converted into yellow quinone; the temperature of the mixture rises to about 40°C (do not allow it to exceed this temperature). Cool the flask in running water, filter the mixture at the pump and wash it with 50 ml of cold water. Dry the quinone upon filter paper in the air (see Method 1) or in a desiccator over anhydrous calcium chloride. The yield is 45 g (83%), m.p. 111-112°C. The crude quinone may be purified by steam distillation as in Method 1, or by recrystallisation from boiling light petroleum, b.p. 100-120°C (12 ml per gram): the resulting pure, bright yellow quinone has m.p. 115°C and the recovery is about 95 per cent.

Conversion of hydroquinone into quinhydrone. Dissolve 100 g of iron alum [iron(III) ammonium sulphate] in 300 ml of water at 65°C. Pour the solution, with stirring, into a solution of 25 g (0.228 mol) of hydroquinone in 100 ml of water contained in a 600-ml beaker. The quinhydrone is precipitated in fine needles. Cool the mixture in ice, filter with suction and wash three or four times with cold water. Dry in the air between filter paper. The yield of quinhydrone, m.p. 172°C, is 15 g (60%).

Conversion of p-benzoquinone into 1,2,4-triacetoxybenzene (Thiele acetylation). Add 11 g (0.1 mol) of p-benzoquinone in small portions to a mechanically stirred mixture of 33 g (0.32 mol) of acetic anhydride and 0.25 ml of concentrated sulphuric acid. The temperature of the mixture rises to 40-50°C and is kept within this range by regulating the rate of addition of the quinone. When the addition is complete allow the solution to cool to about 25°C and pour into 150 ml of cold water. Collect the precipitated triacetate and recrystallise it from about 50 ml of rectified spirit; the yield is 22 g (86%), m.p. 97°C.

Experiment 6.131 1,2-NAPHTHOQUINONE

\[
\begin{align*}
\text{N}=\text{N} & \cdot \text{C}_6\text{H}_4\text{SO}_3\text{Na}^+ \\
\text{OH} & \\
\text{Na}_2\text{SO}_4 & \rightarrow \\
\text{NaOH}:\text{HCl} & \text{FeCl}_3 \\
\text{HCl} & \\
\text{OH} & \rightarrow \\
\text{O} & \\
\end{align*}
\]

Place 20 g (0.057 mol) of Orange II (Expt 6.84) in a 600-ml beaker and dissolve it in 250 ml of water at 40-50°C. Add, with stirring, 24-25 g (0.114 mol) of hydrated sodium dithionite; this discharges the colour and yields a pink or cream-coloured, finely divided precipitate of 1-amino-2-naphthol (compare Expt 6.82). Heat the mixture nearly to boiling until it commences to froth considerably, then cool to 25°C in ice, filter on a Buchner funnel and wash with a little cold water. Transfer the precipitate to a beaker
containing a solution of 0.25 g of tin(II) chloride in 5 ml of concentrated hydrochloric acid diluted with 100 ml of water; upon stirring the aminophthalol dissolves and a small amount of insoluble matter remains. The function of the tin(II) chloride is as an antioxidant, preventing the readily oxidisable aminophthalol hydrochloride from undergoing appreciable change. Stir the solution for 5 minutes with 2 g of decolourising carbon, and filter at the pump. If crystalline material should separate at any stage, dissolve it by warming and by the addition of a little water if necessary. Transfer the clear solution to a beaker, add 25 ml of concentrated hydrochloric acid and warm until the solid dissolves. Cool to 0°C, filter the almost colourless crystals of the aminophthalol hydrochloride with suction and wash with 25 ml of dilute hydrochloric acid (1:4 by volume). From this point all operations must be carried out rapidly. In the meantime, prepare the oxidising solution by dissolving 30 g (0.11 mol) of crystallised iron(III) chloride in a mixture of 10 ml of concentrated hydrochloric acid and 25 ml of water by heating, cool to room temperature by adding c. 30 g of crushed ice and filter the solution at the pump. Wash the crystalline 1-amino-2-naphthol hydrochloride into a 600-ml beaker with water, add 150 ml of water and a few drops of concentrated hydrochloric acid and dissolve the precipitated solid by stirring and warming to about 35°C. If necessary, filter rapidly by suction from a trace of residue, transfer to a 500-ml round-bottomed flask, add the iron(III) chloride solution all at once while shaking the flask vigorously. The quinone separates rapidly as a voluminous micro-crystalline yellow precipitate. Filter on a Buchner funnel and wash it thoroughly with water at 30°C to remove all traces of acid. Dry the product upon filter paper in an atmosphere free from acid fumes. The yield of 1,2-naphthoquinone, which melts with decomposition at 145–147°C, is 7 g (78%).

**Experiment 6.132 2-METHYLANTHRAQUINONE**

![Chemical structure of 2-Methylanthraquinone]

**o-(p-Toluoyl)-benzoic acid.** Using the conditions described in Expt 6.124, react 100 g (115.5 ml, 1.09 mol) of toluene, 25 g (0.17 mol) of phthalic anhydride and 50 g (0.375 mol) of anhydrous aluminium chloride to obtain the corresponding o-aroylbenzoic acid. The air-dried product consists largely of the monohydrate; this becomes anhydrous upon drying at 100°C and melts at 138–139°C. The yield of anhydrous product is 39 g (95%). It may be recrystallised from toluene.

**2-Methylanthraquinone.** Place 25 ml of polyphosphoric acid (Section 4.2.58, p. 458) and 2.0 g of the foregoing aroylbenzoic acid in a 150-ml conical flask fitted with an air condenser to prevent water vapour from the boiling water bath entering the flask during the subsequent heating period of 2 hours. Cool the reaction product in ice and add 40 ml of water with stirring. Filter with suction and wash with water. Boil the residue with 10 ml of concentrated...
ammonia solution for 5 minutes (to remove unchanged acid) and filter at the
pump. Recrystallise from ethanol in the presence of a little decolourising
charcoal; filter off the crystals, wash with a little rectified spirit and dry at
100–120°C. The yield of pure 2-methylantraquinone, m.p. 175°C, is 1.7 g
(92%).

6.12 SOME REACTIONS OF AROMATIC CARBONYL COMPOUNDS

3. The Perkin (Expt 6.138) and Doebner (Expt 6.139) reactions.
5. The benzoin condensation (Expts 6.142 to 6.144).
8. Methods for the protection of the aromatic carbonyl group.

6.12.1 THE CANNIZZARO REACTION

Aromatic aldehydes (and other aldehydes in which α-hydrogen atoms are
absent, e.g. formaldehyde and trimethylacetaldehyde) under the influence of
strong aqueous or alcoholic alkali undergo simultaneous oxidation and
reduction yielding the alcohol and corresponding carboxylate salt. Thus:

$$2Ar\cdot\text{CHO} \xrightarrow{\text{KOH}} Ar\cdot\text{CH}_2\text{OH} + Ar\cdot\text{CO}_2\text{K}$$

This dismutation or disproportionation reaction is known as the Cannizzaro
reaction. The mechanism of the reaction involves the production of the anion (1)
which may transfer a hydride ion to a carbonyl carbon atom in another
aldehyde molecule. The reaction sequence is completed by a proton transfer to
yield the carboxylate anion and the alcohol.

$$\begin{array}{c}
\text{Ar} \overset{\text{O}}{\text{H}} \overset{\text{OH}}{\text{H}} \overset{\text{O}}{\text{H}} \\
\text{(1)}
\end{array}$$

$$\begin{array}{c}
\text{Ar} \overset{\text{O}}{\text{H}} \overset{\text{OH}}{\text{H}} \overset{\text{O}}{\text{H}}
\end{array} \quad \overset{\text{H}^+ + \text{H}^+}{\xrightarrow{\text{Ar} \cdot \text{CH}_2\text{OH} + \text{Ar} \cdot \text{CO}_2\text{O}}}$$

The reaction is illustrated here by the conversion of benzaldehyde into benzoic
acid and benzyl alcohol (Expt 6.133) and by a similar conversion of furfural into
furfuryl alcohol and furoic acid (cognate preparation in Expt 6.133).

A preparatively more useful form of this reaction is the crossed Cannizzaro
reaction which ensues when a mixture of an aromatic aldehyde and formalde-
hyde is allowed to react under the influence of strong base (e.g. the preparation of
p-methylbenzyl alcohol, Expt 6.134). A substantial proportion of the aromatic
aldehyde is reduced to the corresponding alcohol while the formaldehyde is
oxidised to formate. This is a reflection of the fact that nucleophilic attack of the hydroxide ion takes place preferentially at the more electrophilic carbonyl carbon atom in formaldehyde.

\[
\begin{align*}
&\text{H}_2\text{C}=\text{O} + \text{OH}^- \rightarrow \text{H}_3\text{CO}^- \\
&\text{Ar}_2\text{C}=\text{O} + \text{OH}^- \rightarrow \text{Ar}_2\text{CHO} + \text{HO}^-
\end{align*}
\]

**Experiment 6.133 BENZYL ALCOHOL AND BENZOIC ACID**

\[
\text{PhCHO} + \text{PhCHO} \rightleftharpoons \text{PhCH}_2\text{OH} + \text{PhCO}_2^\text{K}^+
\]

Dissolve 29 g of potassium hydroxide in 27 ml of water contained in a beaker or conical flask, and cool the solution to about 20 °C in ice-water. Pour the solution into a 250-ml reagent bottle, and add 32 g (30 ml, 0.3 mol) of pure benzaldehyde (1); cork the bottle securely and shake the mixture vigorously until it has been converted into a thick emulsion. Allow the mixture to stand overnight or for 24 hours in the stopped bottle. Add just sufficient water (about 105 ml) to dissolve the potassium benzoate. Pour the liquid into a separatory funnel, rinse out the bottle with about 30 ml of ether and add this ether to the solution in the funnel. Shake the solution in order to thoroughly extract the benzyl alcohol with the ether, separate the lower aqueous solution and carry out two further extractions each with about 25 ml of ether. Save the aqueous solution. Combine the ether extracts and distil the ether from a water bath (rotary evaporator) until the volume is about 25 ml. Cool and shake the ether solution twice with 5 ml portions of saturated sodium metabisulphite solution in order to remove any benzaldehyde which may be present. Separate the ethereal solution, wash it with 10 ml of 10 per cent sodium carbonate solution (to ensure complete removal of the bisulphite), then with 10 ml of water, and dry with anhydrous magnesium sulphate or anhydrous potassium carbonate. Remove the ether (Fig. 2.98; 50-ml distilling flask) on a water bath, and distil the residual liquid from an air bath; replace the water condenser by an air condenser or empty the water completely from the condenser jacket. Collect the benzyl alcohol at 204–207 °C (the pure compound boils at 205.5 °C). The yield is 13 g (86.5%).

The p.m.r. and $^{13}$C-n.m.r. spectra of benzyl alcohol are given in Figs 3.65 and 3.53 respectively. The i.r. spectrum (thin film) shows absorptions at c. 3300 cm$^{-1}$ (broad, OH stretching), c. 3050 and 2950 cm$^{-1}$ ($C_{\text{AR}}$—H and $C_{\text{AL}}$—H, stretching), 1600, 1590 and 1500 cm$^{-1}$ (ring breathing vibrations), c. 690 and 735 cm$^{-1}$ ($C_{\text{AR}}$—H, out-of-plane vibrations), and 2000–1600 cm$^{-1}$ (summation bands).

Pour the aqueous solution remaining from the ether extraction with stirring into a mixture of 80 ml of concentrated hydrochloric acid, 80 ml of water and about 100 g of crushed ice. Filter the precipitated benzoic acid at the pump, wash it with a little cold water, drain and recrystallise from boiling water. The yield of benzoic acid (colourless crystals), m.p. 121 °C, is 13.5 g (79%) (2).
The i.r. spectrum (KBr disc) should be recorded and interpreted; the p.m.r. spectrum (CCl₄, TMS) should also be recorded and the two groups of aromatic protons assigned, bearing in mind the electron-withdrawing nature of the carboxyl group.

Notes. (1) The benzaldehyde should be free from benzoic acid; it may be purified by washing with aqueous 10 per cent sodium carbonate solution, drying over anhydrous magnesium sulphate, adding a few crystals of hydroquinone or catechol, and distilling under reduced pressure in a stream of nitrogen. Benzaldehyde has a b.p. 79°C/25 mmHg or 62°C/10 mmHg.

(2) The reaction may alternatively be carried out by boiling the benzaldehyde vigorously under reflux for 2 hours with a solution of 20 g of potassium hydroxide in 90 ml of water, and then working up the cooled reaction mixture as described above. Reaction is normally complete under these conditions; the extent of the reaction may be determined by subjecting the crude ether extract, before the latter is washed with bisulphite solution, to g.l.c. analysis on a 1.5 m column of Chromosorb W with 10 per cent of Carbowax as the stationary phase, at 156°C with a nitrogen flow rate of 40 ml per minute. The retention times of benzaldehyde and benzyl alcohol are approximately 2.7 and 9.7 minutes respectively.

Cognate preparation. Furfuryl alcohol and 2-furoic acid.

Place 200 g (172.5 ml, 2.08 mol) of redistilled furfural (1) in a 1-litre beaker provided with a mechanical stirrer and surrounded by an ice bath. Start the stirrer and, when the temperature has fallen to 5–8°C, add a solution of 50 g (1.2 mol) of sodium hydroxide in 100 ml of water from a separatory funnel at such a rate that the temperature of the reaction mixture does not rise above 20°C (20–25 minutes); continue the stirring for a further 1 hour. Much sodium furoate separates during the reaction. Allow to cool to room temperature, and add just enough water to dissolve the precipitate (about 65 ml). Extract the solution at least five times with 60 ml portions of ether in order to remove the furfuryl alcohol: the best results are obtained by the use of the continuous extraction apparatus (charged with 350 ml of ether) depicted in Fig. 2.92. Keep the aqueous layer. Dry the ethereal extract with a little magnesium sulphate, and remove the ether on a rotary evaporator. Distil the residue under reduced pressure (Fig. 2.108) and collect the furfuryl alcohol (a very pale yellow liquid) at 75–77°C/15 mmHg; the yield is 65 g (64%). Because of the tendency to undergo polymerisation, add about 1 per cent of its weight of urea as stabiliser if the furfuryl alcohol is to be stored.

Treat the aqueous solution, containing the sodium furoate, with 40 per cent sulphuric acid until it is acid to Congo red paper, and cool. Filter off the furoic acid, contaminated with a little sodium hydrogen sulphate, at the pump. Dissolve it in 240 ml of boiling water, add 12 g of decolourising carbon, boil the solution for about 45 minutes, filter hot and cool the filtrate with stirring to 16–20°C; below 16°C, sodium hydrogen sulphate also separates. Filter off the furoic acid with suction, and dry. The yield is 65 g (55%), m.p. 123–124°C. It may be further purified either by recrystallisation from carbon tetrachloride to which a little decolourising carbon is added or by distillation under reduced pressure, b.p. 142–144°C/20 mmHg; the resulting pure acid softens at 125°C and is completely melted at 132°C.
The i.r. spectra of 2-furaldehyde, furfuryl alcohol (thin films) and 2-furoic acid (KBr disc) should be recorded and the absorption bands of the functional groups assigned. The p.m.r. spectra are excellent examples of proton coupling in the 2-substituted furan nucleus. In the case of the alcohol and acid the J_3,5 coupling constant is negligible and J_4,5 < J_3,4. Bearing these facts in mind the signals should be assigned from the following data; 2-furaldehyde (CCl₄, TMS) δ 6.52 (d of d, 1H), 7.11 (d, 1H), 7.61 (d, 1H) and 9.63 (s, 1H); 2-furoic acid (Me₂CO, TMS) δ 6.71 (d of d, 1H), 7.32 (d, 1H), 7.89 (d, 1H) and 10.51 (s, 1H). The lesser electron-withdrawing nature of the hydroxymethyl group in furfuryl alcohol results in the C₃ and the C₄ protons having very similar chemical shift values; in the spectrum (CCl₄, TMS) the signals thus appear at δ 3.32 (s, 1H, disappears on treatment with D₂O), 4.50 (s, 2H), 6.29 (m, 2H), and 7.38 (d, exhibiting small coupling, 1H).

Note. (1) Furfural (2-furaldehyde) is best purified by distillation under reduced pressure; b.p. 54–55 °C/17 mmHg.

Experiment 6.134 p-METHYLBENZYL ALCOHOL (Crossed Cannizzaro reaction)

\[ p\text{-Me} \cdot C₆H₄ \cdot CHO \xrightarrow{H\cdot CHO \xrightarrow{\text{OH}}} p\text{-Me} \cdot C₆H₄ \cdot CH₂OH + H \cdot CO₂\text{K}^{\circ} \]

Equip a 1-litre three-necked flask with a reflux condenser, a sealed mechanical stirrer and a thermometer; the bulb of the thermometer should reach almost to the bottom of the flask. Place 170 g of commercial potassium hydroxide pellets (about 85% KOH, c. 2.6 mol) and 250 ml of methanol in the flask and set the stirrer in motion. Most of the alkali dissolves in a few minutes and the temperature rises considerably. Immerse the flask in a large cold-water bath and, when the temperature has fallen to 60–65 °C, add down the condenser a mixture of 120 g (118 ml, 1 mol) of p-tolualdehyde and 100 ml (c. 1.3 mol) of formalin at such a rate (during about 15 minutes) that the internal temperature remains at 60–70 °C: maintain the internal temperature at 60–70 °C for a further 3 hours. Replace the reflux condenser by a condenser set for downward distillation, and distil off the methanol, while stirring, until the temperature reaches about 100 °C. Add 300 ml of water to the warm residue, cool the mixture and separate the resulting two layers at once; if the upper layer is allowed to stand, it will solidify. Extract the aqueous layer with four 50 ml portions of toluene. Wash the combined oil and toluene extracts with five 25 ml portions of water, extract the combined washings with 25 ml of toluene and add the toluene layer to the washed extract. Dry the toluene solution by shaking with a few grams of magnesium sulphate, distil off the toluene and finally distil under reduced pressure (Fig. 2.108) and collect the p-methylbenzyl alcohol at 116–118 °C/20 mmHg (1). The product solidifies in the receiver to a mass (110 g) of oily crystals, m.p. 54–55 °C. Recrystallise from an equal weight of technical heptane (b.p. 90–100 °C); 88 g (72%) of pure p-methylbenzyl alcohol, m.p. 61 °C, are obtained. The p.m.r. spectrum (CDCl₃, TMS) should be recorded and interpreted.

Note. (1) The b.p. at atmospheric pressure is 217 °C.
6.12.2 CLAISEN–SCHMIDT AND RELATED REACTIONS

A retrosynthetic analysis of $\alpha,\beta$-unsaturated ketones leading to various methods of synthesis is outlined in Section 5.18.2, p. 798. These methods are equally applicable to aromatic aldehydes. Aromatic aldehydes condense with aliphatic or mixed alkyl aryl ketones in the presence of aqueous alkali to form $\alpha,\beta$-unsaturated ketones (the Claisen–Schmidt reaction).

\[
\begin{align*}
\text{Ar} & \text{H} \quad \text{Me} \quad \text{R} \quad \overset{\text{OH}}{\rightarrow} \quad \text{Ar} \quad \text{OH} \quad \text{R} \quad \overset{-\text{H}_2\text{O}}{\rightarrow} \quad \text{Ar} \quad \text{=CH} \quad \text{R} \\
\end{align*}
\]

The first step is a condensation of the aldol type (see Section 5.18.2, p. 799) involving the nucleophilic addition of the carbanion derived from the methyl ketone to the carbonyl-carbon of the aromatic aldehyde. Dehydration of the hydroxyketone to form the conjugated unsaturated carbonyl compound occurs spontaneously.

Experiment 6.135 describes the preparation of a range of $\alpha,\beta$-unsaturated ketones, including benzylideneacetone, furfurylideneacetone and benzylideneacetophenone. The conversion of this latter compound into $\beta$-phenylpropionophenone is readily achieved by hydrogenation at atmospheric pressure over an active platinum catalyst.

The formation of $\omega$-nitrostyrenes (illustrated in Expt 6.136) by reaction of nitroalkanes with aromatic aldehydes in the presence of aqueous alkali may be classified with reactions of the Claisen–Schmidt type.

\[
\begin{align*}
\text{Ar} & \text{H} \quad \overset{\text{O}}{\rightarrow} \quad \text{Ar} \quad \text{CH}_2 \quad \overset{\text{NO}_2}{\rightarrow} \quad \text{Ar} \quad \text{CH}_2 \quad \text{NO}_2 \quad \overset{+\text{H}^\circ}{\rightarrow} \quad \text{Ar} \quad \text{=CH} \quad \text{NO}_2 \\
\end{align*}
\]

A further example of the above reaction type is provided by the condensation between an aromatic aldehyde and an ester (the Claisen reaction, e.g. the synthesis of ethyl cinnamate, Expt 6.137), which requires a more powerfully basic catalyst (e.g. sodium ethoxide) to effect conversion of the ester into the corresponding anion.

\[
\begin{align*}
\text{EtO}^\circ & \quad \text{H} \quad \overset{\text{CH}_2 \cdot \text{CO}_2\text{Et}}{\rightarrow} \quad \overset{\text{EtOH} \quad + \quad \text{CH}_2 \cdot \text{CO}_2\text{Et}}{\rightarrow} \quad \text{EtO}^\circ & \quad \text{H} \quad \overset{\text{CH}_2 \cdot \text{CO}_2\text{Et}}{\rightarrow} \quad \overset{+\text{H}^\circ}{\rightarrow} \quad \text{Ar} \quad \text{=CH} \quad \text{CO}_2\text{Et} \\
\end{align*}
\]
Experiment 6.135  *A* BENZYLIDENEACETONE (4-Phenylbut-3-en-2-one)  
*B* DIBENZYLIDENEACETONE (1,5-Diphenylpenta-1,4-dien-3-one)  

**A**

\[
\text{PhCHO} + \text{MeCO} \cdot \text{Me} \rightarrow \text{H}_2\text{O} \rightarrow \text{PhCH}=\text{CHCO} \cdot \text{Me}
\]

**B**

\[
2\text{PhCHO} + \text{MeCO} \cdot \text{Me} \rightarrow 2\text{H}_2\text{O} \rightarrow \text{PhCH}=\text{CHCO} \cdot \text{CH}=\text{CH} \cdot \text{Ph}
\]

**A.** Place 42.5 g (40.5 ml, 0.4 mol) of pure benzaldehyde (Expt 6.133) and 63.5 g (80 ml, 1.1 mol) of pure acetone in a 250-ml flask equipped with a mechanical stirrer. Immerse the reaction vessel in a bath of cold water and add slowly (during about 30 minutes) from a dropping funnel 10 ml of 10 per cent sodium hydroxide solution: adjust the rate of addition so that the temperature remains between 25 and 30°C. Stir the mixture at room temperature for a further 2 hours; alternatively, securely stopper the flask and shake mechanically for the same period. Render the mixture just acid to litmus paper by the addition of dilute hydrochloric acid. Transfer to a separatory funnel. Remove the upper organic layer, extract the lower aqueous layer with 20 ml of toluene and add the extract to the yellow upper layer. Wash the latter with 20 ml of water, and dry with a little magnesium sulphate, and transfer to a distillation assembly incorporating a Claisen still-head and a short fractionating side-arm (compare Fig. 2.108). Remove the toluene by distillation at atmospheric pressure and distil the residue under diminished pressure. The benzylideneacetone distils at 133–143°C/16 mmHg (or at 120–130°C/7 mmHg or at 150–160°C/25 mmHg) and solidifies to a crystalline mass on standing, m.p. 38–39°C; the yield is 45 g (77%). This is pure enough for most practical purposes, but may be further purified by redistillation (b.p. 137–142°C/16 mmHg) or by recrystallisation from light petroleum (b.p. 40–60°C): the pure benzylideneacetone melts at 42°C. The residue in the distilling flask contains some dibenzylideneacetone.

The i.r. spectrum of benzylideneacetone should be recorded and the absorption bands assigned appropriately. The p.m.r. spectrum (CDCl$_3$, TMS) shows signals at δ 2.32 (s, 3H, Me), 6.67 (d, 1H, =CH-CO), 7.44 (d, 1H, Ph-CH=) and 7.21–7.62 (m, 5H, CA–H); careful inspection of the coupling constants observable with the signal at δ 6.67 enables the signal at δ 7.44 to be differentiated from those of the aromatic protons.

**B.** In a 500-ml round-bottomed flask place a cold solution of 25 g of sodium hydroxide in 250 ml of water and 200 ml of ethanol (1); equip the flask with a mechanical stirrer and surround it with a bath of water. Maintain the temperature of the solution at 20–25°C, stir vigorously and add one-half of a previously prepared mixture of 26.5 g (25.5 ml, 0.25 mol) of pure benzaldehyde and 7.3 g (9.3 ml, 0.125 mol) of acetone. A flocculent precipitate forms in 2–3 minutes. After 15 minutes add the remainder of the benzaldehyde–acetone mixture. Continue the stirring for a further 30 minutes. Filter at the pump and wash with cold water to eliminate the alkali as completely as possible. Dry the solid at room temperature upon filter paper to constant weight; 27 g (93%) of crude dibenzylideneacetone, m.p. 105–107°C, are obtained. Recrystallise from hot ethyl acetate (2.5 ml per gram) or from hot rectified spirit. The recovery of pure dibenzylideneacetone, m.p. 122°C, is about 80 per cent.
The p.m.r. spectrum (CDCl₃, TMS) should be recorded and the signals assigned, using that of benzylideneacetone as a guide.

Note. (1) Sufficient ethanol is employed to dissolve the benzaldehyde and to retain the initially-formed benzylideneacetone in solution until it has time to react with the second molecule of benzaldehyde.

Cognate preparations. Furfurylideneacetone

\[
\begin{align*}
\text{H} & \quad \text{Me} \quad \text{Me} \quad \text{OH} \\
\text{O} & \quad \text{O} & \quad \text{Me} \\
\text{O} & \quad \text{Me} & \quad + \quad \text{H}_2\text{O}
\end{align*}
\]

In a 1-litre bolt-head flask, equipped with a mechanical stirrer, mix 75 g (65 ml, 0.78 mol) of redistilled furfural (1) and 600 ml of water. Add 100 g (126 ml, 1.73 mol) of acetone. Stir the mixture, cool to 10°C and add a solution of 5 g of sodium hydroxide in 10 ml of water; some heat is generated. Continue the stirring, without cooling, for 4 hours. Then add 10 per cent sulphuric acid (about 70 ml) until the mixture is acid to litmus, whereupon the milkiness disappears and the liquid separates out into layers. Separate the lower organic layer, dry it with a little anhydrous magnesium sulphate and distil under reduced pressure from a flask with fractionating side-arm (compare Fig. 2.108). Collect the furfurylideneacetone at 114–118°C/10 mmHg; it solidifies on cooling (m.p. 38–39°C) and weighs 65 g (62%). The residue of high boiling point material in the flask contains much difurfurylideneacetone.

Note. (1) Furfural is best purified by distillation under reduced pressure: b.p. 54–55°C/17 mmHg.

Benzyldieneacetophenone (Chalcone or 1,3-diphenylprop-2-en-1-one)

\[
\text{Ph} \cdot \text{CHO} + \text{Me} \cdot \text{CO} \cdot \text{Ph} \xrightarrow{\text{NaOH}} \text{Ph} \cdot \text{CH} = \text{CH} \cdot \text{CO} \cdot \text{Ph}
\]

Place a solution of 22 g of sodium hydroxide in 200 ml of water and 100 g (122.5 ml) of rectified spirit in a 500-ml bolt-head flask provided with a mechanical stirrer. Immerse the flask in a bath of crushed ice, pour in 52 g (0.43 mol) of freshly distilled acetophenone, start the stirrer and then add 46 g (44 ml, 0.43 mol) of pure benzaldehyde. Keep the temperature of the mixture at about 25°C (the limits are 15–30°C) and stir vigorously until the mixture is so thick that stirring is no longer effective (2–3 hours). Remove the stirrer and leave the reaction mixture in an ice chest or refrigerator overnight. Filter the product with suction on a Buchner funnel or a sintered glass funnel, wash with cold water until the washings are neutral to litmus, and then with 20 ml of ice-cold rectified spirit. The crude chalcone, after drying in the air, weighs 88 g and melts at 50–54°C. Recrystallise from rectified spirit warmed to 50°C (about 5 ml per gram). The yield of pure benzyldieneacetophenone (a pale yellow solid), m.p. 56–57°C, is 77 g (85%). This substance should be handled with great care since it acts as a skin irritant.

Hydrogenation to β-phenylpropioophenone.

\[
\text{Ph} \cdot \text{CH} = \text{CH} \cdot \text{CO} \cdot \text{Ph} \xrightarrow{H_2/\text{Pt}} \text{Ph} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{Ph}
\]
Place a solution of 10.4 g (0.05 mol) of benzylideneacetophenone, m.p. 57°C, in 75 ml of pure ethyl acetate (Section 4.1.24, p. 409) in the reaction bottle of the atmospheric pressure hydrogenation apparatus (Section 2.17.1, p. 89) and add 0.2 g of Adams' platinum oxide catalyst (Section 4.2.61, p. 459). Displace the air with hydrogen, and shake the mixture with hydrogen until 0.05 mol is absorbed (i.e. c. 1100 ml at s.t.p.). Filter off the platinum, and remove the ethyl acetate by distillation. Recrystallise the residual β-phenylpropiochinone from about 12 ml of ethanol. The yield of pure product, m.p. 73°C, is 9 g (86%).

**Experiment 6.136 ω-NITROSTYRENE**

\[
\text{Ph-CHO + Me-NO}_2 \xrightarrow{\text{H}_2\text{O}} \text{Ph-CH=CH-NO}_2
\]

Equip a 1500-ml three-necked flask with a thermometer, mechanical stirrer and a dropping funnel. Place 61 g (54 ml, 1 mol) of nitromethane (1), 106 g (101 ml, 1 mol) of purified benzaldehyde (Expt 6.133) and 200 ml of methanol in the flask and cool it with a mixture of ice and salt to about \(-10°C\). Dissolve 42 g of sodium hydroxide in 40–50 ml of water, cool and dilute to 100 ml with ice and water; place this cold solution in the dropping funnel. Add the sodium hydroxide solution, with vigorous stirring, to the nitromethane mixture at such a rate that the temperature is held at 10–15°C. Introduce the first few ml cautiously since, after a short induction period, the temperature may rise to 30°C or higher; check the rise in temperature, if necessary, by adding a little crushed ice to the reaction mixture. A bulky white precipitate forms; if the mixture becomes so thick that stirring is difficult, add about 10 ml of methanol. After standing for about 15 minutes, add 700 ml of ice-water containing crushed ice; the temperature should be below 5°C. Run the resulting cold solution immediately from a dropping funnel and with stirring into 500 ml of \(4\) M hydrochloric acid contained in a 3-litre flask; adjust the rate of addition so that the stream just fails to break into drops. A pale yellow crystalline precipitate separates almost as soon as the alkaline solution mixes with the acid. The solid settles to the bottom of the vessel when the stirrer is stopped. Decant most of the cloudy liquid layer, filter the residue by suction and wash it with water until free from chlorides. Transfer the solid to a beaker immersed in hot water; two layers form and on cooling again, the lower layer of nitrostyrene solidifies; pour off the upper layer. Dissolve the crude nitrostyrene in 85 ml of hot ethanol. (CAUTION: nitrostyrene vapours are irritating to the nose and eyes, and the skin of the face is sensitive to the solid.) Filter through a hotwater funnel and cool until crystallisation is complete. The yield of pure ω-nitrostyrene, m.p. 57–58°C, is 125 g (85%).

**Note.** (1) The commercial material may be redistilled and the fraction having b.p. 100–102°C collected.

**Cognate preparations.** 3,4-Methylenedioxy-ω-nitrostyrene. In a 250-ml round-bottomed flask mix 30 g (0.20 mol) of 3,4-methylenedioxybenzaldehyde (piperonal), 13.4 g (0.22 mol) of nitromethane, 7.8 g (0.1 mol) of ammonium acetate and 50 ml of glacial acid. Attach a reflux condenser, and boil the mixture under gentle reflux for 1 hour. Pour the reaction mixture with stirring into a large excess of ice-water (about 1 litre). When all the ice has
melted, filter off the crude product under suction and recrystallise from a mixture of absolute ethanol and acetone (about 2:1 v/v). Almost pure yellow crystals of the nitrostyrene, m.p. 161 °C, are obtained. The yield is 23.3 g (60%). Further recrystallisation from the same solvent yields the pure compound, m.p. 162 °C.

2,4-Dimethoxy-ω-nitrostyrene. Follow the above procedure, but use 33.2 g (0.20 mol) of 2,4-dimethoxybenzaldehyde as the starting material. The yield of recrystallised product (yellow crystals, m.p. 103 °C) is 28.5 g (68%). Further recrystallisation gives pure product of m.p. 105 °C.

Experiment 6.137 ETHYL CINNAMATE

\[
\text{PhCHO} + \text{MeCO}_2\text{Et} \xrightarrow{\text{Na, EtOH}} \text{PhCH=CHCO}_2\text{Et} + \text{H}_2\text{O}
\]

Prepare powdered (or ‘molecular’) sodium from 14.5 g (0.63 mol) of clean sodium and 150-200 ml of sodium-dried xylene contained in a 1-litre three-necked flask (Section 4.2.6, p. 417) fitted with a mechanical stirrer and a reflux condenser. When cold, pour off the xylene as completely as possible, and then add 220 g (240 ml, 2.5 mol) ethyl acetate (Section 4.1.24, p. 409) containing 2 ml of absolute ethanol (1). Cool the flask rapidly to 0 °C and add 53 g (51 ml, 0.5 mol) of pure benzaldehyde (Expt 6.133) slowly (during 90 minutes) from a dropping funnel while the mixture is stirred. Keep the temperature between 0 and 5 °C; do not allow it to rise above 10 °C otherwise a poor yield will be obtained. The reaction commences as soon as the benzaldehyde is added, as is indicated by the production of a reddish substance on the particles of sodium. Continue the stirring until practically all the sodium has reacted (about 1 hour after all the benzaldehyde has been introduced). Then add 45 ml of glacial acetic acid followed by an equal volume of water (CAUTION: some sodium may be present). Separate the layer of ester, extract the aqueous layer with 25 ml of ethyl acetate, wash the combined organic layers with 150 ml of 1:1 hydrochloric acid and dry with magnesium sulphate or sodium sulphate. Distil off the ethyl acetate on a water bath. Distil the residue under diminished pressure (Fig. 2.108). Collect the ethyl cinnamate (a colourless liquid) at 126–131 °C/6 mmHg; the yield is 65 g (74%) (2).

The p.m.r. spectrum (CDCl₃) should be recorded and the signals which are apparent at δ 1.30 (t, 3H), 4.80 (q, 2H), 6.33 (d, 1H), 7.73 (d, 1H), and 7.2–7.6 (m, 5H) assigned.

Notes. (1) A little ethanol (c. 1%) is required to start the reaction; the yield is consistently lower in its absence.
(2) Ethyl cinnamate may also be prepared by the esterification of cinnamic acid (cf. methyl cinnamate, Expt 6.163). The pure compound boils at 127 °C/6 mmHg.

6.12.3 THE PERKIN AND DOEBNER REACTIONS

A retrosynthetic analysis of α,β-unsaturated acids leading to various methods of synthesis is outlined in Section 5.18.3, p. 804. The following methods are particularly applicable to aromatic aldehydes.

The condensation of an aromatic aldehyde with an acid anhydride in the
presence of the sodium or potassium salt of the acid corresponding to the anhydride to yield an \( \alpha,\beta \)-unsaturated acid is known as the Perkin reaction.

\[
\text{Ar} \cdot \text{CHO} + (\text{Me} \cdot \text{CO})_2 \text{O} \xrightarrow{\text{Me-CO}_2^\ominus \text{Na}^\ominus} \text{Ar} \cdot \text{CH} = \text{CH} \cdot \text{CO}_2\text{H} + \text{Me} \cdot \text{CO}_2\text{H}
\]

The mechanism of the reaction, which is of the aldol type, involves the carbonyl group of the aldehyde and an active methylene group of the anhydride; the function of the basic catalyst (acetate anion, \( \text{Me-CO}_2^\ominus \), or triethylamine, \( \text{Et}_3\text{N} \)) is to form an anion by removal of a proton from the anhydride:

\[
\begin{align*}
\text{B:} + \text{Me-CO-O-CO-Me} & \iff \text{BH} + \text{CH}_2 \cdot \text{CO} \cdot \text{O} \cdot \text{CO-Me} \\
\text{Ar} & \stackrel{\ominus}{\text{CH}_2 \text{O}} \text{Me} & \iff & \text{Ar} & \stackrel{\ominus}{\text{CO}} \text{Me} \\
& \text{OH} \text{O} \text{O} & \iff & \text{Ar} & \text{CH} = \text{CH} \text{O} \text{O} \text{Me} \\
& & & & \text{H}_2\text{O} \\
& & & & \text{Ar} & \text{CH} = \text{CH} \text{O} \text{O} \text{Me} \\
& & & & \text{Ar} & \text{OH} \iff \text{Ar} & \text{CO} & \text{Me} \\
& & & & & & \text{+ Me-CO}_2\text{H} \\
& & & & & & \text{(i) Na}_2\text{CO}_3 \\
& & & & & & \text{+ HCl}
\end{align*}
\]

The standard procedure is illustrated by the preparation of cinnamic acid and furylacrylic acid (Expt 6.138). The cinnamic acid obtained is the more stable (\( E \))-isomer. It may be readily reduced to the saturated acid (3-phenylpropanoic acid) and two procedures are described. Catalytic hydrogenation is a convenient method, but the conjugated double bond may also be reduced with, for example, sodium amalgam in the presence of alkali.

A modified Perkin procedure is illustrated in the synthesis of \( \alpha \)-phenylcinnamic acid in which benzaldehyde is condensed with phenylacetic acid in the presence of acetic anhydride and triethylamine. Presumably equilibria are set up which result in the formation of either a mixed anhydride, phenylacetic acetic anhydride or the symmetrical phenylacetic anhydride.

\[
\text{Ph-CH}_2 \cdot \text{CO}_2\text{H} + (\text{Me} \cdot \text{CO})_2 \text{O} \iff \text{Ph-CH}_2 \cdot \text{CO} \cdot \text{O} \cdot \text{CO-Me} + \text{Me} \cdot \text{CO}_2\text{H} \\
\text{2Ph-CH}_2 \cdot \text{CO}_2\text{H} + (\text{Me} \cdot \text{CO})_2 \text{O} \iff (\text{Ph-CH}_2 \cdot \text{CO}_2\text{H})_2 \text{O} + 2\text{Me} \cdot \text{CO}_2\text{H}
\]

Coumarin is formed from acetic anhydride and salicylaldehyde in the presence of triethylamine as the base catalyst. It is the lactone of the (\( Z \))-form of \( \alpha \)-hydroxycinnamic acid; some of the (\( E \))-isomer in the form of its acetyl derivative (\( \alpha \)-acetoxyacinnamic acid) is also obtained (Expt 6.138).

Arylacrylic acids may alternatively be conveniently prepared by the Doebner modification of the Knoevenagel reaction. The Knoevenagel reaction embraces a number of base-catalysed condensations between a carbonyl compound and a component having an active methylene group (see also Section 5.11.6, p. 681). Examples of the Doebner modification, which usually involves the reaction of an aldehyde with malonic acid in the presence of pyridine or possibly a little piperidine, are given in Expt 6.139. The reaction mechanism is of the aldol type and involves the formation of a hydroxymalonic acid and then an \( \alpha,\beta \)-unsaturated malonic acid, which undergoes decarboxylation at the temperature of refluxing pyridine.
Ar·CHO + CH₂(CO₂H)₂ → [Ar·CH(OH)·CH(CO₂H)₂] → Ar·CH=CH·CO₂H

\[ \text{heat} \quad \text{heat} \]

Experiment 6.138 CINNAMIC ACID

Ph·CHO + (Me·CO)₂O \text{base} → Ph·CH=CH·CO₂H + Me·CO₂H

Place 21 g (20 ml, 0.2 mol) of pure benzaldehyde (1), 30 g (28 ml, 0.29 mol) of acetic anhydride and 12 g (0.122 mol) of freshly fused and finely powdered potassium acetate (2) in a dry, 250-ml round-bottomed flask fitted with an air condenser carrying a calcium chloride guard-tube. Mix well and heat the reaction mixture in an oil bath at 160 °C for 1 hour and at 170–180 °C for 3 hours. Pour the mixture while still hot (80–100 °C) into about 100 ml of water contained in a 1-litre round-bottomed flask which has previously been fitted for steam distillation (Fig. 2.102); rinse the reaction flask with a little hot water. Now add with vigorous shaking a saturated aqueous solution of sodium carbonate (3) until a drop of the liquid withdrawn on the end of a glass rod turns red litmus a distinct blue. Steam distil the solution until all the unchanged benzaldehyde is removed and the distillate is clear. Cool the residual solution and filter at the pump from resinous by-products. Acidify the filtrate by adding concentrated hydrochloric acid slowly and with vigorous stirring until the evolution of carbon dioxide ceases. When cold, filter the cinnamic acid at the pump, wash with cold water and drain well. Recrystallise either from hot water or from a mixture of 3 volumes of water and 1 volume of rectified spirit. The yield of dry cinnamic acid (colourless crystals), m.p. 133 °C, is 18 g (62%).

The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 6.41 (d, 1H, =CH·CO₂), 7.73 (d, 1H, Ph·CH), 7.17–7.69 (m, 5H, CARH) and 11.90 (s, 1H, CO₂H). The m.s. shows principal fragment ions at m/z 148 (M), 147 (M–H), 131 (M–OH), 130 (M–H₂O), 103 (M–CO₂H), 102 (130–CO), 77 (103–C₂H₂) and 51 (77–C₂H₂).

Notes. (1) The benzaldehyde must be free from benzoic acid; it may be purified as detailed in Expt 6.133.
(2) Fused potassium acetate should be freshly prepared following the procedure described for sodium acetate (Section 4.2.69, p. 464). It may, however, be replaced by an equivalent quantity of freshly fused sodium acetate, but the reaction is slower and a further 3–4 hours heating is necessary.
(3) Sodium hydroxide solution cannot be used at this stage since it may produce benzoic acid by the Cannizzaro reaction (Expt 6.133) from any unchanged benzaldehyde. If, however, the reaction mixture is diluted with 3–4 volumes of water, steam distilled to remove the unreacted benzaldehyde, the residue may then be rendered alkaline with sodium hydroxide solution. A few grams of decolourising carbon are added, the mixture boiled for several minutes, and filtered through a fluted filter paper. Upon acidifying carefully with concentrated hydrochloric acid, cinnamic acid is precipitated. This is collected, washed and purified as above.

Reduction of cinnamic acid to 3-phenylpropanoic acid (hydrocinnamic acid).

Method A. Carry out the hydrogenation of 14.8 g (0.1 mol) of pure cinnamic acid dissolved in 100 ml of ethanol using 0.1 g of Adams’ catalyst (Section 4.2.61, p. 459) according to the procedure detailed in Section 2.17.1, p. 89

1038
until hydrogen uptake ceases. Record the volume of hydrogen required, filter off the platinum and evaporate the filtrate on a rotary evaporator. The resulting oil solidifies on cooling to a colourless solid, m.p. 47–48 °C; the yield is 14.3 g (95%). Upon recrystallisation from light petroleum (b.p. 60–80 °C) pure hydrocinnamic acid, m.p. 48–49 °C, is obtained.

Method B. Dissolve 20 g (0.135 mol) of cinnamic acid in 145 ml of approximately 1 M sodium hydroxide solution contained in a 500-ml two-necked flask equipped with a mechanical stirrer and situated within a fume cupboard. Add 350 g (0.38 mol) of 2.5 per cent sodium amalgam (Section 4.2.70, p. 464) gradually during 1 hour through the open side-neck while the mixture is well stirred. When hydrogen is no longer evolved, separate the mercury and wash it with water: add the washings to the solution and acidify the whole with dilute hydrochloric acid (1:1). Hydrocinnamic acid is precipitated, at first in the form of an oil, which solidifies on cooling and rubbing with a glass rod. Filter at the pump and recrystallise as in Method A. The yield of hydrocinnamic acid, m.p. 46–48 °C, is 17 g (85%). The p.m.r. spectrum should be recorded and the signals assigned.

Cognate preparations. Furylecrylic acid

\[
\begin{align*}
\begin{array}{c}
\text{O} \\
\text{O} \\
\text{H}
\end{array}
& \xrightarrow{\text{(i) base}} \xrightarrow{\text{(ii) H_2O}}
\begin{array}{c}
\text{O} \\
\text{O} \\
\text{C} \\
\text{C}
\end{array}
\end{align*}
\]

Place 48 g (41.5 ml, 0.5 mol) of freshly distilled furfural (see Note (1) to cognate preparation in Expt 6.133), 77 g (71 ml, 0.75 mol) of pure acetic anhydride and 49 g (0.5 mol) of dry, powdered, freshly fused potassium acetate in a 500-ml two- or three-necked flask, provided with a mechanical stirrer and a long air condenser. Heat the flask, with stirring, in an oil bath at 150 °C (bath temperature) for 4 hours: when the temperature approaches 145–150 °C, a vigorous exothermic reaction sets in and must be controlled by the application of cold wet towels (or cloths) to the flask in order to avoid too vigorous boiling. Allow to cool slightly, transfer the reaction mixture to a 1-litre round-bottomed flask and add 600 ml of water: use part of this to rinse out the reaction flask. Boil the mixture with 6 g of decolourising charcoal for 10 minutes, and filter hot through a preheated Buchner funnel into a preheated filter flask. Transfer the hot filtrate to a beaker, add dilute hydrochloric acid (1:1) until it is acid to Congo red paper and cool to about 10 °C with stirring. Allow to stand for at least 1 hour, filter at the pump and wash with a little ice-water. The yield of crude furylecrylic acid (a light tan solid), m.p. 138–139 °C, is 41 g (59%). A perfectly pure acid (white solid), m.p. 140 °C, is obtained by recrystallisation from benzene or light petroleum, b.p. 80–100 °C, with the addition of a little decolourising carbon; the loss is about 20 per cent.

\[\alpha\text{-Phenylcinnamic acid}\]

\[
\begin{align*}
\text{Ph} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H} + (\text{Me} \cdot \text{CO})_2\text{O} & \rightleftharpoons (\text{Ph} \cdot \text{CH}_2 \cdot \text{CO})_2\text{O} + \text{Me} \cdot \text{CO}_2\text{H} \\
\text{Ph} \cdot \text{CHO} + (\text{Ph} \cdot \text{CH}_2 \cdot \text{CO})_2\text{O} & \xrightarrow{\text{Et}_3\text{N}} \text{Ph} \cdot \text{CH} = \text{C(Ph)} \cdot \text{CO}_2\text{H}
\end{align*}
\]

Place 42.5 g (40.5 ml, 0.4 mol) of purified benzaldehyde (Expt 6.133), 54.5 g (0.4 mol) of phenylacetic acid, 80 ml (0.83 mol) of redistilled acetic anhydride
and 40 ml of anhydrous triethylamine in a 500-ml round-bottomed flask fitted with a reflux condenser and drying tube. Boil the mixture gently for 5 hours. Steam distil the mixture directly from the reaction flask until the distillate passing over is no longer cloudy, and collect a further 50 ml of distillate: discard the distillate. Cool the residue in the flask and decant the solution from the solid; make up the volume of the solution to 500 ml with water (A). Dissolve the solid in 500 ml of hot 95 per cent ethanol, add the solution (A) followed by 2 g of decolourising carbon; heat the mixture to boiling, filter and acidify the filtrate immediately to Congo red with 1:1-hydrochloric acid. Cool. Collect the separated crystals by suction filtration and recrystallise from 60 per cent ethanol. The yield of α-phenylcinnamic acid (I), m.p. 172–173 °C, is 55 g (61%).

Note. (1) The product is the isomer with the two phenyl groups cis to each other, since decarboxylation with quinoline–copper–chromium oxide at 210–220 °C yields (Z)-stilbene.

**Coumarin**

\[
\text{H}^\text{EtN} \quad \begin{array}{c}
\text{OH} \\
\text{H} \\
\end{array}
\xrightarrow{(\text{Me-CO})_2\text{O}}
\begin{array}{c}
\text{O} \cdot \text{CO} \cdot \text{Me} \\
\text{O} \cdot \text{CO} \\
\end{array}
\]

In a 250-ml round-bottomed flask, provided with a small reflux condenser and a calcium chloride drying tube at the top, place 2.1 g (0.17 mol) of salicylaldehyde, 2.0 ml of anhydrous triethylamine and 5.0 ml (0.052 mol) of acetic anhydride, and reflux the mixture gently for 12 hours. Steam distil the mixture from the reaction flask and discard the distillate. Render the residue in the flask basic to litmus with solid sodium hydrogen carbonate, cool, filter the precipitated crude coumarin at the pump and wash it with a little cold water. Acidify the filtrate to Congo red with 1:1-hydrochloric acid, collect the precipitated α-acetoxycinnamic acid and recrystallise it from 70 per cent propan-2-ol; the yield is 0.40 g (11%), m.p. 153–154 °C.

Boil the crude coumarin with 200 ml of water to which 0.2 g of decolourising carbon is added, filter the hot solution and concentrate it to a volume of 80 ml. Cool, collect the coumarin which separates and recrystallise it from 40 per cent aqueous methanol. The yield of coumarin, m.p. 68–69 °C, is 1.0 g (40%). The p.m.r. spectrum (CDCl\textsubscript{3}, TMS) shows signals at δ 6.33 (d, 1H, =CH-CO), 7.02–7.52 (m, 4H, C\textsubscript{Ar}–H) and 7.65 (d, 1H, Ar-CH=).

**Experiment 6.139 3,4-METHYLENEDIOXYCINNAMIC ACID (β-Piperonylacrylic acid)**

\[
\begin{array}{c}
\text{H} \\
\text{O} \\
\end{array}
+ \text{CH}_2(\text{CO}_2\text{H})_2 \xrightarrow{\text{C}_4\text{H}_8\text{N}, \text{trace} \text{of C}_4\text{H}_8\text{N}, 95–100 \degree \text{C}} \begin{array}{c}
\text{CO}_2\text{H} \\
\text{O} \\
\end{array}
\]
Dissolve 50 g (0.33 mol) of piperonal and 75 g (0.72 mol) of malonic acid (1) in a mixture of 150 ml of pyridine (CAUTION) (2) and 2.5 ml of piperidine contained in a 500-ml round-bottomed flask, and heat under reflux for 1 hour on a water bath. A rapid evolution of carbon dioxide takes place. Complete the reaction by boiling the solution for 5 minutes. Cool, pour into excess of water containing enough hydrochloric acid to combine with the pyridine, filter off the piperonylacrylic acid, wash with a little water, and dry. The yield (64 g) is almost quantitative and the acid is practically pure. It may be recrystallised from glacial acetic acid; m.p. 238 °C.

Record the p.m.r. spectrum (DMSO-d$_6$, TMS) and assign the signals which appear at δ 6.10 (s, 2H), 6.41 (d, 1H), 6.96 (d, 1H), 7.19 (d of d, 1H), 7.36 (d, 1H) and 7.58 (d, 1H); note that the acidic proton does not appear in the spectrum, and that the $J_{2,5}$ value is zero.

Cognate preparations. **p-Methylcinnamic acid.** From p-tolualdehyde; heat for 6 hours. Recrystallise from glacial acetic acid; m.p. 198 °C. Yield: 87 per cent.

**m-Nitrocinnamic acid.** From m-nitrobenzaldehyde. Recrystallise from alcohol; m.p. 197 °C. Yield: 80 per cent.

**p-Methoxycinnamic acid.** From anisaldehyde. Recrystallise from alcohol; m.p. 172 °C. Yield: 80 per cent.

**Furylacrylic acid.** Place 48 g (41.5 ml, 0.5 mol) of freshly distilled furfural, 52 g (0.5 mol) of dry malonic acid (1) and 24 ml (0.31 mol) of dry pyridine (CAUTION) (2) in a 500-ml round-bottomed flask, fitted with a reflux condenser. Heat the flask on a boiling water bath for 2 hours, cool the reaction mixture and dilute with 50 ml of water. Dissolve the acid by the addition of concentrated ammonia solution, filter the solution and wash the filter paper with a little water. Add dilute hydrochloric acid (1:1), with stirring, to the combined filtrate and washings until acid to Congo red paper, and cool in an ice bath for at least 1 hour. Filter the furylacrylic acid and wash it with a little ice-water; it weights 63 g (91%) after drying and melts at 139–140 °C. A purer acid may be obtained by recrystallisation from light petroleum (b.p. 80–100 °C), with the addition of a little decolourising carbon; the loss is about 20 per cent.

**Notes.** (1) Commercial malonic acid is dried at 90–100 °C for 2 hours.
(2) The pyridine is dried by allowing it to stand, with frequent shaking, over potassium hydroxide pellets and then filtering.

### 6.12.4 THE SYNTHESIS OF DIPHENYLPOLYNES

1,8-Diphenylocta-1,3,5,7-tetraene can be prepared (Expt 6.140) by condensing two mols of cinnamaldehyde with succinic acid in the presence of acetic anhydride and lead oxide, in a reaction which bears similarities with those of the Perkin type discussed above.

$$
2 \text{Ph} = \text{CHCH} = \text{O} + \left[ \text{CH$_2$COOH} \right]_2 \rightarrow \text{Ph} \left( \text{OH} \right) \text{CH} = \text{CHCH} = \text{O} \rightarrow \left[ \text{Ph} \left( \text{OH} \right) \text{CH} = \text{CHCH} = \text{O} \right]_2
$$

1041
1,4-Diphenylbuta-1,3-diene (Section Expt 6.141) is prepared by a variant of the general method in which cinnamaldehyde is similarly condensed with phenylacetic acid.

\[
\text{Ph} - \text{C} = \text{C} - \text{OH} + \text{Ph} - \text{C} = \text{O} \rightarrow \text{Ph} - \text{C} = \text{C} - \text{Ph} - \text{C} = \text{O} + \text{Ph} - \text{C} = \text{O} + \text{CO}_2 + \text{H}_2\text{O}
\]

The bathochromic shift which results from the increasing length of the conjugated system is evident from the fact that the substituted butadiene is colourless (\(\lambda_{\text{max}} 344\, \text{nm}\)), while the substituted octatetraene is bright yellow (\(\lambda_{\text{max}} 402\, \text{nm}\)); see also p. 388.

**Experiment 6.140 1,8-DIPHENYLOCTA-1,3,5,7-TETRAENE**

\[
2 \text{Ph} - \text{C} = \text{C} - \text{OH} + \text{Ph} - \text{C} = \text{C} - \text{OH} \rightarrow \text{Ph} - \text{C} = \text{C} - \text{Ph} - \text{C} = \text{C} - \text{Ph} - \text{C} = \text{C} - \text{Ph} - \text{C} = \text{O}
\]

Heat a mixture of 13.2 g (11.9 ml, 0.1 mol) of cinnamaldehyde, 5.9 g (0.05 mol) of succinic acid, 11.2 g of lead oxide and 14.3 ml of acetic anhydride to 140 °C for 10 minutes with frequent shaking in a flask fitted with a reflux condenser. Boil the resulting clear solution under reflux for 2 hours; some of the tetraene crystallises at this stage. Cool the solution to 40 °C and filter the solid rapidly using a large Buchner funnel. Boil the filtrate under reflux with a further 8 ml portion of acetic anhydride for 2 hours to obtain a second crop of product on cooling and filtering. Combine the crystalline material and wash with first a little acetic anhydride and then with a little glacial acetic acid to remove brown resins. Wash the tetraene with alcohol and finally water to obtain 1.9 g (15%) of fairly pure product. Recrystallisation from chloroform gives a specimen as yellow plates, m.p. 232 °C.

**Experiment 6.141 1,4-DIPHENYLBUTA-1,3-DIENE**

In a 100-ml round-bottomed flask fitted with a reflux condenser place 10 g (0.07 mol) of phenylacetic acid, 10 g (9 ml, 0.075 mol) of redistilled cinnamaldehyde, 10 ml of acetic anhydride and 8.5 g of lead oxide. Heat the mixture slowly to boiling with intermittent shaking so that a clear solution is obtained, and then boil under reflux for 5 hours. Pour the hot solution into a beaker and set aside for 12 hours. Filter the semi-solid product under suction and wash the filter-cake with two 5 ml portions of ethanol, stirring the solid...
thoroughly with the wash liquid before applying suction. Transfer the solid to
a small beaker and triturate with 8 ml of ethanol, refilter, suck dry and repeat
the trituration procedure with a further 8-ml portion of ethanol. Dissolve the
filtered solid in 20 ml of hot toluene, treat with 1 g of charcoal and filter the
hot solution (fume cupboard). Add 35 ml of hot ethanol to the filtrate, boil
and cool the solution in ice with shaking. Filter the purified diene, wash with
5 ml of cold ethanol and dry at 50 °C; the final product has m.p. 153 °C. The
yield is 3.5 g (23%).

6.12.5 THE BENZOIN CONDENSATION

Aromatic aldehydes when treated with an alkali metal cyanide, usually in
aqueous solution, undergo condensation to the α-hydroxyketone or benzoin.
The examples in Expt 6.142 are benzoin and furoin.

\[ 2\text{Ar-CHO} \overset{\text{NaCNaq.}}{\rightarrow} \text{Ar-CH(OH)-CO-Ar} \]

By use of 1 mol each of two different aldehydes, an unsymmetrical or mixed
benzoin is obtained (for example, the formation of 4-methoxybenzoin).

\[ \text{Ar}^1\text{-CHO} + \text{Ar}^2\text{-CHO} \overset{\text{NaCN or KCNaq.}}{\rightarrow} \text{Ar}^1\text{-CH(OH)-CO-Ar}^2 \]

The reaction depends upon the catalytic influence of the cyanide ion and the
mechanism may be represented in the following way.

Oxidation of the α-hydroxyketone with concentrated nitric acid, or by
catalytic amounts of copper(II) salts in acetic acid solution which are
regenerated continuously by ammonium nitrate, yields the diketone (e.g. benzil
and furil, Expt 6.143).

\[ \text{Ar-CH(OH)-CO-Ar} \overset{\text{lO}_4^-}{\rightarrow} \text{Ar-CO-CO-Ar} \]

α-Diketones (Ar-CO-CO-Ar) upon refluxing with aqueous–alcoholic potas-
sium hydroxide undergo the benzilic acid rearrangement and are converted into
the salt of a benzilic acid (Expt 6.144).

\[ \text{Ar-CO-CO-Ar} + \text{KOH} \rightarrow (\text{Ar})_2\text{C(OH)CO}_2^-\text{K}^+ \]

The mechanism involves nucleophilic attack of the hydroxide ion at a
carbonyl carbon atom to yield the oxyanion (1) which undergoes a 1,2-
nucleophilic shift of an aryl group as shown. Proton transfer completes the
reaction sequence.
Direct conversion of a benzoin into the corresponding benzilic acid may be accomplished conveniently and in good yield by reaction with alkaline bromate solution at 85–90 °C (see Expt 6.144, Method 2).

**Experiment 6.142 BENZOIN**

\[
2\text{PhCHO} \xrightarrow{\text{NaCN \ EtOH/H}_2\text{O}} \text{Ph-CH(OH)-CO-Ph}
\]

In a 500-ml round-bottomed flask place 65 ml of rectified spirit, 50 g (47.5 ml, 0.47 mol) of pure benzaldehyde (1) and a solution of 5 g of sodium cyanide (96–98%) [CAUTION: see Expt 5.157, Note (I)] in 50 ml of water. Attach a reflux condenser (preferably of the double surface type) and boil the mixture gently for half an hour (2). Cool the contents of the flask (preferably in an ice bath). Filter the crude benzoin, wash it with cold water, drain well (3) and dry. The yield of crude benzoin, which is white or pale yellow in colour, is 45 g (90%).

Recrystallise 5.0 g from about 40 ml of hot rectified (or industrial) spirit; upon cooling, 4.5 g of pure benzoin (a white, crystalline solid, m.p. 137°C) separates. Reserve the remainder of the preparation for benzil and benzilic acid (Expts 6.143 and 6.144 respectively).

**Notes.** (1) For the purification of commercial benzaldehyde, see Expt 6.133.
(2) The reaction sometimes takes place with considerable violence and material may be lost through the condenser unless a large flask (e.g. at least of the size given) is employed.
(3) The filtrate contains sodium cyanide, and should be washed down the sink with a liberal quantity of water; see also Expt 5.157, Note (1).

**Cognate preparations. Furoin**

\[
2\text{CHO} \xrightarrow{\text{CN}} \text{CH(OH)-CO-CHO}
\]

In a 1-litre three-necked flask, equipped with a mechanical stirrer, a reflux condenser and a separatory funnel, place 400 ml of water, 200 g (172.5 ml, 2.08 mol) of freshly distilled furfural (see Expt 6.133) and 150 ml of rectified spirit. Heat the reaction mixture to boiling, remove the source of heat and, when the liquid has just ceased to boil, add with stirring a solution of 10 g of potassium cyanide (CAUTION) in 30 ml of water from the separatory funnel as rapidly as the vigour of the reaction permits. When the ebullition subsides (exothermic reaction), heat to boiling for a further 5 minutes. Acidify the reaction mixture with glacial acetic acid (use litmus paper) and allow to cool overnight, preferably in an ice chest or a refrigerator. Filter off the dark crystals at the pump, wash with cold water and then with cold methanol to remove as much of the tar (colouring matter) as possible. Recrystallise from
methanol with the addition of about 10 g of decolourising carbon. The yield of furoin, m.p. 135–136 °C, is 75 g (37.5%). If the m.p. is slightly low, another recrystallisation from toluene–ethanol will give satisfactory results.

4-Methoxybenzoin. Dissolve 25 g of potassium cyanide (CAUTION) in 175 ml of water in a 1500-ml round-bottomed flask, and add 136 g (121.5 ml, 1 mol) of redistilled p-methoxybenzaldehyde (anisaldehyde), 108 g (103 ml, 1.02 mol) of redistilled benzaldehyde and 350 ml of 95 per cent ethanol. Reflux the mixture (which becomes homogeneous at the boiling temperature) for 90 minutes. Remove all the unreacted aldehydes and the ethanol by steam distillation. Decant the water and set the residue aside to crystallise. Press the product as free as possible from oily material on a suction funnel and wash it with a little ethanol. Recrystallise the crude product (c. 125 g) by dissolving it in hot ethanol and allowing to crystallise slowly. The p-methoxybenzoin separates out first in large clumps of long needles, while the little benzoin present crystallises in small compact balls of needles. With a little experience it is possible to filter off a good yield of the former before the appearance of the benzoin. The yield of 4-methoxybenzoin is about 55 g (23%). Recrystallise again until the m.p. is 105–106 °C.

Experiment 6.143 BENZIL

\[
\text{Ph} \cdot \text{CH(OH)} \cdot \text{CO} \cdot \text{Ph} \xrightarrow{\text{101}} \text{Ph} \cdot \text{CO} \cdot \text{CO} \cdot \text{Ph}
\]

Method 1. Place 20 g (0.094 mol) of crude benzoin (Expt 6.142) and 100 ml of concentrated nitric acid in a 250-ml round-bottomed flask. Heat on a boiling water bath (in the fume cupboard) with occasional shaking until the evolution of oxides of nitrogen has ceased (about 1.5 hours). Pour the reaction mixture into 300–400 ml of cold water contained in a beaker, stir well until the oil crystallises completely as a yellow solid. Filter the crude benzil at the pump, and wash it thoroughly with water to remove the nitric acid. Recrystallise from ethanol or rectified spirit (about 2.5 ml per gram). The yield of pure benzil, m.p. 94–96 °C, is 19 g.

Method 2. Place 0.2 g of copper(II) acetate, 10 g (0.125 mol) of ammonium nitrate, 21.2 g (0.1 mol) of benzoin and 70 ml of an 80 per cent v/v aqueous acetic acid solution in a 250-ml flask fitted with a reflux condenser. Heat the mixture with occasional shaking (1). When solution occurs, a vigorous evolution of nitrogen is observed. Reflux for 90 minutes, cool the solution, seed the solution with a crystal of benzil (2) and allow to stand for 1 hour. Filter at the pump and keep the mother-liquor (3): wash well with water and dry (preferably in an oven at 60 °C). The yield of benzil, m.p. 94–95 °C, is 19 g (90%); the m.p. is unaffected by recrystallisation from alcohol or from carbon tetrachloride (2 ml per gram). Dilution of the mother-liquor with the aqueous washings gives a further 1.0 g of benzil.

Notes. (1) For large-scale preparations use a three-necked flask equipped with two reflux condensers and a sealed mechanical stirrer.
(2) Stirring or vigorous shaking also induces crystallisation.
(3) The mother-liquor should not be concentrated as an explosion may result.

Cognate preparation. Furil. Proceed exactly as for Method 2, using 19.2 g (0.1 mol) of furoin (Expt 6.142) but use 250 ml of the aqueous acetic acid. The
yield of furil, yellow needles of m.p. 165–166°C, after recrystallisation from methanol is 17 g (89%).

**Experiment 6.144 BENZILIC ACID**

\[
\begin{align*}
\text{Ph-CO.CO-PH} & \xrightarrow{\text{OH}} \text{Ph-C(OH).Ph} \\
& \xrightarrow{\text{101 mol OH}} \text{Ph-CH(OH).CO-PH}
\end{align*}
\]

**Method 1.** In a 500-ml round-bottomed flask, place a solution of 35 g of potassium hydroxide in 70 ml of water, then add 90 ml of rectified spirit and 35 g (0.167 mol) of recrystallised benzil (Expt 6.143). A deep bluish-black solution is produced. Fit a reflux condenser to the flask and heat the mixture on a boiling water bath for 10–15 minutes. Pour the contents of the flask into a porcelain dish and allow to cool, preferably overnight. The potassium salt of benzilic acid crystallises out. Filter off the crystals at the pump and wash with a little ice-cold alcohol. Dissolve the potassium salt in about 350 ml of water, and add 1 ml of concentrated hydrochloric acid from a burette slowly and with stirring. The precipitate thus produced is coloured red-brown and is somewhat sticky. Filter this off; the filtrate should be nearly colourless. Continue the addition of hydrochloric acid with stirring until the solution is acid to Congo red paper. Filter off the benzilic acid with suction, wash it thoroughly with cold water until free from chlorides and allow to dry. The yield of crude benzilic acid, which is usually light pink or yellow in colour, is 30 g (79%). Purify the product either by recrystallisation from hot benzene (about 6 ml per gram) or from hot water with the use of a little decolourising carbon. The coloured and sticky material obtained by the first precipitation may be recrystallised from hot water with the addition of a little decolourising carbon, and a further 1–2 g obtained. Pure benzilic acid has m.p. 150°C.

**Method 2.** Prepare a solution of 50 g of sodium hydroxide and 11.5 g of sodium bromate (or 12.5 g of potassium bromate) in 90 ml of water in an evaporating dish. Add 42 g (0.2 mol) of benzoin (1) in portions to this solution while stirring (preferably with a mechanical stirrer) and heating on a water bath at 85–90°C (2). Add small quantities of water from time to time to prevent the mixture becoming too thick; about 80 ml of water are required. Continue the heating and stirring until a test portion is completely or almost completely soluble in water; this usually requires 3–4 hours. Dilute the mixture with 400 ml of water and allow to stand, preferably overnight. Filter off the solid or oil impurity (benzhydrol). Set aside 5 ml of the filtrate (3) and to the bulk add dilute sulphuric acid (4) slowly and with stirring to a point just short of the liberation of bromine; about 130 ml are required. If the end-point is overstepped, add the 5 ml of the filtrate which was set aside and then sufficient sulphuric acid to the end-point. Filter off the product at the pump, wash it well with water and dry. The benzilic acid weighs 39 g (85%) and has a m.p. of 149–150°C, i.e. is practically pure. If desired, it may be recrystallised from benzene, or from water.

**Notes.** (1) The crude benzoin (Expt 6.142) gives satisfactory results.
(2) The reaction mixture should not be heated to boiling since this leads to the formation of much benzhydrol. The temperature attained by heating on a boiling water bath is 85–90°C.
This precaution is generally unnecessary if the addition of sulphuric acid is made carefully.

Prepared by adding 1 volume of concentrated sulphuric acid to 3 volumes of water.

### 6.12.6 Oxime Formation

Benzaldehyde reacts with hydroxylamine in the presence of sodium hydroxide to yield an oxime of low m.p. (α- or syn-benzaldoxime) which is stable to alkali, but is rapidly rearranged by acids to give an isomeric oxime of higher m.p. (β- or anti-benzaldoxime) (Expt 6.145).

Two isomeric oximes of benzin, i.e. the α- and β-forms (1) and (2), are obtained in a similar manner (cognate preparation in Expt 6.145).

Details of the preparation of α-benzoinoxime ('cupron') and salicylaldoxime are also included in Expt 6.145; these are employed as analytical reagents for molybdenum and for copper and nickel respectively.

Oximes of ketones undergo rearrangement (the Beckmann rearrangement) to amides under the influence of a variety of acidic reagents (e.g. sulphuric acid, hydrogen fluoride, acetic anhydride, phosphorus pentachloride, thionyl chloride, etc.). The process is illustrated by the conversion of benzophenone oxime to benzanilide in the presence of phosphorus pentachloride.

In the case of unsymmetrically substituted oximes (e.g. Ar¹·C(=NOH)·Ar²) the structure of the oxime (syn or anti) may be deduced by hydrolysis of the anilide and characterisation of the isolated carboxylic acid and amine. Thus if the products are Ar¹·CO₂H and Ar²·NH₂, the hydroxyl group in the oxime must of necessity be anti to the group Ar² owing to the trans intramolecular rearrangement step specified in the formulation above. Illustrative details for the
hydrolysis of anilides and the isolation of the acidic and basic constituents are given in Expt 6.145.

**Experiment 6.145 α- AND β-BENZALDOXIMES**

\[
\text{Ph-CHO + NH}_2\text{OH} \rightarrow \text{Ph-CH=N-OH + H}_2\text{O}
\]

In a 250-ml conical flask mix a solution of 14 g of sodium hydroxide in 40 ml of water and 21 g (20 ml, 0.2 mol) of pure benzoaldehyde (Expt 6.133). Add 15 g (0.22 mol) of hydroxylamine hydrochloride in small portions, and shake the mixture continually (mechanical stirring may be employed with advantage). Some heat is developed and the benzoaldehyde eventually disappears. Upon cooling, a crystalline mass of the sodium derivative of the oxime separates out. Add sufficient water to form a clear solution, and pass carbon dioxide into the solution until saturated. A colourless emulsion of the α- or synaldoxime separates. Extract the oxime with ether, dry the extract over magnesium or anhydrous sodium sulphate and remove the ether on a water bath using a rotary evaporator. Distil the residue under diminished pressure (Fig. 2.108). Collect the pure syn-benzaldoxime (α-benzaldoxime) at 122–124 °C/12 mmHg; this gradually solidifies on cooling in ice and melts at 35 °C. The yield is 12 g (49%).

To prepare the β-benzaldoxime, dissolve 10 g of α-benzaldoxime in 50 ml of pure anhydrous ether and pass dry hydrogen chloride (Section 4.2.38, p. 438) through a wide delivery tube into the solution with constant shaking. Colourless crystals of the hydrochloride of the β-aldoxime separate. Filter these at the pump through a sintered glass funnel, wash with dry ether, transfer to a separatory funnel and cover with a layer of ether. Add a concentrated solution of sodium carbonate gradually and with constant shaking until effervescence ceases. Separate the ethereal layer, which contains the β-oxime, dry over magnesium sulphate or sodium sulphate and remove the ether using a rotary evaporator. The residue crystallises; remove the small amount of oily matter by pressing on a porous tile. Recrystallise by dissolving the product in the minimum volume of ether and then adding light petroleum (b.p. 60–80 °C). The yield of β-benzaldoxime (anti-benzaldoxime), m.p. 130 °C, is 7–8 g (70–80%).

The p.m.r. spectra of these aldoximes should be recorded and compared, particularly with respect to the chemical shift values of the —CH=N proton.

**Cognate preparations. α-Benzilmonoxime.** Grind 42 g (0.2 mol) of pure benzi (Expt 6.143) to a thin paste with a little ethanol, and add a concentrated aqueous solution of 17.5 g (0.25 mol) of hydroxylamine hydrochloride. Cool to −5 °C in an ice–salt bath, and add 30 g of sodium hydroxide as a 20 per cent aqueous solution dropwise with rapid mechanical stirring: do not allow the temperature to rise above 0 °C. After 90 minutes dilute the mixture with water and filter off the small quantity of unchanged benzil on a sintered glass funnel. Just acidify the filtrate with glacial acetic acid, allow to stand for 30 minutes, filter off the crude pinkish α-monoxime and recrystallise it from aqueous ethanol (60 vol. % alcohol); the resulting oxime weighs 37 g (82%) and melts at 137 °C. To obtain the pure α-benzilmonoxime, recrystallise twice from benzene; the final yield is 28 g (62%) of the pure product, m.p. 140 °C. Animal charcoal must not be used in the recrystallisation (see below).
**β-Benzilmonoxime.** The α-oxime is converted into the β-form by treatment with a solution of hydrogen chloride in benzene (CAUTION) (or ether) at room temperature. From benzene, solvated crystals which melt on rapid heating at about 65 °C are obtained. Removal of benzene of crystallisation in an oven at 50 °C and recrystallisation from carbon disulphide (CAUTION) yields pure β-benzilmonoxime, m.p. 112 °C. The product gives no colour change with aqueous–alcoholic copper acetate solution; if it is contaminated with the α-form a greenish colour is produced. (Conversion of the α-form into the β-form may also be effected by boiling in benzene solution in the presence of animal charcoal, which presumably contains adsorbed acidic catalysts.)

**α-Benzoinoxime.** In a 250-ml round-bottomed flask, fitted with a reflux condenser, place a mixture of 10 g (0.047 mol) of benzoin (Expt 6.142) and 20 g (25 ml) of rectified spirit together with an aqueous solution of 8.0 g (0.087 mol) of hydroxylamine hydrochloride which has previously been neutralised with 4.4 g (0.091 mol) of sodium hydroxide. Reflux for 60 minutes. Add water to precipitate the benzoinoxime, and cool in an ice bath. Filter the solid with suction at the pump, wash it with water and recrystallise from dilute ethanol. Alternatively, the dry solid may be recrystallised from ether. The yield of pure α-benzoinoxime, m.p. 151 °C, is 5 g (47%).

**Salicylaldoxime.** Dissolve 20.0 g (0.164 mol) of salicylaldehyde (Expt 6.116) in 30 ml of rectified spirit, add a solution of 15 g (0.216 mol) of hydroxylamine hydrochloride in 10 ml of water and render the mixture just alkaline with 10 per cent sodium carbonate solution while cooling in ice. Allow to stand overnight. Acidify with acetic acid, distil off the alcohol under reduced pressure on a rotary evaporator, dilute with twice the volume of water and extract with two 50 ml portions of ether. Dry the ethereal extract with sodium sulphate or magnesium sulphate, distil off most of the ether and allow the residue to crystallise. Recrystallise from chloroform–light petroleum (b.p. 40–60 °C). The yield of salicylaldoxime, m.p. 57 °C, is 12 g (40.5%).

**Benzophenone oxime.** Place a mixture of 25 g (0.137 mol) of benzophenone (Expt 6.121), 15 g (0.216 mol) of hydroxylamine hydrochloride, 50 ml of rectified spirit and 10 ml of water in a 500-ml round-bottomed flask. Add 28 g (0.7 mol) of sodium hydroxide (pellet form) in portions with shaking; if the reaction becomes too vigorous, cool the flask with running tap water. When all the sodium hydroxide has been added, attach a reflux condenser to the flask, heat to boiling and reflux for 5 minutes. Cool, and pour the contents of the flask into a solution of 75 ml of concentrated hydrochloric acid in 500 ml of water contained in a 1-litre beaker. Filter the precipitate at the pump, wash thoroughly with cold water and dry in an oven at 40 °C or in a vacuum desiccator. The yield of benzophenone oxime, m.p. 142 °C, is 26.5 g (98%). It may be recrystallised from methanol (4 ml per gram) but the m.p. is unaffected. The oxime is gradually decomposed by oxygen and traces of moisture into benzophenone and nitric acid; it should be preserved in a vacuum desiccator filled with pure dry carbon dioxide or nitrogen.

**Beckmann rearrangement of benzophenone oxime to benzanilide.** Dissolve 2 g of benzophenone oxime in 20 ml of anhydrous ether in a small conical flask and add 3 g of powdered phosphorus pentachloride (or 3 ml of pure thionyl chloride). Distil off the solvent and other volatile products on a water bath on
a rotary evaporator, add 25 ml of water, boil for several minutes and break up any lumps which may be formed. Decant the supernatant liquid, and recrystallise, in the same vessel, from boiling ethanol. The product is benzanilide, 1.6 g (80%), m.p. 163 °C; confirm this by a mixed m.p. determination with an authentic specimen.

**Hydrolysis of benzanilide.** Place 5 g of benzanilide and 50 ml of 70 per cent w/w sulphuric acid (1) in a small flask fitted with a reflux condenser, and boil gently for 30 minutes. Some of the benzoic acid will vaporise in the steam and solidify in the condenser. Pour 60 ml of hot water down the condenser: this will dislodge and partially dissolve the benzoic acid. Cool the flask in ice-water; filter off the benzoic acid (aniline sulphate does not separate at this dilution), wash well with water, drain, dry upon filter paper and identify by m.p. (121 °C). Render the filtrate alkaline by cautiously adding 10 per cent sodium hydroxide solution, cool and isolate the aniline by ether extraction. Remove the ether and distil the aniline, b.p. 184 °C.

**Note.** (1) For preparation see Expt 6.68, Note (3).

### 6.12.7 SOME REACTIONS OF ALKYL ARYL KETONES

Aryl methyl ketones can only give a single enol (or enolate ion) and subsequent reactions are therefore entirely regioselective. These include halogenation (cf. Section 5.11.1, p. 667), and the Mannich reaction (cf. Section 5.18.2, p. 801).

Bromination of the methyl group can be restricted to monosubstitution when the reaction is carried out in acidic media. The mechanism involves protonation of the carbonyl-oxygen, followed by proton loss to give the enol. After monobromination, protonation of the bromoketone is less favourable owing to the presence of the electron-withdrawing halogen atom. Further enolisation does not occur therefore and halogenation ceases (contrast the behaviour of methyl ketones on bromination under alkaline conditions, p. 667); the product is an aryl bromomethyl ketone or phenacyl bromide.

\[
\begin{align*}
\text{Ar-CH}_2\text{Br} & \rightleftharpoons \text{Ar-C}:=\text{H} \\
\text{Ar-CH}_2\text{OH} & \rightleftharpoons \text{Ar-CH}_2\text{OH}^{-} + \text{H}^+ \\
\end{align*}
\]

The preparation of p-bromophenacyl bromide, which is a useful reagent for the characterisation of carboxylic acids (Section 9.6.15, p. 1261), is described in Expt 6.146.

Condensation of the active methyl group in acetophenone with formaldehyde and dimethylamine (in the form of its hydrochloride) is an example of the **Mannich reaction** (e.g. the synthesis of dimethylaminopropiophenone, Expt 6.147). The probable mechanism of the reaction involves the intermediate formation of the hydroxymethyldimethylamine which eliminates water to form the reactive species (1). This condenses with the \(\alpha\)-carbon atom of acetophenone reacting in its enol form.
AROMATIC COMPOUNDS 6.12

\[
\begin{align*}
\text{Me}_2\text{NH}_2\text{Cl} + \text{H-CHO} & \leftrightarrow \text{Me}_2\text{NH} + \text{H-CH}=\text{OH} + \text{Cl} \\
\text{Me}_2\text{NH} \quad \text{CH}_2=\text{OH} & \leftrightarrow \text{Me}_2\text{NH} \cdot \text{CHOH} - \text{H}_2\text{O} \rightarrow \text{Me}_2\text{N}=\text{CH}_2
\end{align*}
\]

Other compounds containing active hydrogen atoms similarly undergo the Mannich reaction, and a further interesting example is provided by the synthesis of dimethylaminomethylindole (gramine), in which indole is the reactive component (cognate preparation in Expt 6.147).

\[
\begin{align*}
\text{Ph} & \quad \text{CH}_2 \quad \text{NMe}_2 \\
\text{CH}_2 & \quad \text{OH} \quad \text{CH}_2 \quad \text{NMe}_2
\end{align*}
\]

The quaternary salts produced by the Mannich reaction undergo a number of conversions useful in synthesis. For example, although stable at room temperature they eliminate an amine hydrochloride on heating to yield an \(\alpha,\beta\)-unsaturated ketone (e.g. the conversion of dimethylaminopropiophenone to phenyl vinyl ketone, Expt 6.147).

\[
\begin{align*}
\text{Ar} & \quad \text{NHMe}_2\text{Cl} \\
& \rightarrow \text{Ar} \quad \text{CH}_2 + \text{Me}_2\text{NH}_2\text{Cl}
\end{align*}
\]

This ready decomposition makes Mannich bases convenient \textit{in situ} sources of \(\alpha,\beta\)-unsaturated carbonyl compounds (see also Section 7.2, p. 1094).

A further example of the usefulness of Mannich bases is illustrated by the reaction of dimethylaminopropiophenone hydrochloride on heating with aqueous potassium cyanide, which results in the ready replacement of the dimethylamino group by the nitrile group forming \(\beta\)-benzoylpropionitrile. This replacement occurs even more readily when the dimethylamino compound is of the benzylic type, as in gramine. When the latter is boiled for a long time with aqueous potassium cyanide, the plant growth hormone 3-indolylacetic acid is formed by way of hydrolysis of the intermediate nitrile.

\[
\begin{align*}
\text{CH}_2 \cdot \text{N(CH}_3)_2 \\
\text{KCN} & \rightarrow \text{CH}_2 \cdot \text{CN} \\
\text{H}_2\text{O} & \rightarrow \text{CH}_2 \cdot \text{CO}_2\text{H}
\end{align*}
\]

When an alkyl aryl ketone is heated with yellow ammonium polysulphide solution at elevated temperature, an aryl-substituted aliphatic acid amide is formed; the product actually isolated is the amide of the \(\omega\)-arylcarboxylic acid together with a smaller amount of the corresponding ammonium salt of the carboxylic acid.
This conversion of a carbonyl compound by ammonium polysulphide solution into an amide with the same number of carbon atoms is known as the Willgerodt reaction. The procedure has been improved by the addition of about 40 per cent of dioxane or of pyridine to increase the mutual solubility of the ketone and aqueous ammonium polysulphide; the requisite temperature is lowered to about 160 °C and the yield is generally better.

A further improvement is embodied in the Kindler variation of the Willgerodt reaction which is illustrated by several examples in Expt 6.148. This consists of heating the ketone with approximately equal amounts of sulphur and a dry amine (e.g. morpholine) instead of aqueous ammonium polysulphide. The principal product is a thioamide, and subsequent hydrolysis with acid or alkali affords the carboxylic acid, usually in good yield.

An evaluation of this complex and variable reaction concludes that it cannot be described by a single mechanism.  

Experiment 6.146  \( \alpha, \beta \)-DIBROMOACETOPHENONE (\( p \)-Bromophenacyl bromide)

\[
p\text{-BrC}_6\text{H}_4\cdot\text{CO}\cdot\text{Me} \xrightarrow{\text{Br}_2, \text{Me}\cdot\text{CO}_2\text{H}} p\text{-BrC}_6\text{H}_4\cdot\text{CO}\cdot\text{CH}_2\text{Br}
\]

Place a solution of 50 g (0.25 mol) of \( p \)-bromooctophenone (Expt 6.122) in 100 ml of glacial acetic acid in a 500-ml flask. Add very slowly (about 30 minutes) from a dropping funnel 40 g (12.5 ml, 0.25 mol) of bromine (CAUTION); shake the mixture vigorously during the addition and keep the temperature below 20 °C. \( p \)-Bromophenacyl bromide commences to separate as needles after about half of the bromine has been introduced. When the addition is complete, cool the mixture in ice-water, filter the crude product at the pump and wash it with 50 per cent alcohol until colourless (about 100 ml are required). Recrystallise from rectified (or industrial) spirit (c. 400 ml). The yield of pure \( p \)-bromophenacyl bromide (colourless needles, m.p. 109 °C) is 50 g (72%).

Cognate preparation. \( \alpha \)-Bromo-\( p \)-phenylacetophenone (\( p \)-phenylphenacyl bromide). Suspend 36 g (0.183 mol) of \( p \)-phenylacetophenone in 200 ml of glacial acetic acid in a 500-ml flask, warm gently on a water bath until a clear solution results, then cool as far as possible without the formation of crystals. To this solution add 29.5 g (9.5 ml, 0.184 mol) of bromine; do not allow the temperature to rise above 45 °C during the addition. The brominated product
separates from the solution when about three-quarters of the bromine has been added. After 2 hours, cool the flask in a bath of ice and salt, filter the product, wash with a little cold glacial acetic acid, followed by small volumes of water until all the acid has been removed. The yield of crude material, m.p. 124.5–125.5 °C, is 42 g (83%). Recrystallise from hot rectified spirit (600–700 ml) and add a little decolourising carbon to remove the colour: pure, colourless p-phenylphenacyl bromide, m.p. 125.5 °C, is obtained.

Experiment 6.147 DIMETHYLAMINOPROPIOPHENONE HYDRO-CHLORIDE (Mannich reaction)

\[
\text{Ph} \cdot \text{CO} \cdot \text{Me} + \text{H} \cdot \text{CHO} + \text{Me}_2\text{NH}_2^+\text{Cl}^- \rightarrow \text{Ph} \cdot \text{CO} \cdot (\text{CH}_2)_2 \cdot \text{NHMe}_2^- \cdot \text{Cl}^-
\]

Place 26.5 g (0.326 mol) of dry dimethylamine hydrochloride, 10 g (0.33 mol) of powdered paraformaldehyde and 30 g (29.3 ml, 0.25 mol) of acetophenone in a 250-ml round-bottomed flask attached to a reflux condenser. Introduce 40 ml of 95 per cent ethanol to which 0.5 ml of concentrated hydrochloric acid has been added, and reflux the mixture on a water bath for 2 hours; the reaction mixture should ultimately be almost clear and homogeneous. Filter the yellowish solution (if necessary) through a hot-water funnel: transfer the filtrate to a 500-ml wide-mouthed conical flask and, while still warm, add 200 ml of acetone. Allow to cool to room temperature and leave in a refrigerator overnight. Filter the crystals at the pump, wash with 10 ml of acetone and dry for 6 hours at 40–50 °C: the yield of crude product, m.p. 152–155 °C, is 38 g (71%). Recrystallise the crude product by dissolving in 45 ml of hot rectified spirit and slowly adding 225 ml of acetone to the solution; collect the solid which separates by suction filtration and dry at 70 °C. The purified material melts at 155–156 °C and the recovery is about 90 per cent.

Conversion into 3-benzoylpropionitrile

\[
\text{Ph} \cdot \text{CO} \cdot (\text{CH}_2)_2 \cdot \text{NHMe}_2^- \cdot \text{Cl}^- \xrightarrow{\text{KCN}} \text{Ph} \cdot \text{CO} \cdot (\text{CH}_2)_2 \cdot \text{CN} + \text{Me}_2\text{NH} + \text{KCl}
\]

To a mixture of 21.4 g (0.1 mol) of dimethylaminopropiophenone hydrochloride and 13.0 g (0.2 mol) of potassium cyanide in a 500-ml flask, add 260 ml of boiling water; heat the heterogeneous mixture under reflux for 30 minutes. Part of the dimethylamine, which is eliminated in the reaction, distils: collect this in dilute hydrochloric acid. Cool the reaction mixture in ice; the oil solidifies and crystals form in the aqueous layer. Collect the solid [crude 3-benzoylpropionitrile, 10.5 g (66%)] by suction filtration and recrystallise it from benzene–light petroleum (b.p. 40–60 °C); the product separates as almost colourless blades, m.p. 76 °C.

Conversion to phenyl vinyl ketone. Place an intimate mixture of 21.4 g (0.1 mol) of β-dimethylaminopropiophenone hydrochloride and 0.2 g of hydroquinone in a 100-ml round-bottomed flask. Attach a Claisen still-head fitted with a stout capillary air leak and condenser arranged for distillation under reduced pressure; place a few crystals of hydroquinone in the receiving flask. Pyrolyse the amine hydrochloride by heating the flask in an electric mantle at 2 mmHg (oil immersion pump), and collect the crude ketone which distils between 70 and 90 °C. On redistillation 7 g (51%) of pure phenyl vinyl ketone, b.p. 72–73 °C/3 mmHg (115 °C/18 mmHg), are obtained. Characterise
the product by reaction with phenylhydrazine in the following way. Dissolve 0.5 g of phenylhydrazine hydrochloride and 0.5 g of sodium acetate trihydrate in the minimum of water, and add 0.5 g of the ketone followed by a little ethanol to give a homogeneous solution. Heat the mixture on a steam bath for 5–10 minutes, collect the product which separates on cooling and crystallise it from ethanol. Yellow needles of 1,3-diphenyl-2-pyrazoline, m.p. 154 °C, are obtained.

Cognate preparation. Dimethylaminomethylindole (gramine). Cool 42.5 ml (0.236 mol) of aqueous dimethylamine solution (c. 25% w/v) contained in a 100-ml flask in an ice bath, add 30 g of cold acetic acid, followed by 17.2 g (0.21 mol) of cold, 37 per cent aqueous formaldehyde solution. Pour the solution on to 23.4 g (0.2 mol) of indole; use 10 ml of water to rinse out the flask. Allow the mixture to warm up to room temperature, with occasional shaking as the indole dissolves. Keep the solution at 30–40 °C overnight and then pour it, with vigorous stirring, into a solution of 40 g of potassium hydroxide in 300 ml of water; crystals separate. Cool in an ice bath for 2 hours, collect the crystalline solid by suction filtration, wash with three 50 ml portions of cold water and dry to constant weight at 50 °C. The yield of gramine is 34 g (97.5%); this is quite suitable for conversion into 3-indolylacetic acid. The pure compound may be obtained by recrystallisation from acetone–hexane; m.p. 133–134 °C.

Conversion into 3-indolylacetic acid. In a 1-litre flask, fitted with a reflux condenser, place a solution of 35.2 g (0.72 mol) of sodium cyanide (CAUTION) in 70 ml of water, then add 25 g (0.144 mol) of gramine and 280 ml of 95 per cent ethanol. Boil the mixture under reflux for 80 hours. Dilute the cooled reaction mixture with 350 ml of water, shake with a little activated charcoal (e.g., Norit), filter and concentrate to about 350 ml under reduced pressure (water pump) in order to remove most of the alcohol. Cool to about 5 °C, filter off the solid and wash it with a little cold water; keep the filtrate (A). Recrystallise the solid from ethanol–ether to obtain 5.0 g (20%) of 3-indolylacetamide, m.p. 150–151 °C.

Concentrate the filtrate (A) to about 300 ml, cool to 5–10 °C and add concentrated hydrochloric acid dropwise and with vigorous stirring (fume cupboard; hydrogen cyanide is evolved) to a pH of 1–2 (about 50 ml); a crude, slightly pink 3-indolylacetic acid is precipitated. The yield of crude acid, m.p. 159–161 °C, is 20 g. Recrystallise from 1,2-dichloroethane containing a small amount of ethanol; 17.5 g (70%) of pure 3-indolylacetic acid, m.p. 167–168 °C, are obtained.

Experiment 6.148 2-NAPHTHYLACETIC ACID (Willgerodt reaction)

\[
2-C_{10}H_7\cdot CO\cdot Me \xrightarrow{\text{S}} 2-C_{10}H_7\cdot CH_2\cdot CS\cdot N\longrightarrow \xrightarrow{H_3O^+} 2-C_{10}H_7\cdot CH_2\cdot CO_2H + H_2S + H\text{N}\cdot \text{O}
\]

In a conical or round-bottomed flask, fitted with a reflux condenser by means of a ground glass joint, place a mixture of 128 g (0.75 mol) of methyl 2-naphthyl ketone (Expt 6.121), 35 g (1.1 mol) of sulphur and 97 g (97 ml,
1.1 mol) of morpholine (b.p. 126–128 °C). Reflux in the fume cupboard gently at first until the evolution of hydrogen sulphide subsides and then more vigorously for a total period of 14 hours. Pour the hot reaction mixture, which has separated into two layers, into 400 ml of warm ethanol and leave to crystallise. The 2-naphthylthioacetomorpholide separates as pale buff crystals. Filter at the pump and wash with a little cold ethanol; the yield of crude thiomorpholide, m.p. 103–108 °C, is 178 g (87%).

Mix 130 g (0.48 mol) of the crude thiomorpholide with 270 ml of glacial acetic acid, 40 ml of concentrated sulphuric acid and 60 ml of water; raise the temperature of the mixture carefully to the boiling point and reflux for 5 hours. Decant the solution from a little tarry matter into 2 litres of water and keep overnight. Collect the solid by suction filtration and wash it well with cold water. Digest the solid with a solution of 50 g of sodium hydroxide in 1 litre of water, filter and acidify the filtrate with hydrochloric acid; filter off the crude 2-naphthylacetic acid, wash with water and dry. The yield of the crude acid, m.p. 137–140 °C, is 75 g (84%). Recrystallisation from benzene raises the m.p. to 142–143 °C; the loss is about 10 per cent.

Cognate preparations. 3-Phenylpropanoic acid (hydrocinnamic acid). Reflux a mixture of 53.5 g (0.4 mol) of propiophenone (Expt 6.126), 20.5 g (0.64 mol) of sulphur and 46 g (46 ml, 0.53 mol) of morpholine for 6 hours. Pour the reaction product into 400 ml of 10 per cent ethanolic sodium hydroxide solution and reflux for 7 hours. Distil off the ethanol, dilute with water, acidify with hydrochloric acid (to Congo red paper) and extract three times with ether. Wash the ether extracts with water, dry, remove the ether and distil. Collect the hydrocinnamic acid at 125–129 °C/6 mmHg; it solidifies completely on cooling, m.p. 46–47 °C. The yield is 39 g (65%).

p-Methoxyphenylacetic acid. Reflux a mixture of 42 g (0.28 mol) of p-methoxyacetophenone (Expt 6.122), 13.5 g (0.42 mol) of sulphur and 36.5 g (36 ml, 0.42 mol) of morpholine for 5 hours. Pour the reaction mixture slowly into water, allowing the first addition to crystallise before the bulk of the mixture is added. Filter off the crude yellow solid, grind it up thoroughly with water, filter again and dry in the air. The yield of crude thioacetomorpholide, m.p. 65–67 °C, is 56 g (80%). Recrystallisation from dilute methanol raises the m.p. to 71–72 °C.

Add 50 g of the crude thioacetomorpholide to 400 ml of 10 per cent ethanolic sodium hydroxide solution and reflux the mixture for 10 hours. Distil off most of the ethanol, add 100 ml of water to the residue and strongly acidify the alkaline solution with hydrochloric acid. Cool, extract thrice with ether, dry the combined ether extracts, evaporate the solvent and recrystallise the residue from water or dilute ethanol. The yield of p-methoxyphenylacetic acid, m.p. 85–86 °C, is 26 g (63% overall). A further quantity of acid may be obtained by extracting the mother-liquors with ether.

p-Bromophenylacetic acid. Reflux a mixture of 50 g (0.25 mol) of p-bromoacetophenone (Expt 6.122), 12.8 g (0.4 mol) of sulphur and 30 ml (0.35 mol) of morpholine for 8 hours. Saponify the crude reaction product with 250 ml of 10 per cent ethanolic sodium hydroxide solution and work up as described for the p-methoxy acid. The yield of crude p-bromophenylacetic acid, m.p. 107–109 °C, is 25 g (46%). Recrystallisation from water gives the pure acid, m.p. 113–114 °C.
6.12.8 SOME METHODS FOR THE PROTECTION OF THE AROMATIC CARBONYL GROUP

The methods which are available for the protection of the aromatic carbonyl group are similar to those for the aliphatic and alicyclic analogues (Section 5.8.8, p. 623). It should be noted however, that when a cyclic acetal is used as the protecting group, a Birch reduction (Section 7.5) on the protected compound usually results in hydrogenolysis of the protecting acetal.

6.13 AROMATIC CARBOXYLIC ACIDS

This section is principally concerned with the synthesis of carboxylic acids in which the carboxyl group is directly attached to the aromatic nucleus. Several examples of the preparation of acids in which the carboxyl group is located in the side chain, i.e. aryl-substituted aliphatic acids, are included in Section 5.12.

2. The hydrolysis of nitriles (Expts 6.153 to 6.155).
3. Carboxylation of the aromatic ring system (Expts 6.156 to 6.158).

Methods for the protection of the aromatic carboxyl group are considered in Section 6.13.5.

SUMMARY OF RETROSYNTHETIC STRATEGIES

Functional group removal/interconversion (FGR/FGI) (methods 1 and 2)

\[
\begin{align*}
\text{C}=\text{N} & \rightleftharpoons \text{HO} \cdot \text{CO} \\
\begin{array}{c}
Z \quad \text{(TM)} \\
\end{array} & \rightleftharpoons \begin{array}{c}
\text{Me} \\
\end{array} \\
\text{OH} \\
\end{align*}
\]

Disconnection (methods 3 and 4)

\[
\begin{align*}
\begin{array}{c}
\text{HO} \cdot \text{CO} \\
\text{(TM)} \\
\end{array} & \longrightarrow \begin{array}{c}
Z \quad \text{(TM)} \\
\end{array} \\
\begin{array}{c}
\text{Z} \cdot \text{Ar} \cdot \text{MgX}(\text{Li}) \\
\text{when } Z = R, \text{ Hal} \\
\text{Z} \cdot \text{ArH when } Z = \text{OH} \\
\end{array} & \quad \text{[} + \text{HOCO (CO}_2\text{)]} \\
\text{RO} \cdot \text{CO} \\
\text{(TM)} & \rightleftharpoons \text{RO} \cdot \text{CO} \\
\text{NO}_2 & + \text{NO}_2 (\text{HNO}_3/\text{H}_2\text{SO}_4) \\
\end{align*}
\]
SPECTROSCOPIC FEATURES

The characteristic profile of the i.r. spectral region (2500–3300 cm\(^{-1}\)), corresponding to absorption arising from the intermolecular hydrogen bonding of the carboxyl group, is easily observed (p. 299). The frequency of absorption arising from the carboxyl group is a little lower than in aliphatic carboxylic acids owing to aromatic mesomeric interaction. The substitution pattern in the aromatic nucleus may be inferred from the longer wavelength region of the i.r. spectrum and may be confirmed by inspection of the p.m.r. spectrum. The latter will also show a low field signal from the acidic proton if the sample is dissolved in a solvent with which it does not undergo a deuterium exchange reaction (e.g. phenylacetic acid, Fig. 3.47). (The \(^{13}\)C-n.m.r. spectrum is given in Fig. 3.55.) The m.s. of ortho-substituted acids (and their derivatives) is discussed on p. 383, and analyses of fragmentation patterns of suitable compounds are included in some of the preparative examples below.

6.13.1 OXIDATIVE METHODS

The oxidation of an alkyl group attached to an aromatic system is a frequently used method for the preparation of the corresponding carboxylic acid.

\[ \text{Ar} \cdot \text{R} \xrightarrow{\text{O}} \text{Ar} \cdot \text{CO}_2\text{H} \]

The conversion can be accomplished most readily in the laboratory by using either a solution of sodium dichromate in concentrated sulphuric acid or aqueous potassium permanganate. The method is not applicable to those cases where activating groups are attached to the aromatic system, since these render the ring susceptible to oxidative cleavage. The use of acid dichromate is illustrated in Expt 6.149 by the oxidation of \( p \)-nitrotoluene and of \( p \)-xylene. The examples illustrating the use of potassium permanganate in Expt 6.150 are the oxidation of two isomeric chlorotoluenes and the three isomeric picolines (methylpyridines).

Diphenic acid (Expt 6.151) is obtained when phenanthrene is oxidised with 30 per cent hydrogen peroxide in glacial acetic acid solution at 85 °C. No phenanthraquinone is formed under these conditions (compare the oxidation of phenanthrene with acid dichromate, Expt 6.128); the reaction is essentially an oxidation by peracetic acid of the reactive 9,10-positions in phenanthrene.

Experiment 6.152 describes a synthesis of quinaldinic acid from quinaldine (2-methylquinoline). The method depends upon the reactive nature of the 2-methyl group in quinaldine which can readily be brominated using bromine in acetic acid. Hydrolysis of the resulting tribromo derivative by boiling with dilute sulphuric acid occurs smoothly to give the corresponding carboxylic acid in good yield.

The use of the haloform reaction for the conversion of methyl ketones into carboxylic acids (Sections 5.11.1, p. 667) is also applicable in the aromatic field. The conditions may be readily adapted from those described for the conversion of aliphatic methyl ketones into carboxylic acids (Expt 5.124).

**Experiment 6.149** \( p \)-NITROBENZOIC ACID

\[ p-O_2N \cdot C_6H_4 \cdot \text{Me} \xrightarrow{\text{Na}_2\text{Cr}_2\text{O}_7} \text{H}_2\text{SO}_4 \]  \( p-O_2N \cdot C_6H_4 \cdot \text{CO}_2\text{H} \]
Place 46 g (0.33 mol) of \(p\)-nitrotoluene, 136 g of sodium dichromate dihydrate and 300 ml of water in a 1-litre, two-necked round-bottomed flask equipped with an unsealed mechanical stirrer. By means of a dropping funnel, add 340 g (185 ml) of concentrated sulphuric acid during about 30 minutes to the well-stirred mixture. The heat of dilution of the acid causes the \(p\)-nitrotoluene to melt and oxidation takes place; if the reaction shows signs of becoming vigorous, the rate of addition must be reduced. When all the sulphuric acid has been introduced and the temperature of the mixture commences to fall, attach a reflux condenser to the flask, and heat to gentle boiling for half an hour. Cool and pour the reaction mixture into 400–500 ml of water. Filter the crude \(p\)-nitrobenzoic acid at the pump and wash it with about 200 ml of water. Transfer the solid to a 1-litre beaker, add about 200 ml of 5 per cent sulphuric acid (11 g or 6 ml of concentrated sulphuric acid added to 200 ml of water) and digest on a water bath, with agitation, in order to remove the chromium salts as completely as possible; allow to cool and filter again. Transfer the acid to a beaker, break up any lumps of material and treat it with 5 per cent sodium hydroxide solution until the liquid remains alkaline. The \(p\)-nitrobenzoic acid passes into solution, any unchanged \(p\)-nitrotoluene remains undissolved and chromium salts are converted into chromic hydroxide and/or sodium chromite. Add about 5 g of decolourising carbon, warm to about 50 °C with stirring for 5 minutes and filter with suction. Run the alkaline solution of sodium \(p\)-nitrobenzoate into about 450 ml of well-stirred 15 per cent sulphuric acid (74 g or 40 ml of concentrated sulphuric acid in 400 ml of water). Do not add the acid to the alkaline solution, for in this way the acid is liable to be contaminated by the sodium salt. Filter the purified acid at the pump, wash it thoroughly with cold water and dry it in the oven. The yield of \(p\)-nitrobenzoic acid, m.p. 237 °C, is 48 g (86%): this is sufficiently pure for most purposes. Upon recrystallisation from glacial acetic acid, the m.p. is raised to 239 °C.

The i.r. spectrum should be recorded and the absorptions of the functional groups assigned. The p.m.r. spectrum (DMSO-\(d_6\), TMS) is a good example of a case where the \(\Delta v\) value for the two pairs of aromatic protons approaches that of their coupling constant (p. 343); \(\delta\) 8.21 (d, 2H, ortho-H’s, to CO\(_2\)H), and 8.30 (d, 2H, ortho-H’s to NO\(_2\)). This spectrum should be compared with that of the \textit{meta} isomer, Expt 6.159.

Cognate preparation. \textit{Terephthalic acid}. Use 18 g (0.169 mol) of \(p\)-xylene in place of the \(p\)-nitrotoluene and proceed as above to the stage of isolation of the crude product. Wash this with 40 ml of water followed by 20 ml of ether and purify, isolate and dry the acid as detailed above for \(p\)-nitrobenzoic acid; the yield of colourless terephthalic acid is 12 g (44%); it sublimes without melting at 300 °C and is almost insoluble in water and ethanol.

\section{Experiment 6.150 \(o\)-CHLOROBENZOIC ACID}

\(o\)-Cl\(\cdot\text{C}_6\text{H}_4\cdot\text{Me} \xrightarrow{\text{KMnO}_4} o\)-Cl\(\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{H}\)

Place 1250 ml of water, 75 g of pure potassium permanganate and 50 g (0.4 mol) of \(o\)-chlorotoluene (Expt 6.71) in a 2.5-litre three-necked flask equipped with a sealed mechanical stirrer and reflux condenser. Stir the mixture and reflux gently until practically all the permanganate colour has
disappeared (about 2 hours). At this point add 37.5 g more of potassium permanganate and reflux the mixture again until the permanganate colour disappears (about 2 hours); the colour of the solution can easily be seen by removing the flame and stopping the refluxing. Finally, add a second 37.5 g (0.95 mol total) of potassium permanganate and continue refluxing until the permanganate colour has disappeared (about 2–4 hours) (1). Steam distil the mixture (Fig. 2.102) to remove unreacted o-chlorotoluene (about 12 g). Filter the hot contents of the flask from the manganese dioxide with suction (2) and wash with two 125-ml portions of hot water. Concentrate the filtrate to about 800 ml using a rotary evaporator (3), and precipitate the o-chlorobenzoic acid by cautiously adding 75 ml of concentrated hydrochloric acid with continual stirring. When cold, filter with suction, wash the acid with cold water and dry at 100 °C. The yield of o-chlorobenzoic acid, m.p. 138–139 °C, is 42 g (68%). Upon recrystallisation from hot water or from toluene (c. 4 ml per gram), the m.p. is raised to 139–140 °C.

The p.m.r. spectra (DMSO-d₆, TMS) of the three isomeric chlorobenzoic acids show the following signals for the aromatic protons: ortho isomer δ 6.8–8.00 (m, 4H); meta isomer δ 7.27–7.72 (m, 2H) and 7.80–8.2 (m, 2H); para isomer δ 7.56 (d, 2H, ortho-H’s to Cl) and 8.0 (d, 2H, ortho-H’s to CO₂H).

Notes. (1) A somewhat lower yield is obtained if all the potassium permanganate (150 g) is added all at once and, furthermore, the reaction may become violent. Addition in three portions results in a more controllable reaction.

(2) The addition of a Whatman filter tablet or of a little diatomaceous earth (Super Cel, etc.) assists in the filtration of the finely divided manganese dioxide.

(3) If the acid is precipitated before the solution is concentrated, the yield is considerably reduced (c. 25 g). If the concentrated solution is not clear, it may be clarified by the addition of 1 g of decolourising charcoal.

Cognate preparations. p-Chlorobenzoic acid. Proceed exactly as for o-chlorobenzoic acid. Use 1250 ml of water, 50 g (0.4 mol) of p-chlorotoluene (Expt 6.71) and 75 g, 37.5 g and 37.5 g (0.95 mol total) of potassium permanganate. When the oxidation is complete, steam distil the mixture to recover any unreacted p-chlorotoluene (3–4 g). Filter the reaction mixture from hydrated manganese dioxide and wash the precipitate with two 100 ml portions of water. Precipitate the p-chlorobenzoic acid in the filtrate (1) by the addition of 75 ml of concentrated hydrochloric acid. Filter the cold solution with suction, wash with cold water and dry in an oven at 100 °C. The yield of p-chlorobenzoic acid, m.p. 234–235 °C, is 55 g (89%). Recrystallisation from hot water raises the m.p. to 238–239 °C.

Note. (1) If the filtrate has a faint permanganate colour, add a few drops of sodium metabisulphite solution until the solution is colourless. In this case (compare o-chlorobenzoic acid) concentration of the solution before precipitation only increases the yield by about 1 g and may cause occlusion of inorganic salts.

Picolinic acid (pyridine-2-carboxylic acid). Equip a 3-litre three-necked flask with a thermometer, sealed stirrer unit and a reflux condenser (Liebig pattern with a wide inner tube). Place a solution of 100 g (106 ml, 1.08 mol) of 2-methylpyridine in 1 litre of water in the flask and heat to 70 °C on a water bath. Add 450 g (2.84 mol) of potassium permanganate in 10 equal portions through the condenser over a period of 3–4 hours; maintain the temperature at 70 °C for the first five additions and at 85–90 °C for the last five. Make each
successive addition of potassium permanganate only after the preceding amount is decolourised and wash it down with 20–25 ml of water. After the last charge of potassium permanganate is decolourised, raise the temperature to 95 °C, filter the hot reaction mixture with suction and wash the manganese dioxide cake on the filter with four 200 ml portions of hot water: allow each portion to soak into the cake without application of vacuum and finally suck dry before adding fresh wash water. Evaporate down the combined filtrate and washings to a volume of about 300 ml: allow to cool and adjust to a pH of 3.2 (the isoelectric point) using narrow-range indicator paper (about 125 ml of concentrated hydrochloric acid are required). Picolinic acid is very soluble in water (90 g in 100 ml of water at 9 °C) and therefore does not separate at this stage. Subject this aqueous acidic solution to continuous extraction with 1 litre of dichloromethane for 6 hours (Fig. 2.95). Dry the dichloromethane extract with anhydrous sodium sulphate, filter and remove the dichloromethane under reduced pressure on a rotary evaporator, removing the residual traces of dichloromethane as completely as possible. Transfer the solid to a vacuum desiccator and leave to dry. Place the powdered solid in the thimble of a large Soxhlet extraction apparatus (Fig. 2.97) with 1250 ml of benzene (CAUTION) in the flask assembled in an efficient fume cupboard (1). Continue the extraction until crystals of picolinic acid separate from the boiling solution. Stop the extraction, cool the benzene to 15 °C and filter to remove the first crop of picolinic acid. Return the benzene filtrate to the Soxhlet extraction flask and exhaustively extract the remainder of the product from the residue in the Soxhlet thimble. The combined yield of picolinic acid of m.p. 137–138 °C is 81 g (61%). The m.p. is unaffected by recrystallisation from ethanol.

Note. (1) The use of toluene as the extraction solution could be usefully explored in this case.

Nicotinic acid (pyridine-3-carboxylic acid). Dissolve 100 g (104.5 ml, 1.08 mol) of 3-methylpyridine (99% purity) in 1 litre of water and oxidise it with 450 g (2.84 mol) of potassium permanganate: follow the experimental details given under picolinic acid. Wash the manganese dioxide cake with four 500 ml portions of water; evaporate the combined filtrate and washings to about 1250 ml. Adjust the pH to 3.4 (the isoelectric point) with the aid of narrow-range indicator paper; 120–130 ml of concentrated hydrochloric acid are required. Allow to cool overnight, collect the voluminous precipitate of nicotinic acid by suction filtration, wash with three 50 ml portions of cold water and dry at 90–100 °C. Concentrate the filtrate to about 650 ml and cool slowly to 5 °C and so obtain a second crop of nicotinic acid: the purpose of the slow cooling is to reduce the contamination by potassium chloride. The first crop of acid weights 90 g and has a purity of about 90 per cent (1); the second crop weighs 10 g and the purity is about 80 per cent. Recrystallise from hot water (2) and dry at 100 °C; the yield of pure nicotinic acid, m.p. 235 °C, from 90 g of the crude acid is 67 g (51%). A further quantity may be obtained by concentrating the mother-liquor.

Notes. (1) The impurity is potassium chloride. The approximate acid content is determined by heating a weighed sample of the acid in a crucible gently at first and finally at a red heat until no trace of black residue remains, and weighing the white residual potassium chloride.
(2) The solubility of pure nicotinic acid in 1000 ml of water at 0, 40, 80 and 100°C is 1.0, 2.6, 8.2 and 12.7 g respectively.

**Isonicotinic acid** *(pyridine-4-carboxylic acid).* Use 100 g (104.5 ml, 1.08 mol) of 4-methylpyridine (98% purity) and oxidise it with 450 g (2.84 mol) of potassium permanganate; follow the experimental details given for *picolinic acid*. Evaporate the combined filtrate and washings to about 1500 ml and add concentrated hydrochloric acid until the pH is 3.6; isonicotinic acid precipitates. Heat to 90–95°C (not all the acid dissolves) and allow the mixture to crystallise slowly. Collect the crude isonicotinic acid by suction filtration, wash well with water and dry at 100°C. Concentrate the mother-liquor to about half the original volume and so obtain a second crop of acid. The first crop of acid weighs 85 g (64%) (99% pure) and the second crop weighs 7 g (80%, pure). Recrystallise from hot water: the resulting isonicotinic acid is pure and has a m.p. of 311°C (sealed tube).

The solubility of isonicotinic acid in 1000 ml of water at 0, 40, 80 and 100°C is 3, 9, 24 and 34 g respectively. The solubility is appreciably less in the presence of potassium chloride.

**Experiment 6.151 DIPHENIC ACID** *(Biphenyl-2,2'-dicarboxylic acid)*

![Diphenic acid reaction](image)

Equip a 3-litre three-necked flask with a sealed mechanical stirrer, a reflux condenser and a thermometer. Dissolve 89 g (0.5 mol) of pure phenanthrene (1) in 1 litre of glacial acetic acid in the flask and warm to 85°C on a water bath. Introduce 345 ml of 30 per cent hydrogen peroxide solution (4 mol) during 40 minutes [CAUTION: see Section 4.2.41, p. 439]; the temperature falls to about 80°C and some phenanthrene may precipitate. After the addition is complete, heat the mixture with stirring on a water bath for a further 3–4 hours. Reduce the volume of the solution to about half by distillation under reduced pressure with a rotary evaporator and allow to cool. Filter off the considerable amount of diphenic acid which crystallises out on cooling. Keep the filtrate and evaporate it almost to dryness under reduced pressure: extract the residue with 375 ml of 10 per cent sodium carbonate solution by warming on a water bath, boil the extract with a little decolourising carbon, filter and add dilute hydrochloric acid until the pH is 4.5 (use narrow-range indicator paper). Stir the solution with a further small amount of active charcoal and filter off the tarry material; cool the clear solution to 0°C and acidify with dilute hydrochloric acid. Collect the precipitate by suction filtration, wash with water and dry at 110°C. The total yield of crude diphenic acid, m.p. 228°C, is 83 g (69%). Recrystallisation from glacial acetic acid raises the m.p. to 230°C.

**Note.** (1) Technical phenanthrene may be purified as follows. Dissolve 500 g of technical 90 per cent phenanthrene in 3 litres of ethanol in a 4-litre flask on a steam bath and decant the hot solution from any insoluble material: collect the solid which crystallises upon cooling the solution. Dissolve 250 g of the crystallised product in
PRACTICAL

157°C.

6.13 PRACTICAL ORGANIC CHEMISTRY

The boiling solution add gradually 18 ml of an aqueous solution containing 15 g of chromium trioxide; then add slowly
7.5 ml of concentrated sulphuric acid from the dropping funnel. Reflux the solution for
15 minutes, and then pour it with vigorous stirring into 1225 ml of water in a 3-litre
round-bottomed flask. Filter when cold, wash with water and dry in the air. Distil the
product under reduced pressure (oil pump) using a short air condenser and collect the
phenanthrene at 148–149 °C/1 mmHg. Recrystallise the solidified distillate from
ethanol: 200–225 g of nearly white phenanthrene, m.p. 99 °C, are obtained.

Experiment 6.152 QUINALDINIC ACID (Quinoline-2-carboxylic acid)

\[
\begin{align*}
\text{Br}_2 & \rightarrow \\
\text{H}_2\text{SO}_4 & \rightarrow \\
\end{align*}
\]

Fit a 500-ml, two-necked round-bottomed flask with a reflux condenser and
dropping funnel. Place a mixture of 50 g (0.61 mol) of anhydrous, powdered
sodium acetate (Section 4.2.69, p. 464), 100 g of glacial acetic acid and 14 g
(0.1 mol) of pure 2-methylquinoline in the flask, and a solution of 48 g
(15.5 ml, 0.3 mol) of bromine (CAUTION) in 100 g of glacial acetic acid in the
dropping funnel. Heat the flask to 70 °C in a water bath, and add the bromine
solution during 10–15 minutes while keeping the mixture thoroughly shaken.
Remove the flask from the water bath, bring the solution to boiling for a few
minutes (until the separation of sodium bromide causes violent bumping)
and then heat for 30 minutes on a boiling water bath and allow to cool. Pour
the reaction mixture into 300 ml of ice-water, collect the precipitate by
suction filtration and wash thoroughly with water. The yield of crude
product, after drying at 100 °C, is 36 g (95%). Recrystallise from ethanol or
glacial acetic acid: the pure \( \omega \)-tribromoquinaldine has m.p. 128 °C.

Hydrolyse the \( \omega \)-tribromoquinaldine by boiling it under reflux with excess
of dilute (1:10) sulphuric acid until a test portion, on neutralisation, yields no
unchanged halogen compound. The quinaldinic acid is best isolated, via the
copper salt, in the following manner. Cool, nearly neutralise the solution and
add excess of copper(II) sulphate solution. Collect the pale green copper
quinaldinate by suction filtration and wash it well with cold water. Suspend
the copper salt in hot water and subject it to prolonged treatment with
hydrogen sulphide gas. Filter off the copper sulphide and evaporate the clear
filtrate to dryness on a water bath. Recrystallise the residual quinaldinic acid
from glacial acetic acid; it then melts at 157 °C. The yield is almost
quantitative.

6.13.2 THE HYDROLYSIS OF NITRILES

The hydrolysis of nitriles under either acidic or basic conditions, which has
already been discussed in Section 5.11.2, p. 671, for alkyl and aralkyl nitriles, is
equally applicable to the synthesis of aromatic carboxylic acids (Expt 6.153).
The aromatic nitriles are readily obtained by the Sandmeyer reaction (see
Section 6.7.1, p. 923).

In the preparation of 2-naphthoic acid (Expt 6.154) the preferred starting
material is 2-naphthylamine-1-sulphonic acid (see Section 6.5.4, p. 900). After
replacement of the amino by the cyano group using the Sandmeyer procedure, subsequent treatment with aqueous acid removes the sulphonic acid group (see Section 6.7.1, p. 924 and Section 6.9.2, p. 975) and hydrolyses the cyano group in one step.

The formation of a carboxyl group by hydrolysis of the corresponding nitrile constitutes the last step in an interesting multi-stage synthesis of homophthalic acid (Expt 6.155). The starting material is phthalic anhydride which is first converted into the cyclic imide, phthalimide (1), by treatment with aqueous ammonia, or more conveniently with urea. Reduction of phthalimide with a zinc–copper couple in the presence of alkali is the most convenient laboratory preparation of phthalide (3), although the latter can also be obtained by the direct reduction of phthalic anhydride.59 The immediate reduction product is the salt of o-hydroxymethylbenzoic acid (2); on acidification this gives the free acid which cyclises to the γ-lactone, phthalide (3). Nucleophilic attack of a cyanide ion on the methylene group in phthalide results in alkyl–oxygen fission of the lactone ring to yield o-cyanomethylbenzoic acid, which on hydrolysis yields homophthalic acid.

![Chemical Reaction Diagram]

**Experiment 6.153 o-TOLUIC ACID**

\[ o-\text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{CN} \xrightarrow{\text{A} \text{H}_2\text{O}^+ \text{ or B } \text{OH}} \ x \text{Me} \cdot \text{C}_6\text{H}_4 \cdot \text{CO}_2\text{H} \]

*Method A (acidic hydrolysis)*. Prepare o-tolunitrile, b.p. 94–96 °C/20 mmHg, from o-toluidine following the method given in Expt 6.76 under p-toluidine. Also prepare 600 g of 75 per cent sulphuric acid by adding 450 g (245 ml) of concentrated sulphuric acid cautiously, with stirring and cooling, to 150 ml of water. Place the latter in a 1-litre three-necked flask, equipped with a dropping funnel, a mechanical stirrer and reflux condenser. Heat the solution in an oil bath to about 150 °C, stir and add 220 g (1.88 mol) of o-tolunitrile during 2 hours. Continue the stirring for a further 2 hours while the temperature is maintained at 150–160 °C; finally raise the temperature to 190 °C and stir for another hour. Some crystalline solid will appear in the condenser at this stage. Allow the reaction mixture to cool, pour into ice-cold water and filter off the precipitated acid. Dissolve the crude acid in an excess of 10 per cent sodium hydroxide solution, filter off any insoluble material (probably o-toluamide, m.p. 141 °C) through a sintered glass funnel while still hot and acidify the filtrate with dilute sulphuric acid. Collect the o-toluic acid on a Buchner funnel, dry in the air and recrystallise from benzene [or better toluene (CAUTION) – fume cupboard]. The yield of pure o-toluic acid, m.p. 102–103 °C, is 200 g (78%).

*Method B (basic hydrolysis)*. Boil a mixture of 5 g of o-tolunitrile, 80 ml of 10 per cent aqueous sodium hydroxide solution and 15 ml of alcohol under a
reflux condenser; the alcohol is added to increase the rate of hydrolysis. The solution becomes clear after heating for about 1 hour, but continue the boiling for a total period of 1.5 hours to ensure complete hydrolysis. Detach the condenser and boil the solution for a few minutes in the open flask to remove dissolved ammonia and some of the alcohol (CAUTION). Cool, and add concentrated hydrochloric acid until precipitation of the o-toluic acid is complete. When cold, filter off the o-toluic acid with suction and wash with a little cold water. Recrystallise from benzene (or toluene). The yield of o-toluic acid, m.p. 102–103 °C, is 5 g (86%).

The p.m.r. spectrum (CDCl₃, TMS) shows signals at δ 2.65 (s, 3H, Me), 7.08–7.50 (m, 3H, C₄, 5, 6-H), 8.03 (m, 2H, ortho-H’s to CO₂H), and 11.69 (s, 1H, OH). This should be contrasted with the p.m.r. spectrum (TFA, TMS) of p-toluic acid (cognate preparation below) which shows signals at δ 2.47 (s, 3H, Me), 7.30 (d, 2H, ortho-H’s to Me), and 8.02 (d, 2H, ortho-H’s, to CO₂H); the hydroxyl proton is obscured by the TFA solvent. The m.s. of the isomers are similar, but with some differences in the RA of particular ions arising from the ortho effect (p. 383); the ortho isomer gives principal fragment ions at m/z 136 (M), 119 (M – OH), 118 (M – H₂O, base peak), 91 (M – CO₂H), 90 (118 – CO), and 65 (91 – C₂H₂).

Cognate preparations. p-Toluic acid may be similarly prepared by either Method A or Method B using p-tolunitrile (Expt 6.76). The spectral features are noted in the main preparation above.

1-Naphthoic acid (by Method A). In a 750-ml or 1-litre flask equipped with a reflux condenser, place 50 g (0.327 mol) of 1-naphthonitrile (Expt 6.168), 100 ml of glacial acetic acid, 100 ml of water and 100 ml of concentrated sulphuric acid. Heat in an oil bath at 115–120 °C for 1.5 hours: do not allow the temperature to rise above 120 °C as the 1-naphthoic acid formed tends to lose carbon dioxide at higher temperatures and the yield will be reduced. Dilute the cold reaction mixture, which contains much crystalline solid, with an equal volume of water and filter at the pump; if the product consists of large lumps, transfer it first to a glass mortar and thoroughly grind it to a fine paste. Wash with water until free from mineral acid. Dissolve the crude acid in dilute aqueous sodium carbonate solution, heat for a short time to separate the resinous impurities and filter the hot solution. Acidify the clear filtrate with a slight excess of dilute sulphuric acid and collect the voluminous precipitate of almost pure 1-naphthoic acid, wash until free from inorganic salts and dry at 100 °C. Recrystallise from toluene or from light petroleum (b.p. 80–100 °C). The yield of pure 1-naphthoic acid, m.p. 160–161 °C, is 50 g (89%).

Experiment 6.154 2-NAPHTHOIC ACID

Diazotise 122 g (0.5 mol) of 2-naphthylamine-1-sulphonic acid (1) as detailed under 2-bromonaphthalene in Expt 6.72. Prepare copper(i) cyanide from
62.5 g (0.25 mol) of copper(II) sulphate pentahydrate (Section 4.2.23, p. 429) and dissolve it in a solution of 32.5 g (0.5 mol) of potassium cyanide (CAUTION) in 250-ml of water contained in a 1-litre three-necked flask. Cool the potassium cuprocyanide solution in ice, stir mechanically and add the damp cake of the diazonium compound in small portions whilst maintaining the temperature at 5–8 °C. Nitrogen is soon evolved and a red precipitate forms gradually. Continue the stirring for about 10 hours in the cold, heat slowly to the boiling point, add 125 g of potassium chloride, stir and allow to stand. Collect the orange crystals which separate by suction filtration; recrystallise first from water and then from ethanol; dry at 100 °C. The product is almost pure potassium 2-cyanonaphthalene-1-sulphonate.

Transfer the product to a 1-litre round-bottomed flask, add a solution prepared from 200 ml of concentrated sulphuric acid and 200 g of crushed ice, and heat the mixture under reflux for 12 hours. Collect the 2-naphthoic acid formed (some of which sublimes from the reaction mixture) by suction filtration on a sintered glass funnel, wash well with water and dry at 100 °C; recrystallise from rectified spirit. The yield of 2-naphthoic acid, m.p. 184–185 °C, is 65 g (75%).

**Note.** (1) Tobias acid, available from Fluka AG Chemische Fabrik.

### Experiment 6.155 HOMOPHTHALIC ACID (o-Carboxyphenylacetic acid)

Phthalimide. **Method 1.** Place 100 g (0.675 mol) of phthalic anhydride and 105 ml of concentrated ammonia solution (d 0.88) in a 1-litre round-bottomed flask fitted with a wide air condenser (<10 mm in diameter). Heat on a sand bath, gradually at first until the mixture is in a state of quiet fusion and forms a homogeneous melt (the temperature reaches 300 °C in about 1.5–2 hours; all the water is evaporated during the first hour). Shake the flask occasionally during the heating and push down any material which sublimes into the condenser with a glass rod. Pour the contents of the flask while still hot into a porcelain basin, allow to cool and grind to a fine powder in a mortar. The phthalimide (95 g, 96%) is practically pure and melts at 233–234 °C. It may be recrystallised from ethanol, but the solubility is only slight (about 5%).

**Method 2.** Intimately mix 99 g (0.67 mol) of pure phthalic anhydride and 20 g
(0.33 mol) of urea, and place the mixture in a 1-litre, long-necked, round-bottomed flask. Heat the flask in an oil bath at 130–135 °C. When the contents have melted, effervescence commences and gradually increases in vigour: after 10–20 minutes, the mixture suddenly froths up to about three times the original volume (this is accompanied by a rise in temperature to 150–160 °C) and becomes almost solid. Remove the heat from beneath the bath and allow to cool. Add about 80 ml of water to disintegrate the solid in the flask, filter at the pump, wash with a little water and then dry at 100 °C. The yield of phthalimide, m.p. 233 °C (i.e., it is practically pure), is 86 g (87%). If desired, the phthalimide may be recrystallised from 1200 ml of industrial spirit; the first crop consists of 34 g of m.p. 234 °C, but further quantities may be recovered from the mother-liquor.

**Phthalide.** In a 1-litre three-necked flask stir 90 g (1.37 mol) of a high quality zinc powder to a thick paste with a solution of 0.5 g of crystallised copper(II) sulphate in 20 ml of water (this serves to activate the zinc), and then add 165 ml of 20 per cent sodium hydroxide solution. Cool the flask in an ice bath to 5 °C, stir the contents mechanically and add 73.5 g (0.5 mol) of phthalimide in small portions at such a rate that the temperature does not rise above 8 °C (about 30 minutes are required for the addition). Continue the stirring for half an hour, dilute with 200 ml of water, warm on a water bath until the evolution of ammonia ceases (about 3 hours) and concentrate to a volume of about 200 ml by distillation under reduced pressure (rotary evaporator). Filter, cool in ice and render the filtrate acid to Congo red paper with concentrated hydrochloric acid (about 75 ml are required). Much of the phthalide separates as an oil, but, in order to complete the lactonisation of the hydroxymethylbenzoic acid, boil for an hour: transfer while hot to a beaker. The oil solidifies on cooling to a hard red-brown cake. Leave overnight in an ice chest or refrigerator, and then filter at the pump. The crude phthalide contains much sodium chloride. Recrystallise it in 10 g portions from 750 ml of water: use the mother-liquor from the first crop for the recrystallisation of the subsequent portion. Filter each portion while hot, cool in ice below 5 °C, filter and wash with small quantities of ice-cold water. Dry in the air upon filter paper. The yield of phthalide (transparent plates), m.p. 72–73 °C, is 47 g (70%).

**o-Cyanomethylbenzoic acid.** This preparation must be conducted in an efficient fume cupboard. Into a 1-litre three-necked flask, provided with a mechanical stirrer and a thermometer, place 40 g (0.33 mol) of phthalide and 40 g (0.615 mol) of powdered potassium cyanide (CAUTION). Heat the stirred mixture to 180–190 °C (internal temperature) in an oil bath for 4–5 hours. Allow to cool, add 400 ml of distilled water and stir the mixture until all the solids are dissolved (about 1 hour). Filter off any unreacted phthalide. Add dilute hydrochloric acid (1:1) to the dark aqueous solution (CAUTION: hydrogen cyanide is evolved) until it becomes turbid (about 20 ml are required), and continue the addition until the solution is slightly acid: filter off any dark impurities which may separate. Neutralise the solution carefully with sodium hydrogen carbonate, add a few grams of decolourising carbon, stir the mixture for several minutes and filter. Acidify the nearly colourless filtrate with about 20 ml of concentrated hydrochloric acid, cool in ice and filter at the pump. The resulting o-cyanomethylbenzoic acid (36 g) melts at
114–115 °C and is satisfactory for most purposes. It may be crystallised from benzene or glacial acetic acid, but with considerable loss. See Section 4.2.17 for disposal of aqueous solutions containing alkaline cyanides.

**Homophthalic acid.** Place a mixture of 25 g (0.155 mol) of o-cyanomethyl benzoic acid and 25 g of 50 per cent sulphuric acid in a 100-ml flask, heat the mixture on a boiling water bath for 10–12 hours and then pour it into twice its volume of ice and water. Filter the precipitate at the pump and dry in the air. The yield of crude homophthalic acid is 21 g. Recrystallise by dissolving it in 500 ml of boiling water, add decolourising carbon, filter the hot solution through a hot water funnel and cool the filtrate in an ice bath: collect the acid and dry at 100 °C. The yield of practically colourless acid, m.p. 181 °C, is 17 g (61%). The melting point depends upon the rate of heating; immersion of the capillary in a bath at 170 °C gives a m.p. of 182–183 °C.

### 6.13.3 Carboxylation of the Aromatic Ring System

In general a phenol will undergo direct carboxylation of the nucleus when the dry sodium salt is heated under pressure with carbon dioxide (the Kolb–Schmidt reaction). Addition of the weakly electrophilic carbon dioxide is promoted by electron release from the oxyanionic site. With phenol itself the ultimate product is salicylic acid (o-hydroxybenzoic acid); predominantly ortho attack may be attributable to stabilisation of the transition state through chelation.

![Chemical reaction](image)

It is of interest to record that p-hydroxybenzoic acid may be prepared by the vigorous thermal rearrangement of potassium salicylate (Expt 6.157).

The carboxylation reaction is particularly facile with di- and tri-hydric phenols. Thus 2,4-dihydroxybenzoic acid (Expt 6.156) is readily obtained by passing carbon dioxide through a boiling aqueous solution of the potassium or sodium salt of resorcinol.

The standard carboxylation reaction of a Grignard reagent (Section 5.11.3, p. 673) is also applicable in the aromatic series. The similar carboxylation of organosodium or organolithium compounds is described in the preparation of p-toluic acid (Expt 6.158). The organosodium compound is prepared by the direct reaction of sodium metal with p-chlorotoluene; the organolithium compound is similarly obtained from p-bromotoluene and lithium metal. The preparation of m-chlorobenzoic acid (cognate preparation in Expt 6.158) illustrates an alternative preparation of the required organolithium compound by means of a transmetalation process between butyllithium and m-bromochlorotoluene.
Experiment 6.156 2,4-DIHYDROXYBENZOIC ACID (\(\beta\)-Resorcylic acid)

\[
1,3-(\text{HO})_2C_6H_4 + CO_2KHCO_3 \rightarrow 2,4-(\text{HO})_2C_6H_3 \cdot CO_2H
\]

Place a solution containing 40 g (0.364 mol) of resorcinol, 200 g of potassium hydrogen carbonate and 400 ml of water in a litre flask fitted with a reflux condenser and gas inlet tube. Heat gently on a steam bath for 4 hours; then reflux vigorously over a flame for 30 minutes while passing a rapid stream of carbon dioxide through the solution. Acidify the solution while still hot by adding 180 ml of concentrated hydrochloric acid from a separatory funnel with a long tube delivering acid to the bottom of the flask. Allow to cool to room temperature, chill in an ice bath and collect the crude \(\beta\)-resorcylic acid by filtration with suction. Recrystallise by boiling the crude acid with 180–200 ml of water in the presence of a little decolourising carbon, filter through a hot water funnel and cool in an ice–salt mixture with stirring. Collect and dry the pure \(\beta\)-resorcylic acid; the yield is 36 g (64%), m.p. 216–217 °C. The p.m.r. spectrum should be recorded and the aromatic region expanded to allow a correlation of coupling constants; assign the signals bearing in mind that \(J_{3,6} = 0\).

Experiment 6.157 \(p\)-HYDROXYBENZOIC ACID

Place 100 g (0.725 mol) of salicylic acid and 150 ml of water in a 20-cm porcelain dish and slowly stir in 60 g of potassium carbonate. Evaporate the solution on a steam bath to a thick, pasty solid; break this up into small pieces and dry at 105–110 °C for 2 hours. Finely grind the solid, dry for a further 2 hours at 105–110 °C and grind again to a fine powder. Transfer the powder (a mixture of potassium salicylate and potassium carbonate) to a 500-ml round-bottomed flask fitted with an air condenser set for downward distillation and immersed in an oil bath. Heat the oil bath to 240 °C and maintain this temperature for 90 minutes, stirring the solid occasionally with a glass rod; phenol formed in the reaction distils out of the mixture. When the reaction is complete (i), transfer the contents of the flask while still hot to a 2-litre flask containing 1 litre of hot water; rinse the reaction flask with several portions of the hot solution. Acidify with concentrated hydrochloric acid (c. 75 ml are required), heat nearly to boiling, add 5 g of decolourising carbon, filter, cool and collect the brown solid by suction filtration. Concentrate the filtrate to about 300 ml cool and collect a second crop of the acid. Dissolve the crude acid in 300 ml of hot water, boil for a few minutes with 5 g of decolourising carbon and filter. Cool the filtrate under the tap, filter the solid with suction, wash with 15 ml of cold water and dry. The yield of \(p\)-hydroxybenzoioc acid, m.p. 211–212 °C, is 40 g (40%). The p.m.r. spectrum should be recorded and interpreted.
Note. (1) This may be determined roughly by treating a small test portion with 3–4 ml of hot water and acidifying with concentrated hydrochloric acid; the absence of a precipitate in the warm solution indicates the essential completeness of the reaction. Salicylic acid is sparingly soluble and p-hydroxybenzoic acid is relatively soluble under these conditions.

**Experiment 6.158 p-TOLUIC ACID**

\[ p-\text{Me}\cdot C_6\text{H}_4X \xrightarrow{\text{Na} \text{ or Li}} p-\text{Me}\cdot C_6\text{H}_4\text{Na(Li)} \xrightarrow{(i) \text{CO}_2} p-\text{Me}\cdot C_6\text{H}_4\cdot \text{CO}_2\text{H} \]

*Method A (use of organosodium reagent).* Equip a 250-ml, three-necked round-bottomed flask with a reflux condenser carrying a pressure-equalising dropping funnel to which is attached a calcium chloride guard-tube, a sealed stirrer unit and a thermometer combined with a gas inlet tube to allow the air in the apparatus assembly to be displaced by nitrogen (cf. p. 85). Introduce 50 ml of dry light petroleum (b.p. 40–60 °C) and 4.6 g (0.2 mol) of sodium wire and pass a slow stream of nitrogen through the apparatus. Add 12.6 g (0.1 mol) of redistilled p-chlorotoluene (Expt 6.71) from the dropping funnel, while stirring vigorously, during 90 minutes: maintain the temperature at 25 °C and continue stirring for a further 2 hours. Pour the reaction mixture on to 200 g of crushed Cardice in the form of a slurry with 200 ml of dry ether contained in a large beaker. After 30–45 minutes, while some of the solid carbon dioxide still remains, add water cautiously to destroy the excess of sodium and to dissolve the sodium salt of the acid. Separate the aqueous layer, extract it once with 50 ml of ether and warm the aqueous solution on a boiling water bath to remove the dissolved solvent. Filter if necessary, and acidify the aqueous solution with dilute hydrochloric acid. Collect the precipitated acid by suction filtration, wash it with a little water and dry at 100 °C. The yield of p-toluic acid, m.p. 175–176 °C, is 9.8 g (72%).

*Method B (use of organolithium reagent).* Fit a 250-ml three-necked flask with a reflux condenser, protected with a calcium chloride guard-tube, a sealed mechanical stirrer and a dropping funnel combined with a T-connection to provide for the inlet of nitrogen.

Place 35 ml of anhydrous ether in the flask, displace the air by nitrogen and continue passing the nitrogen in a slow stream throughout the duration of the experiment. Introduce 1.90 g (0.274 mol) of lithium in the form of fine shavings (1) into the ether and start the stirrer. Place a solution of 21.5 g (0.125 mol) of p-bromotoluene (Expt 6.72) in 35 ml of ether in the dropping funnel. Run in about 1 ml of the solution into the stirred mixture. The ether in the flask soon becomes turbid; if the ether does not reflux within 10 minutes, immerse the flask in a beaker of warm water and remove it immediately refluxing commences. Add the remainder of the p-bromotoluene solution dropwise or at such a rate that the solvent reflexes continuously (60–90 minutes). Stir the mixture while refluxing gently (warm water bath) for a further 45–60 minutes; at the end of this period most of the lithium will have disappeared. Cool the reaction mixture in ice-water, dilute it with 50–60 ml of anhydrous ether and cool (with stirring) to about −50 °C with the aid of an acetone–Cardice bath. Pour the contents of the flask slowly and with stirring (use a long glass rod) on to 200 g of crushed Cardice in the form of a slurry with 200 ml of dry ether contained in a large beaker. Rinse the flask with a
little of the solid carbon dioxide–ether slurry and add the rinsings to the contents of the beaker. Allow the Cardice to evaporate (3–4 hours or preferably overnight). Add about 200 ml of water to the contents of the beaker; rinse the reaction flask with 10 ml of 10 per cent sodium hydroxide solution and pour the rinsings into the beaker. A white solid appears which dissolves upon stirring. (If most of the ether has evaporated on standing, add a further 50 ml.) Separate the two layers, extract the aqueous solution with 50 ml of ether (to remove traces of neutral products) and combine the extract with the ether layer. Shake the combined ethereal solutions with 10 per cent sodium hydroxide solution and add the alkaline extract to the aqueous layer. Warm the combined aqueous layers to 60–70 °C (water bath) to drive off the dissolved ether, then cool to about 5 °C and strongly acidify with hydrochloric acid. Collect the precipitated p-toluic acid by suction filtration and wash it with a little cold water. The yield of the crude acid, m.p. 174–176 °C, is 11.9 g (70%); recrystallisation from dilute alcohol gives pure p-toluic acid, m.p. 176–177 °C.

Evaporate the dried ethereal extract; the residue, m.p. 85–90 °C, weighs 3.3 g. Recrystallise it from alcohol: pure di-p-tolyl ketone, m.p. 95 °C, is obtained.

Note. (1) A convenient method of preparing the lithium shavings is as follows. Place a piece of lithium weighing about 3 g and slightly moist with paraffin oil on a dry surface (slate or tiles) and pound it with a clean hammer or 500-g weight into a thin sheet about 0.5 mm thick. Cut the sheet into thin strips about 2–3 mm wide and transfer it to a beaker containing anhydrous ether. Weigh out the quantity of lithium required under dry ether or paraffin oil. Dry each strip with filter paper, cut it by means of a pair of scissors into small pieces about 1 mm wide and allow the small pieces to fall directly into the anhydrous ether in the reaction flask. The lithium thus retains its bright lustre.

The lithium may also be pressed into wire of about 0.5 mm diameter; a rather sturdy press is necessary. The wire may be collected directly in sodium-dried ether.

**Cognate preparation. m-Chlorobenzoic acid.** Prepare a solution of butyllithium in anhydrous ether as follows.

Place 100 ml of sodium-dried ether in a 500-ml three-necked flask equipped as in Method A. Displace the air and maintain a slow stream of nitrogen throughout the experiment. Introduce 4.3 g (0.62 mol) of fine lithium shavings into the reaction flask. Place a solution of 34.5 g (26.5 ml, 0.25 mol) of butyl bromide (Expt 5.54) in 50 ml of anhydrous ether in the dropping funnel, start the stirrer and run in 1–2 ml of the solution into the reaction flask cooled to about −10 °C (Cardice–acetone bath). The reaction has commenced when bright spots appear on the lithium and the reaction mixture becomes slightly cloudy. Add the remainder of the butyl bromide solution during about 30 minutes while the internal temperature is maintained at about −10 °C. Then allow the reaction mixture to warm up to 0–10 °C during 1 hour (with stirring) in order to complete the formation of butyllithium (1).

Cool the solution of butyllithium to −35 °C in a Cardice–acetone bath and add, while stirring vigorously, a solution of 48 g of m-bromochlorobenzene (Expt 6.72) in 75 ml of anhydrous ether. Stir for 15 minutes and pour the mixture with stirring on to a large excess of solid carbon dioxide in the form of a Cardice–ether slurry contained in a large
beaker. Isolate the acid as detailed above for p-toluic acid and recrystallise it from hot water. The yield of m-chlorobenzoic acid, m.p. 150–151 °C, is 27 g.

Note. (1) If a clear solution of butyllithium is required for any purpose, it may be decanted through a glass wool plug as detailed under 2-phenylpyridine [Expt 8.32, Note (2)].

6.13.4 NUCLEAR NITRATION OF AROMATIC CARBOXYLIC ACIDS AND ESTERS

The carboxyl and alkoxy carbonyl groups exert an electron-withdrawing influence when attached to the aromatic ring system, and are thus deactivating and meta directing in electrophilic substitution reactions. Electrophilic substitution is illustrated by the nitration of methyl benzoate (Expt 6.159) and of benzoic acid and phenylacetic acid (Expt 6.160). In the former instance nitration is effected with 'mixed acid' at a temperature below 15 °C, conditions which effect monosubstitution. The resulting methyl m-nitrobenzoate may be hydrolysed to the corresponding nitro acid with aqueous alkali. Nitration of benzoic acid with a hot mixture of concentrated sulphuric acid and fuming nitric acid results in substitution in both meta positions to yield 3,5-dinitrobenzoic acid. Dinitration of phenylacetic acid is achieved using fuming nitric acid alone, the directive influence of the —CH₂-CO₂H group is to the ortho and para positions.

Experiment 6.159 m-NITROBENZOIC ACID

\[
\text{Ph}\cdot\text{CO}_2\text{Me} + \text{HNO}_3 + \text{H}_2\text{SO}_4 \quad \xrightarrow{\text{Heat}} \quad m\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{Me} \quad \xrightarrow{\text{OH}} \quad m\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{H}
\]

Methyl m-nitrobenzoate. In a 1-litre, round-bottomed three-necked flask, fitted with a mechanical stirrer and a thermometer, place 102 g (94 ml, 0.74 mol) of pure methyl benzoate (Expt 6.163). Prepare a mixture of 62.5 ml of concentrated sulphuric acid and 62.5 ml of concentrated nitric acid in a dropping funnel, cool the flask in an ice bath to 0–10 °C and then run in the nitrating mixture, with stirring, while maintaining the temperature of the reaction mixture between 5 and 15 °C; the addition requires about 1 hour. Continue the stirring for 15 minutes longer, and pour the mixture upon 700 g of crushed ice. Filter off the crude methyl m-nitrobenzoate at the pump and wash it with cold water. Transfer the solid to a 500-ml bolt-head flask and stir it with 100 ml of ice-cold methanol in order to remove a small amount of the ortho isomer and other impurities. Filter the cooled mixture with suction, wash it with 50 ml of ice-cold methanol and dry in the air. The practically colourless methyl m-nitrobenzoate weighs 115 g (84%) and melts at 75–76 °C; it is sufficiently pure for conversion into m-nitrobenzoic acid. The pure ester, m.p. 78 °C, may be obtained by recrystallisation from an equal weight of methanol.

Hydrolysis of methyl m-nitrobenzoate to m-nitrobenzoic acid. Place 90.5 g (0.5 mol) of methyl m-nitrobenzoate and a solution of 40 g of sodium hydroxide in 160 ml of water in a 1-litre round-bottomed flask equipped with a reflux condenser. Heat the mixture to boiling during 5–10 minutes or until the ester has disappeared. Dilute the reaction mixture with an equal volume of water. When cold pour the diluted reaction product, with vigorous stirring, into 125 ml of concentrated hydrochloric acid. Allow to cool to room
temperature, filter the crude acid at the pump and wash it with a little water. Upon drying at 100°C, the crude m-nitrobenzoic acid, which has a pale brownish colour, weighs 80 g (96%) and melts at 140°C. Recrystallisation from 1 per cent hydrochloric acid affords the pure acid, m.p. 141°C, as a pale cream solid; the loss of material is about 5 per cent.

The p.m.r. spectra of m-nitrobenzoic acid (CDCl₃ + TFA) and its ester (CDCl₃) should be recorded and the signals assigned appropriately.

Experiment 6.160 3,5-DINITROBENZOIC ACID

\[
\text{Ph CO}_2\text{H} + \text{HNO}_3 \xrightarrow{\text{H}_2\text{SO}_4} 3,5-(\text{NO}_2)\text{C}_6\text{H}_3\cdot\text{CO}_2\text{H}
\]

**CAUTION:** This preparation must be carried out in the fume cupboard since nitrous fumes are evolved.

Dissolve 50 g (0.41 mol) of pure benzoic acid in 230 ml of concentrated sulphuric acid in a litre flask equipped with a reflux condenser. Add 73 ml of fuming nitric acid (d 1.5) a few ml at a time (CAUTION). Shake the flask well and cool in ice-water during the addition; much heat is evolved and a clear yellow solution results. Add a few fragments of porous porcelain and heat the mixture gradually on a water bath to 100°C during 45 minutes. At 70–80°C the reaction may (and usually does) become vigorous; moderate, when necessary, by cooling the flask in cold water. Maintain the mixture at 100°C for 15 minutes with occasional shaking, and then transfer it to an oil bath at 100°C; raise the temperature to 130°C over 30 minutes and keep it at 130–140°C for 1 hour. Allow the flask to cool: crystals commence to separate at about 90°C. When cold, pour the reaction mixture into 3–4 litres of ice-water, filter the separated crystals, wash with water and dry. The yield of 3,5-dinitrobenzoic acid, m.p. 204°C, is 50 g (57%): this acid is pure enough for most purposes. Upon recrystallisation from 50 per cent alcohol (4.5 ml per gram), the m.p. is raised to 207°C.

**Cognate preparation. 2,4-Dinitrophenylacetic acid.** Place 25 g (0.184 mol) of phenylacetic acid (Expt 5.128) in a 500-ml round-bottomed flask, cool the latter in running water and add from a suitably supported dropping funnel 250 ml of fuming nitric acid, rather slowly at first and then more rapidly. The addition occupies about 15 minutes. Attach a reflux condenser to the flask and heat the mixture under reflux for 1 hour, and then carefully pour the cooled solution into 500 ml of cold water. When cold, filter the crude product at the pump and wash it with a little cold water: the resulting acid, after drying at 100°C, is almost pure (m.p. 181°C) and weighs 31 g. Recrystallise it from 300 ml of 20 per cent ethanol. Collect the first main crop (25 g), and allow the mother-liquor to stand overnight when a further 2 g of pure acid is obtained; dry at 100°C. The yield of pure 2,4-dinitrophenylacetic acid, m.p. 183°C, is 27 g (64%).

**6.13.5 SOME METHODS FOR THE PROTECTION OF THE CARBOXYL GROUP**

The esterification procedures suitable for the protection of aliphatic carboxylic acids (Section 5.11.8, p. 690) are equally applicable in the aromatic series. These methods for protection, and the methods for deprotection are exemplified under

6.14 AROMATIC CARBOXYLIC ACID DERIVATIVES

1. Acid halides (Expt 6.161).
3. Esters (Expts 6.163 to 6.166).

The structural interrelationships of these aromatic carboxylic acid derivatives and the retrosynthetic analyses that indicate the broad methods of synthesis are similar to the aliphatic analogues. The methods of preparation described in these sections are those which appear to work best in the aromatic field.

SPECTROSCOPIC FEATURES

All these derivatives show strong i.r. absorption arising from the stretching vibration of the carbonyl group. They may be distinguished from each other by inspection of the appropriate region for absorption arising from the carbonyl-bound halogen, acyloxy, alkoxyloxy, or amino groups (p. 296). The p.m.r. spectra provide predictable evidence for the pattern of aromatic substitution, for the structure of the alkyl group and for the presence of nitrogen-bound hydrogens. Suitable ortho-substituted compounds give expected fragmentation patterns in the m.s. (p. 383). Further descriptive analyses of the spectra of specific compounds are given in the preparative examples below.

6.14.1 ACID HALIDES

General methods for the preparation of acid halides from aliphatic carboxylic acids are described in Section 5.12.1, p. 692. Phosphorus pentachloride is the preferred chlorinating agent for aromatic acids which contain electron-withdrawing substituents, and which do not react readily with thionyl chloride. The preparation of both p-nitrobenzoyl chloride and 3,5-dinitrobenzoyl chloride is described in Expt 6.161. These particular acid chlorides are valuable reagents for the characterisation of aliphatic alcohols and simple phenols, with which they form crystalline esters (see Section 9.6.4, p. 1241 and Section 9.6.6, p. 1248).

Experiment 6.161 p-NITROBENZOYL CHLORIDE

\[ p\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{H} + \text{PCl}_5 \rightarrow p\text{-O}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{COCl} + \text{POCl}_3 + \text{HCl} \]

Mix 100 g (0.6 mol) of pure p-nitrobenzoic acid (Expt 6.149) and 126 g (0.6 mol) of pure phosphorus pentachloride in a 500-ml round-bottomed flask. Fit the flask with a calcium chloride guard-tube and connect the latter to a gas absorption device (e.g. Fig. 2.61). Heat the flask on a water bath, with occasional shaking, until the reaction commences and then for a further 30 minutes or until the vigorous evolution of hydrogen chloride has almost ceased: a pale yellow homogeneous liquid is formed. Attach a Claisen still-
head connected with a water-cooled condenser, and remove the phosphorus oxychloride (b.p. 107°C) at ordinary pressure either by heating in an oil bath gradually to 200–220°C or by heating in an air bath until the boiling point is about 150°C. Allow to cool, replace the water condenser by a short air-cooled condenser and distil the residual liquid under reduced pressure (water pump) (1). A small quantity of phosphorus oxychloride passes over first and the temperature rises rapidly to about 150°C/20 mmHg; change the receiver and collect the p-nitrobenzoyl chloride at 155°C/20 mmHg. Pour the product while still fluid into a small wide-mouthed bottle and allow it to solidify: this prevents any moisture in the air from decomposing more than the surface layer of acid chloride. The yield of p-nitrobenzoyl chloride (a yellow crystalline solid, m.p. 71°C) is 105 g (95%) and is pure enough for most purposes. A perfectly pure product, m.p. 73°C, is obtained by recrystallising from carbon tetrachloride.

Note. (1) Either an oil bath (maintained at 210–215°C for a pressure of 20 mmHg) or an air bath must be used. If the flask is heated with a free flame, superheating will occur leading to decomposition (sometimes violent) of the p-nitrobenzoyl chloride.

Cognate preparations. 3,5-Dinitrobenzoyl chloride. Place a mixture of 30 g (0.141 mol) of 3,5-dinitrobenzoic acid (Expt. 6.160) and 33 g (0.158 mol) of phosphorus pentachloride in a round-bottomed flask: fit a reflux condenser, and heat the mixture in an oil bath at 120–130°C for 75 minutes. Allow to cool. Remove the phosphorus oxychloride by distillation under reduced pressure (25°C/20 mmHg); raise the temperature of the bath to 110°C. The residual 3,5-dinitrobenzoyl chloride solidifies on cooling to a brown mass; the yield is quantitative. Recrystallise from carbon tetrachloride: the yield is 25 g (77%), m.p. 67–68°C, and this is satisfactory for most purposes. Further recrystallisation from a large volume of light petroleum, b.p. 40–60°C, gives a perfectly pure product, m.p. 69.5°C.

3,5-Dinitrobenzoyl chloride reacts readily with water and it should be kept in sealed tubes or under light petroleum. When required for the preparation of derivatives it is usually best prepared in small quantities from 3,5-dinitrobenzoic acid immediately before use.

2-Naphthoyl chloride. This compound may be prepared from 57.4 g (0.33 mol) of 2-naphthoic acid and 69 g (0.33 mol) of phosphorus pentachloride following the procedure described above for p-nitrobenzoyl chloride. After removing the phosphorus oxychloride by distillation, the product is collected as a fraction of b.p. 160–162°C/11 mmHg. This solidifies on cooling to a colourless solid, m.p. 51–52°C; The yield is 60 g (95%).

CAUTION: The preparation of o-nitrobenzoyl chloride, o-nitrophenoacetyl chloride and all o-nitroacid chlorides should not be attempted by the above methods: a violent explosion may occur upon distilling the product.

### 6.14.2 Acid Anhydrides

o-Dicarboxylic acids (e.g. phthalic acid) readily form intramolecular anhydrides on heating. In Expt. 6.162 the nitrination of phthalic anhydride to yield a mixture of the isomeric 3- and 4-nitrophthalic acids is described, which can be separated by fractional crystallisation from water. The 3-nitrophthalic acid is efficiently
converted into the corresponding anhydride by warming with acetic anhydride and allowing the product to crystallise.

Phthalic anhydrides readily form hydrogen phthalate esters on reaction with alcohols; the derivatives from 3-nitrophthalic anhydride are usually nicely crystalline compounds and are hence suitable for purposes of characterisation. Hydrogen phthalate esters are also useful in appropriate instances for the resolution of racemic alcohols (Section 5.19).

**Experiment 6.162 3-NITROPHTHALIC ANHYDRIDE**

\[
\begin{align*}
\text{Phthalic anhydride} & \rightleftharpoons \text{3-Nitrophthalic anhydride} \\
& \rightleftharpoons \text{Hydrogen phthalate ester}
\end{align*}
\]

**CAUTIONARY NOTE:** The nitration of phthalic anhydride has been reported to proceed with explosive violence.\(^{60a}\) The reaction may be carried out with safety on the scale adopted here provided that strict attention to detail is paid to the rate of addition of the acid and to the control of the temperature. A modified procedure for use in large-scale nitration has been published.\(^{60b}\)

3-Nitrophthalic acid. Equip a 500-ml, three-necked round-bottomed flask, supported on a water bath, with a dropping funnel, a thermometer and a stirrer supported in the central (open) neck connected by means of a flexible drive to a stirrer motor. The latter should not be sited near the open neck since the nitrous fumes evolved in the subsequent reaction may otherwise cause damage. Place 100 g (0.675 mol) of technical phthalic anhydride and 100 ml of concentrated sulphuric acid in the flask and heat it until the temperature of the mixture rises to 80°C. Remove the water bath, and add a mixture of 42 ml of fuming nitric acid (d 1.5) and 30 ml of concentrated sulphuric acid slowly from the dropping funnel at such a rate as to maintain the temperature of the stirred mixture at 100–110°C (about 1 hour). Then add 180 ml of concentrated nitric acid (d 1.42) as rapidly as possible without causing the temperature to rise above 110°C. Heat the mixture on the water bath, with stirring, for 2 hours. Allow the reaction mixture to stand overnight and then pour it into 300 ml of water contained in a 2-litre beaker. Cool and filter the mixture of 3- and 4-nitrophthalic acids through a sintered glass funnel. Return the wet cake of acids to the rinsed-out beaker and stir it thoroughly with 40 ml of water, which dissolves a large amount of the 4-nitrophthalic acid (1). Filter again at the pump and dissolve the solid in 40–60 ml of boiling water; filter the hot solution and stir until crystallisation
commences and then leave overnight until crystallisation is complete. Filter again with suction and dry upon filter paper. The yield of crude 3-nitrophthalic acid, m.p. 208–210°C (sealed tube), is 44 g. Recrystallisation from about 100 ml of boiling water (2) gives about 36 g (25%) of the pure acid, m.p. 216–218°C (sealed tube).

Notes. (1) The mother-liquors from the washings and recrystallisations are saved for the recovery of 4-nitrophthalic acid. The combined mother-liquors are concentrated to small bulk and the organic acids extracted into ether. Upon esterification of the residue after evaporation of the ether by the Fischer–Speier method (Section 5.12.3, p. 695), the 3-nitro acid forms the acid ester and may be removed by shaking the product with sodium carbonate solution, while the 4-nitrophthalic acid yields the neutral diester. Hydrolysis of the neutral ester gives the pure 4-nitrophthalic acid, m.p. 165°C. (2) The acid may also be recrystallised from glacial acetic acid.

3-Nitrophthalic anhydride. In a 100-ml round-bottomed flask fitted with a reflux condenser, place 21 g (0.1 mol) of 3-nitrophthalic acid and 20 g (18.5 ml, 0.2 mol) of redistilled acetic anhydride. Heat the mixture to gentle boiling until a clear solution is obtained, and then for about 10 minutes longer. Pour the hot mixture (fume cupboard) into a large porcelain dish and allow to cool. Grind the crystalline mass thoroughly in a mortar and filter at the pump through a sintered glass funnel. Return the crystals to the mortar, grind them with 15 ml of sodium-dried ether and filter. Again return the crystals to the mortar and wash once more with 15 ml of dry, alcohol-free ether. Dry in air for a short time, and then to constant weight at 100°C. The yield of 3-nitrophthalic anhydride, m.p. 163–164°C, is 17 g (88%). If the m.p. is unsatisfactory, recrystallise the anhydride from benzene or from benzene-light petroleum (b.p. 40–60°C).

6.14.3 ESTERS

Aromatic esters may be prepared by direct esterification methods similar to those already described for aliphatic esters (Section 5.12.3, p. 695). A large range of examples of simple alkyl esters of aromatic carboxylic acids is included in Expt 6.163. Corresponding esterification of a simple aliphatic acid (e.g. acetic acid) with benzyl alcohol is illustrated in Expt 5.142.

Methyl esters may be prepared by reaction of the aromatic carboxylic acid with diazomethane (cf. Section 4.2.25, p. 433) or, more conveniently, by reaction with a boron trifluoride–methanol reagent. The latter procedure is illustrated by the preparation of methyl m-chlorobenzoate and dimethyl terephthalate (Expt 6.164). t-Butyl esters may be prepared by conversion of the acid into an N-acylimidazole by reaction with N,N'-carboxyliimidazole, followed by reaction with t-butyl alcohol in the presence of DBU62 (Expt 6.165).

Esterification of aromatic carboxylic acids with phenols, however, cannot be accomplished by a direct esterification procedure and resort must be made to the greater reactivity exhibited by the acid chlorides. Reaction is usually carried out in dilute aqueous alkali (Schotten–Baumann conditions, Section 6.6.2, pp. 916 and 1248). The preparation of 2-naphthyl benzoate is a typical example of this procedure (Expt 6.166). The preparation of a carboxylic ester by a variant of the Grignard carbonylation route has been described.61 The arylmagnesium bromide is first prepared and added to an excess of diethyl carbonate, conditions which
minimise the possibility of further reaction of the Grignard reagent with the ester initially produced to form the tertiary alcohol.

\[
\text{Ar} \cdot \text{MgBr} + (\text{EtO})_2\text{CO} \rightarrow \text{Ar} \cdot \text{C} = \text{O} \cdot \text{MgX} \rightarrow \text{Ar} \cdot \text{CO}_2\text{Et}
\]

**Experiment 6.163 METHYL BENZOATE**

\[
\text{Ph} \cdot \text{CO}_2\text{H} + \text{MeOH} \xrightarrow{\text{H}^+} \text{Ph} \cdot \text{CO}_2\text{Me} + \text{H}_2\text{O}
\]

In a 500-ml round-bottomed flask place a mixture of 30 g (0.246 mol) of benzoic acid, 80 g (101 ml, 2.5 mol) of absolute methanol and 5 g (2.7 ml) of concentrated sulphuric acid. Add a few small chips of porous porcelain, attach a reflux condenser and boil the mixture gently for 4 hours (1). Distil off the excess of alcohol on a water bath (rotary evaporator) and allow to cool. Pour the residue into about 250 ml of water contained in a separatory funnel and rinse the flask with a few ml of water which are also poured into the separatory funnel. If, owing to the comparatively slight difference between the density of the ester and of water, difficulty is experienced in obtaining a sharp separation of the lower ester layer and water, add 10–15 ml of carbon tetrachloride (2) and shake the mixture in the funnel vigorously; upon standing, the heavy solution of methyl benzoate in the carbon tetrachloride separates sharply and rapidly at the bottom of the separatory funnel. Run off the lower layer carefully, reject the upper aqueous layer, return the methyl benzoate to the funnel and shake it with a strong solution of sodium hydrogen carbonate until all free acid is removed and no further evolution of carbon dioxide occurs. Wash once with water, and dry by pouring into a small dry conical flask containing about 5 g of magnesium sulphate. Stopper the flask, shake for about 5 minutes and allow to stand for at least half an hour with occasional shaking. Filter the methyl benzoate solution through a small fluted filter paper directly into a round-bottomed flask fitted with a still-head carrying a 360 °C thermometer and an air condenser. Add a few boiling chips and distil from an air bath; raise the temperature slowly at first until all carbon tetrachloride has passed over and then heat more strongly. Collect the methyl benzoate (a colourless liquid) at 198–200 °C. The yield is 31 g (92%).

**Notes.** (1) Slightly improved results may be obtained by increasing the time of heating.

(2) Alternatively, the ester may be extracted with two 50 ml portions of ether. The ethereal solution is washed with concentrated sodium hydrogen carbonate solution (handle the separatory funnel cautiously as carbon dioxide is evolved) until effervescence ceases, then with water, and dried over magnesium sulphate. The ether is removed by flash distillation and the residual ester distilled.

**Cognate preparations.** [The p.m.r. spectra (CDCl₃ or CCl₄, TMS) of the ethyl, propyl and butyl esters should be recorded and interpreted, since the signals corresponding to the protons of these alkyl groups, afford good examples of the \((N + 1)(M + 1)\) rule for multiplicity (p. 341).]

**Ethyl benzoate (sulphuric acid as a catalyst).** Use 30 g (0.246 mol) of benzoic
acid, 115 g (145 ml, 2.5 mol) of absolute ethanol and 5 g (2.7 ml) of concentrated sulphuric acid. Reflux the mixture for 4 hours and work up as for methyl benzoate. The yield of ethyl benzoate, b.p. 212–214°C, is 32 g (86%).

**Propyl benzoate.** Into a 500-ml round-bottomed flask place 30 g (0.246 mol) of benzoic acid, 30 g (37.5 ml, 0.5 mol) of propan-1-ol, 50 ml of sodium-dried toluene and 10 g (5.4 ml) of concentrated sulphuric acid. Reflux the mixture for 10 hours. Pour the reaction product into about 250 ml of water, and extract with ether. Wash the ethereal extract with saturated sodium hydrogen carbonate solution and then with water: dry over magnesium sulphate. Distil off the ether and some of the toluene through a fractionating column, and distil the residue from a Claisen flask. Collect the propyl benzoate at 229–230°C. The yield is 37 g (91%).

**Butyl benzoate.** Use 30 g (0.246 mol) of benzoic acid, 37 g (46 ml, 0.5 mol) of butan-1-ol, 50 ml of sodium-dried toluene and 10 g (5.4 ml) of concentrated sulphuric acid, and reflux the mixture for 12 hours. Work up the product as for propyl benzoate; after the ether and toluene have been removed with the aid of a rotary evaporator, distil the residue under reduced pressure. The yield of butyl benzoate, b.p. 119–120°C/11 mmHg, is 35 g (80%).

**Methyl salicylate.** Use 28 g (0.2 mol) of salicylic acid, 64 g (81 ml, 2 mol) of dry methanol and 8 ml of concentrated sulphuric acid. Reflux the mixture for at least 5 hours and work up as for methyl benzoate. Collect the pure methyl salicylate (a colourless oil of delightful fragrance, ‘oil of wintergreen’) at 221–224°C; the yield is 25 g (81%). The ester may also be distilled under reduced pressure; the b.p. is 115°C/20 mmHg and a 2°C fraction should be collected.

**Ethyl salicylate.** This colourless ester, b.p. 231–234°C, is similarly obtained in 75 per cent yield from salicylic acid, ethanol and sulphuric acid as catalyst. It is best to distil the ester under reduced pressure; the boiling points under various pressures are given in Table 2.10.

**Methyl cinnamate.** Use 59 g (0.4 mol) of cinnamic acid (Expt 6.138), 128 g (162 ml, 4 mol) of absolute methanol and 6 ml of concentrated sulphuric acid; reflux the mixture for 5 hours. Remove excess methanol, pour the residue into about 500 ml of water and add 300 ml of ether. Separate, wash and dry the ether solution in the usual way. Remove the ether on a rotary evaporator; the residue crystallises on cooling, yielding 58 g (90%) of methyl cinnamate, m.p. 33–34°C. To obtain a pure specimen, m.p. 36°C, dissolve a sample in the minimum of methanol maintained at 30°C in a water bath, and add water slowly from a dropping pipette with stirring until the oily ester just begins to separate. Seed the solution and transfer rapidly to an ice bath with a glass rod, scratching the sides of the vessel vigorously with a glass rod. Filter the resulting colourless needles rapidly.

**Ethyl nicotinate** (*ethyl pyridine-3-carboxylate*). Reflux a mixture of 37 g (0.3 mol) pure nicotinic acid (Expt 6.150), 92 g (115 ml, 2 mol) of absolute ethanol and 90 g (50 ml) of concentrated sulphuric acid on a steam bath. Cool the solution and pour it slowly and with stirring on to 200 g of crushed ice. Add sufficient ammonia solution to render the resulting solution strongly alkaline: generally, some ester separates as an oil but most of it remains dissolved in the alkaline solution. Extract the mixture with five 25 ml portions

1078
of ether, dry the combined ethereal extracts over magnesium sulphate, remove the ether by flash distillation and distil the residue under reduced pressure. The ethyl nicotinate distils at 117–118 °C/16 mmHg; the yield is 32 g (71%). The boiling point under atmospheric pressure is 222–224 °C.

Experiment 6.164 METHYL m-CHLOROBENZOATE

\[ m-\text{Cl} \cdot \text{C}_6\text{H}_4 \cdot \text{CO}_2\text{H} \xrightarrow{\text{BF}_3/\text{Me}_2\text{CO}_2\text{H}} m-\text{Cl} \cdot \text{C}_6\text{H}_4 \cdot \text{CO}_2\text{Me} \]

Place 9.4 g (0.06 mol) of \( m \)-chlorobenzoic acid and 66 ml (0.12 mol) of boron trifluoride–methanol complex (14% w/v of BF₃; Section 4.2.8, p. 421) in a 250-ml round-bottomed flask. Heat the mixture under reflux on an oil bath for 2 hours, cool and pour into about 250 ml of saturated sodium hydrogen carbonate solution. Extract the organic product with three 50 ml portions of ether, dry the ethereal extract over magnesium sulphate and evaporate on a rotary evaporator. Distil the residue under reduced pressure and collect the methyl \( m \)-chlorobenzoate as a colourless liquid of b.p. 63 °C/3 mmHg; the yield is 9.3 g (91%).

Cognate preparation. Dimethyl terephthalate. Use 9.97 g (0.06 mol) of terephthalic acid, 132 ml of boron trifluoride–methanol complex (14% w/v) and 100 ml of dry methanol (1) and heat the mixture under reflux for 6 hours. Cool the reaction mixture and pour into excess (500 ml) of saturated sodium hydrogen carbonate solution. Filter the precipitated dicarboxylic ester under suction and recrystallise from methanol. The yield is 9.8 g (84%); m.p. 139–140 °C. The p.m.r. spectrum (CDCl₃, TMS) of this ester should be recorded and compared with those of the ortho and meta isomers. It should be noted that dimethyl terephthalate gives an \( A_4 \) pattern for the aromatic protons, the ortho isomer gives an \( A_3B_2 \) splitting pattern, and the meta isomer shows signals at \( \delta \) 7.50 (t, 1H, \( C_5^-H \)), 8.19 (d of d, 2H, \( C_4,6^-H \)) and 8.63 (t, 1H, \( C_2^-H \)) for the aromatic region of the spectrum.

Note. (1) Additional methanol is used in this case because of the low solubility of the di-acid and di-ester. Dry the methanol by distillation from magnesium (Section 4.1.8).

Experiment 6.165 t-BUTYL o-CHLOROBENZOATE

\[ \text{N}, \text{N}'-\text{Carbonyldiimidazole (1.65 g, 10 mmol) was added to a solution of o-} \]

\( \text{chlorobenzoic acid (1.57 g, 10 mmol) in dimethylformamide (10 ml) held under nitrogen, and the mixture was stirred for 1 hour at 40 °C. t-Butyl alcohol (1.48 g, 20 mmol) and DBU (1,8-diazabicyclo[5.4.0]undec-7-ene, 1.52 g, 10 mmol) were added and the mixture stood for 24 hours at 40 °C. Ether (100 ml) was then added, and the solution was washed with 10 per cent hydrochloric acid (20 ml), water (20 ml), aqueous potassium hydrogen carbonate (20 ml) and dried over anhydrous sodium sulphate. The solvent} \]
was removed and the oily residue distilled in vacuo to yield the ester (1.80 g, 85%), b.p. 135–140 °C/2 mmHg.

Experiment 6.166 2-NAPHTHYL BENZOATE

\[ 2\text{-C}_9\text{H}_5\text{OH} + \text{Ph\textcdot COCl} \xrightarrow{\text{NaOH}} 2\text{-C}_9\text{H}_5\text{O\textcdot CO\textcdot Ph} \]

Dissolve 7.2 g (0.05 mol) of 2-naphthol in 40 ml of 5 per cent sodium hydroxide solution in the cold; add a little more water if necessary. If the solution is highly coloured, add 1.5 g of decolourising carbon and filter the cold solution through a hardened filter paper. Pour the solution into a 100-ml conical flask and run in 7.0 g (5.8 ml, 0.05 mol) of benzoyl chloride. Stopper the flask and shake vigorously until the odour of benzoyl chloride has disappeared (10–15 minutes). Filter off the solid product on a Buchner funnel and wash it with a little cold water. Recrystallise it from about 60 ml of rectified spirit. Filter off the crystals which separate and dry them upon filter paper in the air. The yield of pure 2-naphthyl benzoate, m.p. 110 °C, is 11 g (89%).

6.14.4 ACID AMIDES

The preparation of toluamide (Expt 6.167) illustrates a useful procedure for the conversion of aromatic nitriles into acid amides with the aid of alkaline hydrogen peroxides (see discussion, Section 5.12.4, p. 708).

A further example of the preparation of amides by the ammonolysis of esters (cf. succinamide, Expt 5.155) is provided by the preparation of nicotinamide described in Expt 6.169 as a stage in the synthesis of 3-cyanopyridine.

Experiment 6.167 o-TOLUAMIDE

\[ 2\text{ o-Me\cdot C}_6\text{H}_4\cdot CN + 2\text{H}_2\text{O}_2 \xrightarrow{\text{OH}} 2\text{ o-Me\cdot C}_6\text{H}_4\cdot CO\cdot NH}_2 + \text{O}_2 \]

Place 29 g (0.25 mol) of o-tolunitrile (Expt 6.76), 130 ml of rectified spirit (1) and 10 ml of 25 per cent sodium hydroxide solution in a 1-litre bolt-necked flask. Set up the flask inside an aluminium bowl placed on a magnetic stirrer/hotplate unit which is supported on an adjustable laboratory jack. Insert into the flask a magnetic stirrer follower and a thermometer, start the stirrer motor and run in steadily 100 ml of 30 per cent hydrogen peroxide (CAUTION: see Section 4.2.41, p. 439 for precautions in the use of this reagent) (2). Oxygen is soon evolved and the mixture becomes warm; when the temperature approaches 40 °C add an ice-water slurry to the bowl in order that the temperature may be controlled within the 40–50 °C range. If the temperature tends to fall below this range it may be necessary to remove the cooling bath for a while. If the temperature is permitted to rise above 50 °C not only may the evolution of oxygen become so rapid as to cause the mixture to foam out of the flask, but also there is a danger of a violent explosion due to the ignition of an oxygen–ethanol vapour mixture (3). The exothermic reaction is complete after about 1 hour and then the temperature of the reaction mixture is kept at 50 °C for a further 3 hours by external heating. While still warm, add 5 per cent sulphuric acid until exactly neutral to litmus, and remove the ethanol and concentrate the residue to about
200 ml under reduced pressure using a rotary evaporator. Cool the residue to 20 °C, filter off the crystals at the pump and grind them to a paste with 30 ml of cold water in a mortar. Filter again, wash the product in the filter with a further 30 ml of water and dry in the air upon filter paper. The yield of o-toluamide (white crystals), m.p. 141 °C, is 30 g (90%). It may be recrystallised from hot water (1 g per ml), but the m.p. is unchanged.

Notes. (1) This volume of rectified spirit is required to produce a homogeneous solution.
(2) Difficultly hydrolysable nitriles, such as o-tolunitrile, require 30 per cent hydrogen peroxide. For most nitriles, however, both aromatic and aliphatic, an equivalent amount of 6–12 per cent hydrogen peroxide gives more satisfactory results; the above procedure must, however, be modified, according to the solubility of the nitriles and amides.
(3) To minimise this explosion danger, the reaction should be carried out in a well-ventilated fume cupboard in the absence of free flames; brisk stirring should be maintained throughout the exothermal stage.

6.15 AROMATIC NITRILES

1. The Sandmeyer procedure (see Expt 6.76).
2. The displacement of halogen by cyanide in an aryl halide (Expt 6.168).
3. The dehydration of amides and aldoximes (Expts 6.169 and 6.170).

SUMMARY OF RETROSYNTHETIC STRATEGIES

Functional group interconversion (method 3), e.g.

\[
\text{C} = \text{N} \quad \xrightarrow{(3)} \quad \begin{array}{c}
\text{H}_2\text{N} - \text{CO} \\
\text{or} \\
\text{H} - \text{NOH}
\end{array}
\]

Disconnection (methods 1 and 2), e.g.

\[
\text{C} = \text{N} \quad \xrightarrow{(1),(2)} \quad \begin{array}{c}
\overset{\ominus}{\text{CN}} \\
\equiv \text{PhN}^\oplus + \text{Cu}^\ominus \text{CN}
\end{array}
\]

The i.r. spectrum of benzonitrile is reproduced on p. 315. An illustrative spectral analysis for o- and p-tolunitrile is to be found under Expt 6.76.

6.15.1 THE SANDMEYER PROCEDURE

This valuable method for the preparation of aryl nitriles via the diazonium salt is discussed in Section 6.7.1, p. 922, and offers one of the most convenient routes for obtaining this class of compound. Experimental procedures are described in Expt 6.76.
6.15.2 THE DISPLACEMENT OF HALOGEN BY CYANIDE IN AN ARYL HALIDE

The ready replacement of the halogen in an alkyl or an aralkyl halide illustrated in Expt 5.157 by reaction with sodium or potassium cyanide is inapplicable in the case of aryl halides wherein the halogen is relatively inert. However, aryl bromides can be converted into nitriles in good yield by heating them for several hours at about 200 °C with copper(i) cyanide in the presence of pyridine (e.g. 1-naphthonitrile, Expt 6.168). This displacement may be achieved more readily by using dimethylformamide as the solvent, when reaction is usually completed in a few hours at reflux temperature.

Experiment 6.168 1-NAPHTHONITRILE

\[ 1-C_{10}H_7Br + CuCN_{\text{pyridine}} \rightarrow 1-C_{10}H_7\cdot CN \]

Place 80 g (54 ml, 0.386 mol) of redistilled 1-bromonaphthalene (Expt 6.125), 43 g (0.48 mol) of dry powdered copper(i) cyanide (Section 4.2.23, p. 429) and 36 g (37 ml, 0.457 mol) of dry pure pyridine (CAUTION) (1) (Section 4.1.29, p. 410) in a 250-ml round-bottomed flask fitted with a reflux condenser carrying a calcium chloride guard-tube, and heat the mixture in a metal bath at 215–225 °C for 15 hours (2). Pour the resulting dark brown solution while still hot (ca. 100 °C) into a litre flask containing 180 ml of concentrated ammonia solution (d 0.88) and 180 ml of water. Add 170 ml of toluene (CAUTION), stopper the flask and shake until all the lumps have disintegrated. When cold, add 100 ml of ether and filter through a sintered glass funnel (3). Add a further 50 ml of ether, transfer to a separatory funnel, separate the ether–toluene layer and wash it successively with: (i) four 125 ml portions of dilute ammonia solution (or until the organic layer is colourless); (ii) two 125 ml portions of dilute hydrochloric acid (1:1) (any precipitate which separates should be filtered off); (iii) two 125 ml portions of water; and (iv) two 125 ml portions of saturated sodium chloride solution. Finally, dry with magnesium sulphate, remove the ether and toluene by distillation on a rotary evaporator and distil the residue under reduced pressure (water pump) through a short fractionating column (compare Fig. 2.108). Collect the 1-naphthonitrile at 166–169 °C/18 mmHg as a colourless liquid. The yield is 50 g (84%).

Notes. (1) Much heat is liberated when pyridine is added to the mixture.
(2) The metal bath may be replaced by a bath of Silicone oil.
(3) The cuprammonium solution attacks filter paper.

6.15.3 THE DEHYDRATION OF AMIDES AND ALDOXIMES

Two examples of the dehydration of aromatic carboxamides using phosphorus pentoxide (cf. Section 5.13.3, p. 715) are given in Expt 6.169; these are the preparation of benzonitrile and 3-cyanopyridine.

The one-pot conversion of an aromatic carboxylic acid into the corresponding nitrile may be effected by reaction with ammonia in the presence of ethyl polyphosphate; the initial stage is the formation of the amide and this is followed by dehydration to the nitrile. The reaction has been used successfully with a range of aromatic carboxylic acids.
The indirect conversion of an aromatic aldehyde into the corresponding nitrile by dehydration of an oxime is illustrated by the synthesis of veratronitrile (Expt 6.170). The dehydrating agent is acetic anhydride which probably effects an initial acetylation of the oximino group followed by the elimination of acetic acid.

$$\text{Ar-CHO} \rightarrow \text{Ar-CH=NOH} \rightarrow \text{Ar-CH=N-O-CO-Me}$$

$$\text{Me\cdot CO}_2^\text{H} \xrightarrow{} \text{Ar-C≡N}$$

Conditions for effecting this conversion in one step have been described. The method involves heating a mixture of the aldehyde, hydroxylamine hydrochloride, sodium formate and formic acid; and the reaction is considered to proceed through the intermediate formation of an oxime formate.

**Experiment 6.169 BENZONITRILE**

$$\text{Ph\cdot CO\cdot NH}_2 \xrightarrow{P_2O_5} \text{Ph\cdot CN}$$

Place 45 g (0.37 mol) of benzamide (prepared from benzoyl chloride, cf. Expt 5.154) and 80 g (0.56 mol) of phosphorus pentoxide in a 250-ml round-bottomed flask (for exact experimental details on the handling and weighing out of phosphoric oxide, see isobutyronitrile, Expt 5.160). Mix well. Fit the flask with a Claisen distillation head (Fig. 2.13(c)) and distil under reduced pressure using a water pump with an air leak in the system so that a pressure of about 100 mmHg is attained. Heat the flask with a free flame until no more liquid distils: the nitrile will pass over at 126–130°C/100 mmHg. Wash the distillate with a little sodium carbonate solution, then with water, and dry over anhydrous calcium chloride or magnesium sulphate. Distil under normal pressure from a 50-ml flask: the benzonitrile passes over as a colourless liquid at 188–189°C. The yield is 28 g (74%). The i.r. spectrum of benzonitrile is shown in Fig. 3.39.

**Cognate preparation. 3-Cyanopyridine**

$$\text{CO}_2^\text{Et} \xrightarrow{\text{NH}_3} \text{CO\cdot NH}_2 \xrightarrow{P_2O_5} \text{CN}$$

**Nicotinamide.** Place 50 g (0.33 mol) of pure ethyl nicotinate (Expt 6.163) in a 350-ml flask and add 75 ml of cold concentrated aqueous ammonia saturated at 0°C. Keep the flask loosely stoppered for 18 hours, after which time the lower layer generally dissolves on shaking. Again saturate the solution with ammonia and allow it to stand for a further 4 hours. Repeat the saturation with ammonia; crystals of the amide commence to appear in the solution. Evaporate to dryness in a dish on the steam bath and dry at 120°C. The yield of nicotinamide, m.p. 130°C, is usually quantitative.

**3-Cyanopyridine.** Mix 24 g (0.2 mol) of powdered nicotinamide with 30 g of phosphoric oxide in a 150-ml round-bottomed flask by shaking. Immerse the
flask in a Silicone oil or fusible metal bath and arrange for distillation under a pressure of about 30 mmHg. Raise the temperature of the bath rapidly to 300 °C, then remove the bath and continue the heating with a free flame as long as a distillate is obtained. The nitrile crystallises on cooling to a snow-white solid. Redistil the solid at atmospheric pressure; practically all of it passes over at 201 °C and crystallises completely on cooling. The yield of 3-cyanopyridine, m.p. 49 °C, is 18 g (86%).

**General procedure for the direct conversion of a carboxylic acid into a nitrile.**

In a 50-ml three-necked flask are placed the carboxylic acid (0.01 mol), ethyl polyphosphate (6 g, PPE) and purified chloroform (5 ml). The mixture is cooled in an ice bath and the flask is connected to a balloon containing ammonia gas (≈3 litres). Air in the flask is replaced with ammonia and the mixture is mechanically stirred at 0–5 °C for 30 minutes and then at room temperature for one and a half hours whereupon the mixture turns very viscous (1). The balloon is removed and PPE (10 g) is added. The stirring is continued at 80 °C until the reaction is complete (usually within several hours); the dehydration is monitored by t.l.c. analysis (1). The mixture is stirred with aqueous 25 per cent sodium carbonate solution (150 ml), and then extracted with benzene (3 × 40 ml; **CAUTION**). The combined organic extracts are dried with sodium sulphate and evaporated. The residual oil is passed through a short column packed with silica gel (≈20 g) and the product eluted with benzene. The eluate is evaporated and the residue purified by short path distillation under reduced pressure (Kugelrohr apparatus).

**Note.** (1) Formation of the amide and the nitrile may be monitored by t.l.c. analysis.

**Experiment 6.170 VERATRONITRILE**

\[
\begin{align*}
\text{CHO} & \quad \xrightarrow{\text{NH}_2\text{OH}} \quad \text{CH} = \text{NOH} \\
\text{OMe} & \quad \xrightarrow{(\text{CH}_3\text{CO})_2\text{O}} \quad \text{CN} \\
\text{OMe} & \\
\end{align*}
\]

Dissolve 83 g (0.5 mol) of veratraldehyde (Expt 6.111) in 200 ml of warm rectified spirit in a 1-litre round-bottomed flask, and add a warm solution of 42 g (0.6 mol) of hydroxylamine hydrochloride in 50 ml of water. Mix thoroughly and run in a solution of 30 g of sodium hydroxide in 40 ml of water. Allow the mixture to stand for 2.5 hours, add 250 g of crushed ice and saturate the solution with carbon dioxide. The aldoxime separates as an oil: allow the mixture to stand for 12–24 hours in an ice chest or refrigerator when the oil will solidify. Filter off the crystalline aldoxime at the pump, wash well with cold water and dry in the air upon filter paper. The yield of veratraldoxime is 88 g (96%).

Into a 250-ml round-bottomed flask, fitted with a reflux air condenser, place 88 g of veratraldoxime and 100 g (92.5 ml) of redistilled acetic anhydride. Heat cautiously. Immediately the vigorous reaction commences, remove the flame. When the reaction subsides, boil the solution gently for 20 minutes and then pour it carefully with stirring into 300 ml of cold water.
Continue the stirring and cool in ice. Filter off the almost colourless crystals of veratronitrile and dry in the air. The resulting nitrile (60 g, 73.5% overall) is quite pure and melts at 67°C.

REFERENCES

49. Chapter 4, p. 469, see reference 28.
51. The editors are grateful to Dr R. Thomas, School of Chemistry, Thames Polytechnic, for the experimental details of the acetylation of ferrocene.
In this chapter some illustrative and interesting examples of ring-forming reactions leading to a selection of compounds having a range of ring sizes are discussed. The reactions are grouped under the following general procedures.

1. Intramolecular nucleophilic displacement reactions.
2. Intramolecular addition reactions of carbanions to a carbonyl group.
3. Insertion reactions.
4. Ring expansion and ring contraction reactions.
5. Reduction of aromatic compounds.
6. Cycloaddition reactions.

Procedures 1 and 2, in which the key reaction step is the formation of a carbon–carbon bond by an intramolecular process, provide important syntheses for ring sizes from three carbon atoms upwards. For a discussion of the kinetic and thermodynamic factors of these ring-forming reactions, and of the Baldwin Rules, the reader is referred to standard and specialised texts. These aspects are briefly referred to here in the context of particular syntheses. The insertion of a carbon species (procedure 3) into a carbon–carbon multiple bond uniquely provides a route to three-membered rings. Ring contraction and ring expansion reactions (procedure 4) are of value for the conversion of a readily available ring compound into a smaller or a larger ring that could be difficult to form by the other general methods. The reduction of aromatic compounds (procedure 5) is an important route to six-membered ring compounds. The examples of cycloaddition reactions (procedure 6), which illustrate the formation of four- and six-membered rings, involve the probable simultaneous formation of two carbon–carbon bonds under the influence of either thermal or photochemical conditions.

### 7.1 INTRAMOLECULAR NUCLEOPHILIC DISPLACEMENT REACTIONS

Three target molecules, namely, cyclopropyl methyl ketone (1), cyclobutane-carboxylic acid (2) and 3-benzylcyclobutanone (3), are used to illustrate appropriate retrosynthetic disconnection strategies that may be applied to devise suitable synthetic procedures for these compounds.
In the case of cyclopropyl methyl ketone, disconnection of either the 1,2- or 1,3-carbon–carbon bond of the cyclopropane ring results in the preferred charge distribution shown in (4), namely, the carbanion site is adjacent to the mesomerically stabilising carbonyl group, and the carbocation site may be viewed as a halide-carrying carbon. The reagent equivalent may therefore be 5-chloropentan-2-one.

\[
\begin{align*}
\text{O} & \text{Me} \quad \text{O} \quad \text{Me} \\
\text{(1)} & \quad \text{O} \quad \text{Me} \quad \text{Me} \\
\text{Cl} & \quad \text{(4)} \\
\end{align*}
\]

A retrosynthetic analysis for this latter compound (as shown below) shows that it could arise from ethylene oxide [reagent equivalent to (5), see Section 5.4.2, p. 533], and ethyl acetoacetate [reagent equivalent to (6), see Section 5.8.5, p. 619].

\[
\begin{align*}
\text{Cl} & \text{Me} \quad \text{O} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{H} \quad \text{Cl} \\
\text{Me} & \text{Me} \quad \text{Me} \quad \text{H} \quad \text{Cl} \\
\end{align*}
\]

The synthetic route (Expt 7.1) uses 2-acetylbutyrolactone, which is available commercially, as a convenient source of the required chloropentanone.

\[
\begin{align*}
\text{Me} & \quad \text{O} \quad \text{Me} \quad \text{O} \quad \text{Me} \quad \text{Me} \quad \text{Me} \\
\text{CO}_2\text{Et} & \quad \text{O} \quad \text{Me} \quad \text{O} \quad \text{Me} \quad \text{Me} \\
\text{HCl} & \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \\
\end{align*}
\]

The three-membered ring system, although the most highly strained of all the ring sizes, is readily formed in the cyclisation step. This arises from the fact that carbon–carbon bond formation in this case is an irreversible intramolecular S\text{N}2 displacement of halogen reaction, which is facilitated by the thermodynamically favourable \textit{anti}-periplanar conformation of the anion.

A retrosynthetic disconnection for cyclobutane-carboxylic acid (2) gives rise to a synthon having the charge distribution shown in (7).
The carbocation site may be seen to arise from a carbon-carrying halogen; the reagent equivalent of the carbanion site is a substituted malonic ester (see Section 5.11.6, p. 680). The reagent equivalent of the synthon could therefore reasonably be 3-bromopropylmalonic ester (8). Disconnection of this latter compound would yield, as reagent equivalents, 1,4-dibromobutane and malonic ester. Overall, therefore, the synthetic route may be seen to be the reaction of the dianion of malonic ester with an α,ω-dihalide, followed by hydrolysis and decarboxylation (Expt 7.2). This general strategy of ring synthesis is an important method which is applicable to ring sizes from three- to seven-membered rings, and is only limited by the availability of the appropriate dihalogen compounds.

The synthesis of 3-benzylcyclobutanone (3) is an illustration of an overall intramolecular alkylation of an acyl anion equivalent (Section 5.9). The α,ω-dihalide is 2-benzyl-1,3-dibromopropane, and the acyl anion equivalent is methyl methylthiomethyl sulphoxide; the product is 1-methylsulphinyl-1-methylthio-3-benzylcyclobutane which is obtained as a mixture of cis/trans isomers [(9) and (10)] (Expt 7.3). Aqueous acid hydrolysis in ethereal solution unmasks the carbonyl group. The possible mechanism of the reaction is via a Stevens-type rearrangement of the intermediate sulphur ylide, which may proceed in a pericyclic, radical or ion pair fashion.

**Experiment 7.1 CYCLOPROPYL METHYL KETONE**
5-Chloropentan-2-one. Assemble a distillation unit consisting of a 500-ml round-bottomed flask, a still-head, a large double surface condenser and a 250-ml receiving flask; cool the latter in an ice bath. Place into the flask 64 g (0.5 mol) of 2-acetylbutyrolactone, 90 ml of water and a few chips of broken porcelain, and then add 75 ml of concentrated hydrochloric acid and shake to mix. Heat the flask gently on a wire gauze until carbon dioxide is evolved briskly, and continue to heat cautiously until effervescence moderates and the contents of the flask become very dark (about 5–10 minutes). Then heat the flask strongly, preferably using two burners, so that rapid distillation ensues. When about 125 ml of distillate has been collected, add 75 ml of water steadily to the flask from a dropping funnel fitted to the still-head without interrupting the distillation. Collect a total of 200 ml of distillate; the entire distillation should be completed within about 75 minutes. Separate the pale yellow organic phase from the distillate, extract the aqueous phase with three 30 ml portions of ether and dry the combined organic layers over anhydrous calcium chloride. Remove the ether by distillation through a lagged 10 × 1.5 cm fractionating column packed with glass helices and distil the residue (1) under reduced pressure (water-pump). Collect the 5-chloropentan-2-one at 70–73 °C/20 mmHg, the yield is 45 g (75%).

Cyclopropyl methyl ketone. Place a solution of 20 g (0.5 mol) of sodium hydroxide in 20 ml of water in a 250-ml three-necked flask fitted with a dropping funnel, a reflux condenser and an efficient sealed stirrer unit. With vigorous stirring add 42 g (0.35 mol) of 5-chloropentan-2-one during 30 minutes; heat the flask gently during the addition so that the reaction mixture refluxes steadily. Continue heating under reflux for a further period of 1 hour, and then add slowly 45 ml of water and continue to reflux for 1 hour more, maintaining vigorous stirring throughout. Rearrange the condenser for distillation and distil out the reaction product until an organic layer no longer remains in the flask. Saturate the distillate with potassium carbonate, separate the organic phase and extract the aqueous phase with three 15 ml portions of ether. Dry the combined organic extracts over anhydrous calcium chloride and then over anhydrous calcium sulphate. Remove the ether by flash distillation through a lagged 10 × 1.5 cm fractionating column (glass helices), and continue distilling collecting the cyclopropyl methyl ketone as a fraction of b.p. 111–112 °C; the yield is 24 g (82%).

Note. (1) The crude residue may be used directly in the next stage.

**Experiment 7.2 CYCLOBUTANE-1,1-DICARBOXYLIC ACID AND CYCLOBUTANECARBOXYLIC ACID**

![Diagram]

Equip a 3-litre three-necked flask with a thermometer, a sealed mechanical stirrer and a double surface reflux condenser. It is important that all the
apparatus be thoroughly dry. Place 212 g (1.05 mol) of 1,3-dibromopropane (Expt 5.54) and 160 g (1 mol) of diethyl malonate (dried over anhydrous calcium sulphate) in the flask. Start the stirrer and add a solution of 46 g (2 mol) of sodium in 800 ml of super-dry ethanol (Section 4.1.9, p. 401) (1) down the condenser from a dropping funnel at such a rate that the temperature of the reaction mixture is maintained at 60–65 °C (50–60 minutes). When the addition is complete, allow the mixture to stand until the temperature falls to 50–55 °C, and then heat on a water bath until a few drops of the liquid when added to water are no longer alkaline to phenolphthalein (about 2 hours). Add sufficient water to dissolve the precipitate of sodium bromide, and remove the ethanol by distillation from a water bath. Steam distil the residue until all the diethyl cyclobutane-1,1-dicarboxylate and unchanged diethyl malonate are removed; collect about 4 litres of distillate during 9–10 hours. Extract the entire steam distillate with three 350 ml portions of ether; remove the ether from the combined extracts on a water bath (rotary evaporator). Reflux the residual liquid with a solution of 112 g of potassium hydroxide in 200 ml of ethanol for 2 hours. Distill off most of the ethanol and then evaporate the residue to dryness on a water bath (rotary evaporator). Dissolve the solid residue in 100 ml of hot water, and add concentrated hydrochloric acid (c. 80 ml) cautiously until the solution is just acid to litmus. Boil for a few minutes to remove carbon dioxide, render slightly alkaline with ammonia solution and add a slight excess of aqueous barium chloride to the boiling solution. Filter the hot solution to remove the barium malonate, cool the filtrate and render it strongly acid with concentrated hydrochloric acid (90–100 ml of acid: use Congo red paper). Extract the solution with four 250 ml portions of ether. Dry the combined extracts with anhydrous calcium chloride and remove the ether on a rotary evaporator. Spread the solid on a porous tile to remove oily impurities. The beautifully crystalline product (55 g, 38%) consists of pure cyclobutane-1,1-dicarboxylic acid, m.p. 158 °C. It may be recrystallised from hot ethyl acetate, but the m.p. is unchanged.

Place 30 g (0.28 mol) of cyclobutane-1,1-dicarboxylic acid in a 100-ml flask fitted with a still-head carrying a thermometer and leading to a cooled receiver flask via a short air condenser. Heat the flask in a Silicone oil bath at 160–170 °C until all effervescence ceases. Then raise the temperature of the bath to 210 °C; the cyclobutanecarboxylic acid passes over at 191–197 °C. Redistil the acid; the pure acid distils at 195–196 °C. The yield of cyclobutanecarboxylic acid (a colourless liquid) is 18 g (86%).

Note. (1) See Expt 5.95 for experimental details pertaining to the preparation of an ethanolic solution of sodium ethoxide.

**Experiment 7.3 3-BENZYL-CYCLOBUTANONE**

1-Methylsulphonyl-1-methylthio-3-benzylcyclobutane. To a solution of methyl methylthiomethyl sulphoxide (1.01 g, 8.15 mmol) in dry tetrahydrofuran (15 ml), is added a 1.44 mol/litre hexane solution (6 ml) of butyllithium (8.64 mmol) at −10 °C, and the mixture is stirred for 2 hours. After the addi-
tion of 2-benzyl-1,3-dibromopropane (1.03 g, 3.53 mmol) (1) at $-10^\circ$C, the mixture is stirred at $-10^\circ$C for 100 minutes and then at room temperature for 3 hours. Dichloromethane (100 ml) is added and the organic layer washed with water (30 ml). The aqueous layer is extracted with two 50 ml portions of dichloromethane. The organic layers are combined, washed with brine (20 ml) and dried (sodium sulphate). The solvents are evaporated and the residue subjected to column chromatography on silica gel using dichloromethane–ethyl acetate (9:1) as eluant to give the product as a pale yellow oil, 686 mg, 77 per cent; i.r. 1055, 1035 cm$^{-1}$. The product consists of two diastereoisomers in the ratio 2:1; the methyl signals of the major isomer appeared at $\delta$2.12 and 2.49, and of the minor isomer at $\delta$2.08 and 2.42.

3-Benzylcyclobutanone. The foregoing compound (2.70 g, 10.6 mmol) is dissolved in ether (140 ml), and 4.5 m sulphuric acid (2.8 ml) is added. The resulting mixture is stirred at room temperature for two days, and then heated under reflux for two days. After the addition of sodium hydrogen carbonate and magnesium sulphate, the mixture is stirred for a while and then the insoluble solid filtered off. The filtrate is concentrated and the residue subjected to column chromatography on silica gel using dichloromethane and hexane as eluants to give 3-benzylcyclobutanone as a colourless oil, 1.13 g, 66 per cent; i.r. (neat) 1785 cm$^{-1}$; p.m.r. (CDCl$_3$, TMS), $\delta$2.43–3.49 (m, 7H), and 7.21 (s, 5H).

Note. (1) 2-Benzyl-1,3-dibromopropane may be prepared from diethyl benzylmalonate (Expt 5.132), by lithium aluminium hydride reduction to give 2-benzylpropane-1,3-diol (for conditions compare Expt 5.38), and subsequent conversion into the dibromo derivative using the conditions described in Expt 5.54 as a guide.

### 7.2 Intramolecular Addition Reactions of Carbanions to a Carbonyl Group

The intramolecular carbon–carbon bond-forming reactions considered in this section are based on the aldol condensation (see Section 5.18.2, p. 799), the Claisen–Schmidt reaction (see Section 6.12.2, p. 1032), the Claisen ester condensation (see Section 5.14.3, p. 736), and the Claisen reaction (see Section 6.12.2, p. 1032). Since these carbonyl addition reactions are reversible, the methods of synthesis are most successful for the formation of the thermodynamically stable five- and six-membered ring systems. The preparation of the starting materials for some of these cyclisation reactions further illustrates the utility of the Michael reaction (see Section, 5.11.6, p. 681).

The first group of target molecules that are considered are the cyclic $\alpha,\beta$-unsaturated ketones, 3-methylcyclopent-2-enone (11), 3-methylcyclohex-2-enone (12), (+)-7a(S)-7,7a-dihydro-7a-methyl-1,5(6H)-indanedione (13), and tetraphenylcyclopentadienone (14).
In the case of (11), retrosynthetic functional group interconversion into the aldol followed by disconnection of the \( \alpha, \beta \)-bond gives the dipolar synthon (15), of which the reagent equivalent is the 1,4-dicarbonyl compound, hexane-2,5-dione (i.e. a retro-aldol condensation). The action of base on this diketone effects the forward aldol reaction followed by spontaneous dehydration (see Expt 7.4 for formulation).

A similar retrosynthetic analysis for (12), gives the 1,5-diketone, heptane-2,6-dione. Disconnection on this diketone, similar to those described in Section 5.9 for 1,2- to 1,4-diketones, would lead to a number of possible methods of synthesis. In the synthesis described in Expt 7.5, 3,5-diethoxycarbonylheptane-2,6-dione (ethyl methylenebisacetooacetate) (16) is formed from formaldehyde (as paraformaldehyde) and ethyl acetoacetate in the presence of piperidine (Knoevenagel/Michael reactions) (cf. the synthesis of pyridines, Expt 8.29). Cyclisation of (16) is effected on heating in the presence of base to give 4,6-diethoxycarbonyl-3-methylcyclohex-2-enone (17). Both ethoxycarbonyl groups are removed when the diester is heated for some time with aqueous acid, forming 3-methylcyclohex-2-enone (12). The further reaction of this compound with a Grignard reagent, which proceeds by 1,4-conjugate addition to the enone system, gives a 3-alkyl-3-methylcyclohexanone (18).

The chiral target molecule (13) is of particular interest. Setting aside asymmetric aspects of the reaction, a retrosynthetic analysis, similar to the cases above, is as follows.
The forward synthetic sequence would therefore involve the Michael reaction of 2-methylcyclopentane-1,3-dione with methyl vinyl ketone to give (20), followed by cyclisation to the hydroxyketone (19), and then dehydration to the target molecule (13a). The overall process of addition and cyclisation is known as the Robinson annelation reaction. In this preparative example (Expt 7.6) the methyl vinyl ketone is used directly under conditions which minimise its polymerisation; it should be noted, however, that many literature examples of the annelation reaction use Mannich bases or the corresponding methiodides as an in situ source of the \(\alpha,\beta\)-unsaturated carbonyl component (see Section 5.18.2, p. 801).

When the cyclisation step (20) to (19) is carried out in the presence of \((S)-(\ldots)\)-proline as the chiral inducing reagent, the bicyclic hydroxydiketone (22) is obtained in 93.4 per cent optical purity. It is suggested that proline adds to one of the carbonyl groups of the cyclopentanedione, and the formation of two hydrogen bonds as shown, imposes topographical rigidity on the conformation of the tricyclic transition state (21). The proline residue is thus trans-related to the angular methyl group, and carbon–carbon bond formation would then occur from the side opposite to the methyl group to give the cis-fused hydroxy diketone. Dehydration by azeotropic distillation in benzene then gives the target molecule (13) (Expt 7.6).

The disconnection of both carbon–carbon double bonds in tetraphenylcyclopentadienone (14) ('tetracyclone'), in the manner of the examples above, leads to recognition of benzil and dibenzyl ketone as the reagents for its synthesis.
This double Claisen–Schmidt reaction takes place under the influence of ethanolic potassium hydroxide (Expt 7.7) and presumably proceeds in the stepwise manner (cf. formulation in Section 6.12.2, p. 1032). The four aryl groups in tetracyclopentadienone effectively stabilise the cyclopentadienone system, which otherwise has only a transient existence and readily undergoes dimerisation by way of a diene–dienophile interaction (Diels–Alder reaction, Section 7.6). The use of tetracyclone as a dienophile for the preparation of 3,4,5,6-tetraphenyl-dihydrophthalic anhydride is noted on p. 1121.

The second group of cyclic compounds which illustrate the intramolecular carbanion addition to a carbonyl group, include 2-ethoxycarbonylcyclopentanone (23) and indane-1,3-dione (24).

Disconnection of the cyclic $\beta$-keto ester (23) gives the dipolar synthon (25), the reagent equivalent of which is diethyl adipate.

The synthesis may thus be seen to be an intramolecular Claisen ester condensation, which is known as the Dieckmann reaction. The procedure is an important method for the synthesis of five- and six-membered ring systems, and the cyclic $\beta$-keto ester product may be converted into the corresponding cyclic ketone by hydrolysis followed by decarboxylation (ketonic hydrolysis, see Section 5.8.5, p. 619). The base catalyst used in Expt 7.8 is sodium ethoxide, but sodium hydride as a 50 per cent dispersion in oil is a recommended alternative.

A similar disconnection for indane-1,3-dione (24) gives the dipolar synthon (26), from which it may be inferred that the reagent equivalent could be $o$-ethoxycarbonylacetophenone.
The synthesis of this starting material may prove troublesome, but if an activating group (CO₂Et) is formally added to the methyl group, further disconnection leads to the recognition of diethyl phthalate and ethyl acetate as the reagent equivalents of the synthons (27) and (28) respectively.

\[
\begin{align*}
\text{O} & \quad \text{CO}_2\text{Et} \\
\text{O} & \quad \text{Et} \\
\implies & \\
\text{O} & \quad \text{CO}_2\text{Et} \\
\text{O} & \quad \text{Et}
\end{align*}
\]

(27)  (28)

The forward synthetic reaction (formulated in Expt 7.9) is thus an initial mixed Claisen ester condensation, followed by a Dieckmann cyclisation, hydrolysis and decarboxylation. Indane-1,3-dione is used for the synthesis of the trione, ninhydrin (Expt 5.99).

The radical reductive cyclisation of diesters to acyloins (see also Section 5.9.1, p. 628) is an important method of synthesis for ring sizes from four-membered upwards. The example selected here is 2-hydroxy-3-methylcyclopent-2-enone (‘corylone’) (29) (Expt 7.10), which is an important perfumery and flavouring material.\(^5\) In the first step (i), methyl acrylate is converted into its dimer with tris(cyclohexyl)phosphine in pyridine solution.\(^5\) Step (ii) is the protection of the double bond by conversion into the dimethylamino adduct. The acyloin reaction is step (iii), and the product is trapped as its bis(trimethylsilyl)ether. Finally, in step (iv), the protecting dimethylamino and trimethylsilyl groups are removed by passage down a column of silica gel.

\[
\begin{align*}
\text{MeO} & \quad \text{CH}_2 \\
\text{O} & \quad \text{CH}_2\text{OMe} \\
\implies & \\
\text{MeO} & \quad \text{CH}_2\text{OMe} \\
\text{O} & \quad \text{CH}_2\text{OMe}
\end{align*}
\]

The third group of cyclic compounds formed by intramolecular carbanion addition to the carbonyl group are the target molecules 5,5-dimethylcyclohexane-1,3-dione (dimedone, 30) and 3-methylcyclopentane-1,2,4-trione (31).
Disconnection of either of the carbonyl-carbon bonds to the common methylene group in dimedone gives the δ-keto ester (32) as the reagent equivalent. A further disconnection of this ester reveals the synthons (33) and (34), the reagent equivalents of which are 4-methylpent-3-en-2-one (mesityl oxide) and malonic ester. The overall synthesis (see Expt 7.11 for formulation) is thus a Michael reaction between these latter reagents followed by a Claisen condensation in the cyclisation step, and then hydrolysis and decarboxylation to remove the activating ethoxycarbonyl group originally sited in the malonic ester molecule.

Suitable retrosynthetic disconnections of 3-methylcyclopentane-1,2,4-trione may not be immediately obvious owing to the presence of the three carbonyl groups. However, disconnection in the manner shown gives the reagent equivalents diethyl oxalate and butan-2-one.

In practice the synthesis requires two molar equivalents of diester to one molar equivalent of ketone in the presence of sodium ethoxide.

The initial step is a Claisen condensation involving both the α-methyl and α'-methylene groups, followed by a Dieckmann-type cyclisation to form ethyl 4-methyl-2,3,5-trioxocyclopentylglyoxalate (35). When heated with hot aqueous
phosphoric acid the ester grouping is hydrolysed and this is followed by the overall loss of a molecule of oxalic acid, to yield finally the trione product (Expt 7.12).

Cyclobutanone is an important synthetic starting material (e.g. see Expt 5.41); recently a simple synthesis from readily available materials has been reported. The synthesis (Expt 7.13) involves the formation of 1,3-bis[bromomagnesio]propane and its further reaction with carbon dioxide to form the complex (36), which precipitates from solution thus simplifying the purification procedure. Although the overall yield is low (13%), this is compensated for by the cheapness of the reagents and the simplicity of the procedure.

Experiment 7.4 3-METHYLCYCLOPENT-2-ENONE

Dissolve 2.5 g of sodium hydroxide in 250 ml of water in a 500-ml two-necked flask fitted with a reflux condenser and a dropping funnel. Bring the solution to the boil, add rapidly from the dropping funnel 28.5 g (0.25 mol) of hexane-2,5-dione (Expt 5.104) and continue to boil steadily under reflux for exactly 15 minutes (1). Cool the resulting dark-brown solution rapidly in an ice-salt bath, saturate with sodium chloride and extract with one 100 ml and two 50 ml portions of ether. Wash the ether extract with three 5 ml portions of water, dry over anhydrous sodium sulphate and remove the ether on a rotary evaporator. Distil the residual dark oil under reduced pressure and collect the colourless 3-methylcyclopent-2-enone as a fraction of b.p. 74–76 °C/16 mmHg, \( n_D^0 \) 1.4818; yield 9.5 g (40%). The product thus obtained is pure enough for most purposes; when perfectly pure the refractive index is 1.4893. The product may darken on storage.

Note. (1) The reaction conditions are critical; excessive boiling or the use of more concentrated alkali increases the formation of tarry by-products.

Experiment 7.5 3-METHYLCYCLOHEX-2-ENONE
4,6-Diethoxycarbonyl-3-methylcyclohex-2-enone. Place 130 g (1.0 mol) of ethyl acetoacetate, 15.0 g (0.5 mol) of powdered paraformaldehyde and 5 g (5.8 ml) of piperidine in a 500-ml round-bottomed flask. Allow the reaction to proceed at room temperature; after a short period (about 5 minutes) the contents of the flask rapidly heat up and the solid paraformaldehyde begins to dissolve. Moderate the reaction as required by cooling in iced water. When the vigorous reaction is over and the reaction mixture is homogeneous (about 20 minutes) heat the mixture on a water bath for 1 hour. The flask now contains the crude product together with a little water formed in the reaction. The crude product may be used directly for conversion into 3-methylcyclohex-2-enone by acid hydrolysis as described below. If required, it may be purified and dried in the following way. Dissolve the crude material in 200 ml of dichloromethane in a separatory funnel and wash successively with two 100 ml portions of 2.5 M hydrochloric acid, then two 100 ml portions of saturated aqueous sodium hydrogen carbonate and two 200 ml portions of water. Dry the organic phase over anhydrous calcium sulphate and remove the solvent on a rotary evaporator. The yield of crude 4,6-diethoxycarbonyl-3-methylcyclohex-2-enone is 106.5 g (84%). This compound cannot be purified by vacuum distillation since extensive decomposition takes place. It is, however, pure enough for most purposes.

3-Methylcyclohex-2-enone. Dissolve the crude product from the previous preparation in a mixture of 300 ml of glacial acetic acid, 30 ml of concentrated sulphuric acid and 200 ml of water and boil the solution under reflux for 6 hours. Add a solution of 254 g of sodium hydroxide in 700 ml of water carefully and with cooling to the cooled reaction solution. Extract with three 150 ml portions of ether, dry the ethereal extract over anhydrous sodium sulphate and remove the ether on a rotary evaporator. Distil the residue under reduced pressure through a short fractionating column and collect the 3-methylcyclohex-2-enone as a fraction, b.p. 95°C/25 mmHg. The yield is 24 g (44%).

Conversion into 3-ethyl-3-methylcyclohexanone. Prepare a solution of ethylmagnesium iodide in 120 ml of ether from 18.7 g (0.77 mol) of dry magnesium turnings and 120 g (0.77 mol) of ethyl iodide in a 500-ml, three-necked round-bottomed flask equipped with a sealed stirrer unit, a pressure-equalising funnel and a reflux condenser. When all the magnesium has dissolved, clamp the flask in a cooling bath of Cardice--acetone and replace the condenser with a low-temperature-reading thermometer. When the temperature has fallen to −10°C, add 1.5 g (0.15 mol) of thoroughly dried copper(i) chloride (1). Then while maintaining the internal temperature of the reaction mixture between −10 and −5°C (2), and with rapid stirring add dropwise a solution of 55 g (0.50 mol) of 3-methylcyclohex-2-enone in 150 ml of ether. After all the ketone has been added, continue stirring for a further 2 hours at −5°C. Decompose the reaction complex by adding 150 ml of a cold saturated ammonium chloride solution, with continued stirring and cooling, followed by dilute hydrochloric acid to give a clear solution. Separate the ethereal layer and thoroughly extract the aqueous phase with six portions of ether. Dry the combined ethereal extracts with anhydrous calcium sulphate, remove the ether on a rotary evaporator and distil the residue under reduced pressure. Collect the 3-ethyl-3-methylcyclohexanone as a fraction, b.p. 97–98°C/
22 mmHg, \( n_D^2 = 1.4594 \); the yield is 48 g (68%). The product is sufficiently pure for most purposes; the semicarbazone has m.p. 181–182°C.

**Notes.** (1) Temperature control is important at this stage, otherwise the yield of product is considerably reduced.
(2) Careful temperature control is important, or the yield of product is reduced and considerable quantities of the by-product 1-methyl-3-ethyl-1,3-cyclohexadiene are produced.

**Experiment 7.6** (+)-(7aS)-7,7a-DIHYDRO-7a-METHYL-1,5(6H)-INDANEDIONE⁴

\[
\begin{align*}
\text{O} & \quad \text{Me} \\
\text{CH}_2 & \quad \text{Me}
\end{align*}
\]

2-methyl-2-(3-oxobutyl)cyclopentane-1,3-dione. To a suspension of 2-methylcyclopentane-1,3-dione (65 g) in demineralised water (136 ml) is added at once methyl vinyl ketone (96 ml), and the mixture stirred under nitrogen at 20 °C for 5 days. It is then extracted with benzene (CAUTION) and treated with sodium sulphate, charcoal and magnesium sulphate. After filtration, the solids are extracted with boiling benzene (100 ml). Evaporation in vacuo of the combined benzene extract gives the crude product (100.9 g). Fractional distillation gives the pure triketone (92.5 g, 87.6%) as a pale yellow oil; b.p. 100–109 °C/0.08–0.1 mmHg); i.r. 1770 (C=O) and 1725 cm⁻¹ (C=O); p.m.r. (CDCl₃, TMS) δ 1.12 (s, 3H, 2-Me), 2.22 (s, 3H, Me.CO), 2.82 (m, 4H, -CO·CH₂·CH₂·CO—).

(+)-(3aS, 7aS)-3a, 4, 7, 7a-Tetrahydro-3a-hydroxy-7a-methyl-1,5(6H)-indanedione. The foregoing triketone (1.82 g, 10 mmol) and (S)-(−)-proline (34.5 mg, 0.3 mmol) are stirred in anhydrous N,N-dimethylformamide (10 ml; distilled from calcium hydride) under argon for 20 hours. The brown-coloured reaction mixture is filtered, and the filtrate evaporated under high vacuum at 22 °C (bath temperature) to give 2.4 g of an oil. This is dissolved in 10 ml of ethyl acetate and filtered through 8.0 g of silica gel. The absorbent is eluted with 150 ml of ethyl acetate, and the solvent evaporated in vacuo to give 2.0 g of an oil, which crystallises on seeding. The crystalline mass is broken up and placed under high vacuum at 55 °C (bath temperature) for 1 hour to remove traces of dimethylformamide to give 1.82 g (100%) of crude product as a tan-coloured solid, \([\alpha]_D^{5} + 56.1° (c 1.0 \text{ in CHCl}_3)\). Recrystallisation from ether gives the analytically pure compound, m.p. 119–119.5 °C, \([\alpha]_D^{5} + 60.4° (c 1.06 \text{ in CHCl}_3)\); i.r. 3600 and 3350–3508 (OH), 1742 (5-ring C=O), and 1722 cm⁻¹ (6-ring C=O); p.m.r. (CDCl₃, TMS) δ 1.26 (s, 3H, 7a-Me), 2.63 (s, 2H, -CO·CH₂·COH), and 2.92 (s, 1H, OH).

**Dehydration to** (+)-(7aS)-7,7a-dihydro-7a-methyl-1,5(6H)-indanedione. The
above dextrorotatory ketol (1.79 g) obtained as above is refluxed in 0.01 M
toluene-p-sulphonic acid–benzene (15 ml) with stirring under nitrogen for 15
minutes. Water is removed from the azeotrope by a Dean and Stark water
separator filled with Linde Type 4A molecular sieves. After cooling to room
temperature, it is stirred with 1 M aqueous sodium hydrogen carbonate solu-
tion (0.3 ml) for 5 minutes, dried with magnesium sulphate, and filtered, and
the solids are rinsed with chloroform. The filtrate is evaporated in vacuo to
give 1.6 g (99.4%) of crude product as an oil, which crystallises rapidly on
seeding with an authentic sample, [α]$_D$$^+$ +322° (c 0.94 in C$_6$H$_6$), u.v. 233 nm
(ε 10 200). The quotient of 87.7 per cent optical yield and 92.4 per cent chem-
ical purity by u.v. represents 94.9 per cent optical yield.

A portion of 1.56 g of the crude crystalline product is broken up in a small
amount of ether on a coarse sintered funnel. Removal of this ether by suction
gives 1.11 g of a colourless crystalline product (70.2% yield based on the trike-
tone), m.p. 64–65.5 °C, [α]$_D$$^+$ +356° (c 0.99 in C$_6$H$_6$), u.v. 233 nm (ε 11 540).
This represents a chemically pure sample of 97 per cent purity. Recrystallisa-
tion from ether gives optically pure (+)-(7aS)-7,7a-dihydro-7a-methyl-
1,5(6H)-indandione, m.p. 66–66.5 °C, [α]$_D$$^+$ +367° (c 1.0 in C$_6$H$_6$) (1).

Note. (1) Physical constants for this compound, obtained by a chemical resolution
process, are: m.p. 66–66.5 °C, [α]$_D$$^+$ +362° (c 1.0 in C$_6$H$_6$), i.r. (CHCl$_3$) 1746 (5-mem-
bered ketone), 1665 cm$^{-1}$ (α,β-unsaturated ketone).

**Experiment 7.7 TETRAPHENYLCYCLOPENTADIENONE**

\[
\begin{align*}
\text{Ph}O + \text{Ph} \cdot \text{CH}_2 \rightarrow & \quad \text{KOH} \quad \text{EtOH} \\
\text{Ph}O + \text{Ph} \cdot \text{CH}_2 \\
\end{align*}
\]

Dissolve 4.2 g (0.02 mol) of benzil (Expt 6.143) and 4.2 g (0.02 mol) of dibenzyl
ketone (Expt 6.127) in 30 ml of hot absolute ethanol in a 100-ml round-
bottomed flask fitted with a reflux condenser. Heat the solution to near its
boiling point on a steam bath and then add in portions a solution of 0.6 g
(0.011 mol) of potassium hydroxide in 6 ml of absolute ethanol. Some foam-
ing may occur. Heat the reaction mixture under reflux for 15 minutes (1) and
cool to below 5 °C in an ice bath. Collect the dark crystalline product by fil-
tration with suction, wash with three 5 ml portions of rectified spirit and dry
in an oven at 50 °C. The tetraphenylcyclopentadienone has m.p. 217–220 °C
and is sufficiently pure for most purposes; the yield is 7.0 g (91%). Recrystal-
lise a portion from toluene–ethanol (1:1) to obtain the pure compound as
deep purple crystals, m.p. 219–200 °C; λ$_{max}$ 340 and 510 nm, ε 1.26 × 10$^3$ and
0.33 × 10$^3$ respectively.

Note. (1) In a modified procedure$^8$ using triethylene glycol as solvent and benzyltri-
methylammonium hydroxide (‘Triton B’) as the base catalyst, the reaction may be
completed in a very short time.
Experiment 7.8 2-ETHOXYCARBONYLCYCLOPENTANONE

\end{align*}
\]

Prepare 25 g (1.09 mol) of granulated sodium in a 1500-ml round-bottomed flask (Section 4.2.68, p. 462, Method 2). Cover the sodium with 625 ml of sodium-dried benzene (CAUTION); fit the flask with an efficient reflux condenser protected from the air by means of a calcium chloride guard-tube. Add 151.5 g (0.75 mol) of diethyl adipate (Expt 5.144) in one lot, followed by 1.5 ml of absolute ethanol. Warm the flask on a water bath until, after a few minutes, a vigorous reaction sets in and a cake of the sodio compound commences to separate. Keep the flask well shaken by hand during the whole of the initial reaction. After the spontaneous reaction has subsided, reflux the mixture on a water bath overnight, and then cool in ice. Decompose the product with ice and dilute hydrochloric acid (1:1); add the acid until Congo red paper is turned blue. Separate the benzene layer, and extract the aqueous layer with 100 ml of benzene. Wash the combined extracts with 100 ml of 5 per cent sodium carbonate solution and 150 ml of water; dry over magnesium sulphate. Remove the benzene on a rotary evaporator (fume cupboard), and fractionate the residue under reduced pressure. Collect the 2-ethoxycarbonylcyclopentanone at 108–111 °C/15 mmHg (95 g, 81%). Upon redistillation, the product boils at 102 °C/11 mmHg.

\end{align*}
\]

Place 125 g (106.5 ml, 0.563 mol) of diethyl phthalate and 25 g (1.09 mol) of sodium wire (Section 4.2.68, p. 462) in a 500-ml round-bottomed flask fitted with a reflux condenser and dropping funnel, each protected with a calcium chloride tube. Heat the flask on a steam bath and add a mixture of 122.5 g (136 ml, 1.39 mol) of dry ethyl acetate and 2.5 ml of absolute ethanol over a period of 90 minutes. Continue the heating for 6 hours, cool and add 50 ml of ether. Filter the sodium salt on a sintered glass funnel and wash by stirring with ethyl acetate; filter. Dissolve the sodium salt (96 g) in 1400 ml of hot water in a 3-litre beaker, cool the solution to 70 °C, stir vigorously and add 100 ml of sulphuric acid (3 parts of concentrated acid to 1 part of water). Cool the mixture to 15 °C in an ice bath, collect the indane-1,3-dione by suction filtration, wash with a little water and dry at 100 °C; the yield is 58 g (71%). Recrystallisation from a dioxane–benzene mixture by the addition of light petroleum (b.p. 80–100 °C) gives the pure compound, m.p. 130 °C.
Experiment 7.10 2-HYDROXY-3-METHYLCYCLOPENT-2-ENONE

\[ \text{MeO} \rightleftharpoons \text{CH}_2 \rightleftharpoons \text{MeO} \quad \text{OMe} \quad \text{Me}_2\text{NH} \]

\[ \text{MeO} \rightleftharpoons \text{CH}_2 \rightleftharpoons \text{MeO} \quad \text{OMe} \quad \text{OSiMe}_3 \quad \text{NMe}_2 \]

**Dimethyl 2-methylenepentanediolate.** Methyl acrylate (30.0 g, 349 mmol) (distilled immediately before use) and dry pyridine (30 ml, CAUTION) containing tris(cyclohexyl)phosphine-carbon disulphide complex (2.0 g, 6 mmol) (1) are refluxed under nitrogen for 16 hours. The deep red solution is cooled and the pyridine removed under reduced pressure. The residue is taken up in ether (400 ml) and the solution washed with aqueous 1 M hydrochloric acid (3 x 40 ml). The combined aqueous layers are extracted with ether (2 x 50 ml) and the combined organic layers washed with 1 M hydrochloric acid (30 ml), saturated brine (40 ml) and saturated aqueous sodium hydrogen carbonate (2 x 30 ml), dried over sodium sulphate and evaporated. Distillation of the oil gives dimethyl 2-methylenepentanediolate (23.8 g, 79%) as a liquid, b.p. 66–68 °C/1 mmHg; i.r. (thin film) 1738, 1715, 1635 cm⁻¹.

**Dimethyl 2-(dimethylaminomethyl)pentanediolate.** To a stirred solution of dimethylamine (28%) in anhydrous methanol (100 ml) held at 0 °C (ice bath), under nitrogen, is added, via a syringe, dimethyl 2-methylenepentanediolate (10.3 g, 60 mmol) in one portion. The solution is stirred for 4 hours, during which period the temperature must never exceed 5 °C. Removal of excess amine and methanol under reduced pressure gives a pale yellow oil, which is distilled under reduced pressure to give dimethyl 2-(dimethylaminomethyl)pentanediolate (12.8 g, 99%) as an oil b.p. 81–83 °C/0.4 mmHg; i.r. (thin film) 1735 cm⁻¹; p.m.r (CDCl₃, TMS) δ 1.8–3.0 (m, 7H), 2.22 (s, 6H), 3.67 (s, 3H) and 3.69 (s, 3H).

**3-(Dimethylaminomethyl)-1,2-bis(trimethylsilyloxy)-cyclopentene.** In a 500-ml three-necked flask, equipped with a ‘football’ stirrer, a reflux condenser and a 100-ml pressure-equalising dropping funnel (maintained under oxygen-free nitrogen), are added toluene (200 ml) (2) and sodium (4.0 g, 174 mmol). The toluene is brought to reflux on an oil bath (bath temperature 135 °C) and the mixture stirred until a fine suspension of sodium is produced. Dimethyl 2-(dimethylaminomethyl)pentanediolate (10.6 g, 48 mmol) and chlorotrimethylsilane (20.0 g, 184 mmol, CAUTION) (distilled from calcium hydride, under nitrogen, immediately prior to use) in dry toluene (80 ml) are added dropwise
over 2 hours. A dark purple precipitate appears within a few minutes of the ester being added. After heating and stirring for a further 12 hours the contents of the flask are cooled and filtered, under nitrogen, through a 76.2 mm number three sinter. The precipitate is washed with anhydrous light petroleum (3 \times 40 ml, b.p. 40–60 °C). The solvent is removed under reduced pressure to give a pale yellow oil that is purified by short-path distillation (bath temperature 85 °C at 0.1 mmHg) to give the bis-silyl ether (11.2 g, 78%); i.r. (CCl₄) 1700 cm⁻¹; p.m.r. (CDCl₃, TMS) δ 0.14 (s, 18H), 2.17 (s, 6H), 1.62–2.80 (m, 7H).

2-Hydroxy-3-methylcyclopent-2-enone. The bis-silyl ether (1.0 g, 3 mmol) is dissolved in anhydrous ether (50 ml) under nitrogen. The solution is added to a column of silica gel [150 g, 100–200 mesh (BDH)] [made in 2:1, light petroleum (b.p. 40–60 °C)/ether] over 15 minutes. The material is eluted with light petroleum–ether (2:1; 200 ml). Elution is halted for 6 hours; further elution after that time (1:1, light petroleum–ether) gives the ketone (0.26 g, 76%); i.r. (CHCl₃) 3500, 1710 and 1605 cm⁻¹; p.m.r. (CDCl₃, TMS) δ 2.00 (s, 3H), 2.41 (s, 4H) and 6.79 (broad s, 1H, removed by D₂O); m/z 112 (M, base peak), 83 (22%), 69 (44%), 55 (26%), 43 (27%) and 41 (39%).

Notes. (1) Pyridine was stored over potassium hydroxide and distilled immediately before use. The tris(cyclohexyl)phosphine–carbon disulphide complex is prepared by the method of K. Issleib and A. Brack. This involves the addition of carbon disulphide to an ethereal solution of tricyclohexylphosphine, the precipitate is washed with light petroleum (b.p. 50–60 °C), and recrystallised under a nitrogen atmosphere from either methanol, ethanol or dioxane; the complex has m.p. 118 °C.

(2) Toluene is distilled and the first 10 per cent and last 15 per cent are discarded. The distillate is refluxed over sodium for 24 hours, under nitrogen, before being distilled (under nitrogen) for use.

Experiment 7.11 5,5-DIMETHYLCYCLOHEXANE-1,3-DIONE
(Dimedone)

\[
\begin{align*}
\text{Me} & \quad \text{Me} \\
\text{O} & \quad + \text{CH}_2(\text{CO}_2\text{Et})_2 \\
\Theta & \quad \text{Et} \\

\text{Me} & \quad \text{Me} \\
\end{align*}
\]

Equip a dry 1-litre three-necked flask with a dropping funnel, a sealed stirrer unit and an efficient double surface condenser. Place 11.5 g (0.5 mol) of sodium in the flask, cool in an ice bath and add 200 ml of absolute ethanol in one portion. When the initial vigorous reaction has subsided, remove the ice bath and allow the reaction to proceed until all the sodium has reacted: warming on a water bath is sometimes necessary to dissolve the last traces of sodium. Place a calcium chloride guard-tube at the top of the condenser. Introduce 85 g (0.53 mol) of diethyl malonate, and then add through the dropping funnel 50 g (0.51 mol) of freshly distilled mesityl oxide (Expt 5.213)
slowly. Reflux the mixture with stirring for 2 hours, then add a solution of 62.5 g (1.11 mol) of potassium hydroxide in 300 ml of water, and reflux again on a water bath with stirring for 6 hours. Acidify the reaction mixture (to litmus) while still hot with dilute hydrochloric acid (1:2 by volume): about 275 ml are required. Fit the flask with a condenser for distillation, and distil off as much alcohol as possible by heating with stirring on a water bath. Allow the residue in the flask to cool somewhat, add 8 g of decolourising carbon slowly, boil for 10 minutes and filter; repeat the treatment with decolourising carbon. Neutralise the residue to litmus by the addition of dilute hydrochloric acid (about 75 ml) and boil again with 8 g of decolourising charcoal. Filter and render the hot yellow filtrate distinctly acid to methyl orange with dilute hydrochloric acid (25–50 ml), boil for a few minutes and allow to cool whereupon the dimedone crystallises out. Filter at the pump, wash with ice-cold water and dry in the air. The yield of dimedone, m.p. 147–148 °C, is 60 g (84%). Recrystallisation from acetone (about 8 ml per gram) raises the m.p. to 148–149 °C, but this is generally unnecessary.

**Experiment 7.12 3-METHYLCYCLOPENTANE-1,2,4-TRIONE**

\[
\begin{align*}
\text{Me} & \quad \text{Me} + 2(\text{CO}_2\text{Et})_2 \xrightarrow{\text{COEt}} \text{Me} & \quad \text{O} & \quad \text{Me} & \quad \text{O} \\
\text{CO}_2\text{Et} & \quad \text{H}_3\text{PO}_4 & & \text{Me} & \quad \text{O} & \quad \text{O} & \quad \text{(CO}_2\text{H})_2 \\
\end{align*}
\]

**Ethyl 4-methyl-2,3,5-trioxocyclopentylglyoxalate.** Equip a 2-litre, three-necked round-bottomed flask with an efficient sealed stirrer unit and a reflux condenser protected with a calcium chloride tube, and insert a stopper in the third neck. Place 315 ml of absolute ethanol in the flask and add portionwise 23 g (1 mol) of sodium metal; if necessary moderate the initial vigour of the reaction by external cooling (see Expt 5.95). When all the sodium metal has reacted cool the flask in an ice–salt cooling bath, replace the stopper with a dropping funnel protected with a calcium chloride guard-tube and add drop-wise over a period of about half an hour a mixture of 36 g (0.5 mol) of dry redistilled butan-2-one and 160 g (1.1 mol) of dry redistilled diethyl oxalate. Allow the red solution to attain room temperature and, with continued stirring, heat the reaction mixture under reflux for 30 minutes. Cool the reaction mixture again in an ice–salt bath and slowly add from the dropping funnel with efficient stirring 55 ml of dilute sulphuric acid (prepared by adding concentrated sulphuric acid to an equal volume of water). Remove the sodium sulphate which crystallises out by filtration and wash it with ethanol; concentrate the combined filtrate and washings on a rotary evaporator to a volume of about 100 ml. Cool the residual aqueous solution in an ice–salt cooling bath for several hours, filter the glyoxalate ester and wash with a little ice-cold water. The yield of crude product is 39.5 g (35%), which may be used for the next stage. A small portion of the product may be recrystallised from ethyl acetate (decolourising charcoal), when it has m.p. 162–164 °C.
3-Methylcyclopentane-1,2,4-trione. In a 500-ml round-bottomed flask fitted
with a reflux condenser place 300 ml of dilute phosphoric acid (prepared by
diluting phosphoric acid with an equal volume of water) and add 30 g
(0.133 mol) of the foregoing glyoxalate ester. Heat the solution under reflux
for 30 minutes; cool the solution to about $-10^\circ C$ and allow to stand at this
temperature for 2 hours. Remove the oxalic acid which crystallises out by fil-
tration and wash it with small portions of iced water. Extract the filtrate with
eight 120 ml portions of ether, combine the extracts and rinse with a little
water, dry and evaporate to dryness. Dissolve the residue in about 10 ml of
water, cool and filter off crystals of the monohydrate which have a wide melting
range of about 72–79 °C according to the rate of heating. Anhydrous
3-methylcyclopentane-1,2,4-trione may be obtained as colourless plates,
m.p. 118–119 °C, by sublimation under reduced pressure (≈0.1 mmHg); the
yield is 9 g (54%).

Experiment 7.13 CYCLOBUTANONE

A 4-litre, three-necked round-bottomed flask, equipped with a nitrogen inlet,
a reflux condenser, a mechanical stirrer and a pressure-equalising dropping
funnel, is dried by heating with a flame under evacuation. Under nitrogen, it
is charged with magnesium (264 g, 11 mol) and anhydrous ether (1.5 litres).
Under rapid stirring, a solution of 1,3-dibromopropane (212 g, 1.05 mol) in ether (1.5 litres) is added during 15 hours. Afterwards, the reaction mixture is
transferred by nitrogen pressure through a glass tube plugged with glass wool
into another dry 4-litre, three-necked round-bottomed flask equipped with a
gas inlet, a reflux condenser and a mechanical stirrer. At room temperature,
a gaseous mixture (2:1) of nitrogen and carbon dioxide (30.2 litres, carbon
dioxide from dry ice, dried by leading the gas through a tube filled with a mix-
ture of calcium chloride and phosphorus pentoxide) is introduced above the
surface of the rapidly stirred solution during 3 hours. Then the supernatant
solution is decanted; to the white, solid residue, water (150 ml) is added drop-
wise, followed by 4 M hydrochloric acid (250 ml). The mixture is extracted
with pentane (400 ml) by continuous extraction (14 hours); g.l.c. analysis
(Carbowax 20M, isothermal, 90 °C) of the pentane solution and comparison
with authentic samples reveals the presence of cyclobutanone (41%), and cyc-
lobutanol (2%); p.m.r. spectroscopy shows that glutaric acid (17%) is also
present. The pentane solution is subjected to distillation on a spinning band
column (0.65 m) at normal pressure; after removal of the pentane, cyclobuta-
none is obtained by vacuum distillation. The yield is 9.7 g (13%, based on
dibromopropane), b.p. 44 °C/140 mbar, purity >98 per cent by g.l.c.; p.m.r.
(CDCl$_3$, TMS, 90 MHz) $\delta$ 1.93 (m, 2H) and 3.02 (m, 4H).

7.3 INSERTION REACTIONS

A most convenient method for the formation of cyclopropane ring systems is the
insertion of a carbon residue into a carbon–carbon double bond. The reagents
may be carbenes or carbenoids generated from diazomethane and related diazo compounds (cf. also Sections 5.11.4, p. 675 and 6.1.5, p. 848), diiodo- or dibromo-methane and zinc–copper couple, or chloroform and alkali (cf. also Section 6.10.1, p. 991), or the sulphur ylide generated from trimethyl-sulphoxonium iodide and sodium hydride (cf. also Section 8.1.2, p. 1131).

The illustrative examples of these reactions are the synthesis of \((-\text{2,7,7-trimethyltricyclo[4.1.1.0}}^{2,4}\text{]octane (37), 7,7-dichlorobicyclo[4.1.0]heptane (38), and ethyl trans-2-methylcyclopropane-1-carboxylate (39).\)

Diiodomethane with zinc–copper couple is a particularly good reagent for the insertion of a methylene group into an olefinic bond. The reaction is known as the Simmons–Smith procedure, and is likely to proceed as follows:

\[
\text{ZnI}_2 + \text{CH}_2=CH_2 \rightarrow \text{ZnCH_2CH_2I} \rightarrow \text{ZnI}_2
\]

Since the free carbene (\(\text{CH}_2\)) is not thought to be present, the reagent (40) is termed a carbenoid. The activity of the zinc surface is of crucial importance to the smoothness and success of the reaction. Failure to ensure appropriate activation procedures may cause the reaction to fail, or the onset of the exothermic reaction may be delayed and then proceed with excessive vigour. The recent use of ultrasonic activation of the zinc surface from the outset of the reaction results in a smoother, less unpredictable reaction rate, and leads to satisfactory yields. Furthermore, sonication enables the cheaper dibromomethane to be employed.

The reaction is illustrated by the cyclopropanation of \(\alpha\)-pinene (Expt 7.14); a general procedure which is applicable to a wide range of olefins is also noted.

Dichlorocarbene is the reactive intermediate formed by the reaction of alkali on chloroform, and typically it adds to olefins to give 1,1-dichlorocyclopropanes. The PTC procedure for the generation of dichlorocarbene is particularly useful and is illustrated by its reaction with cyclohexene to form (38) (Expt 7.15). The mechanism is formulated below and probably involves the reaction of the quaternary ammonium hydroxide with chloroform at the phase boundary, and dissolution into the organic phase of the quaternary ammonium derivative of the trichloromethyl anion (41). This species breaks down to form dichlorocarbene and the quaternary ammonium chloride. The latter returns to the aqueous phase to maintain the cycle of events, while the dichlorocarbene reacts rapidly with the cyclohexene in the organic phase.
The use of dimethylsulphoxonium methyldide, as a specific methylene insertion reagent for α, β-unsaturated ketones and esters, is illustrated by its reaction with ethyl crotonate in dimethylformamide solution to form (39) (Expt 7.16). The sulphur ylide initially attacks the β-carbon of the conjugated system (Michael acceptor site), and this is followed by cyclisation and loss of dimethyl sulphoxide.

Experiment 7.14  (-)-2,7,7-TRIMETHYLTRICYCLO[4.1.1.0².⁴]-OCTANE¹¹ᵃ

A 1-litre, four-necked round-bottomed flask, equipped with a thermometer, two condensers, mechanical stirrer and nitrogen-inlet tube, is charged with 1,2-dimethoxyethane (200 ml) (1) and mossy zinc (35.6 g, 0.544 mol), and irradiated with ultrasound for 2 hours (2). (-)-α-Pinene (21.0 g, 0.154 mol) is added rapidly, and the mixture heated to reflux. Diiodomethane (44.8 ml, 0.556 mol) (3) is added with stirring. The mixture is heated to reflux (the reaction temperature rises from 85 to 96 °C, therefore an efficient condenser is required) and continuously irradiated with ultrasound, until g.l.c. indicates that the reaction has stopped at 90 per cent completion (4 hours); [g.l.c. conditions: column (2 m x 2 mm) of 3% OV-1 on 80/100 Supercelcopport, isothermal 100 °C, helium 30 ml/minute; retention time, starting material 1.7 minutes, product 3.2 minutes]. The mixture is cooled to 25 °C, pentane (200 ml), saturated ammonium chloride (200 ml), and solid ammonium chloride are added slowly until all solids dissolve. The aqueous phase is extracted with two 150 ml portions of pentane, and the combined organic layers are washed with two 150 ml portions of saturated aqueous sodium chloride. The solution is dried over magnesium sulphate, filtered and evaporated at atmo-
spheric pressure. The residual yellow oil (30 ml) is fractionally distilled at 78–80°C/36 mmHg to obtain the product as an oil, 15.5 g (67%, 97% pure by g.l.c.); [α]_D²⁵ = 70.0° (c 1.67 in EtOH); p.m.r. (CDCl₃, TMS) δ 0.20 (m, 1H), 0.72 (m, 2H), 0.93 (d, 1H), 1.04 (s, 3H), 1.08 (s, 3H), 1.26 (s, 3H), 1.65 (m, 2H), 1.84 (d of d, 1H), and 2.02 (m, 2H); ¹³C-n.m.r. (CDCl₃, TMS) δ 16.0 d, 19.1 t, 20.3 s, 21.1 q, 25.5 q, 27.0 q, 27.1 t, 27.5 t, 41.0 s, 41.6 d, and 45.5 d.

Notes. (1) 1,2-Dimethoxyethane (Aldrich) is used without purification or drying.
(2) A laboratory ultrasonic cleaner (150 W, 50–55 kHz) manufactured by Branson Co. is employed.
(3) Before use diiodomethane is fractionally distilled at 5 mmHg, fractionally crystallised by partial freezing and stored over mercury.

Cognate preparation. General procedure for cyclopropanations using dibromomethane.¹¹b A 500-ml, three-necked round-bottomed flask is fitted with a Graham (coil) condenser and drying tube over an Allihn condenser, a pressure-equalising dropping funnel, and equipped with mechanical stirring. Into the flask are added zinc dust (52 g, 0.80 mol), copper(i) chloride (8 g, 0.08 mol), anhydrous ether (75 ml) and dibromomethane (70 g, 0.40 mol). To the addition funnel is added the alkene (0.20 mol) in anhydrous ether (50 ml). The apparatus is positioned in a 125 W Branson ultrasonic bath which is filled to about 3 cm from the top with water preheated to 45–50°C. Sonication and stirring are started, and the position of the bath beneath the reaction vessel is varied so as to achieve maximum cavitation. Then the alkene is added dropwise to the reaction mixture over a 5–10 minute period. After approximately a 1 hour induction period, the reaction of the dibromomethane and zinc–copper couple usually starts. This is evidenced by the change in the colour of the reaction mixture from grey to a purple grey and by the onset of rapid refluxing. The stirring and sonication are continued for an additional 3 hours.

As an alternative procedure, which results in a shorter induction period but otherwise has no major effect on the reaction, addition of the alkene is postponed until after the reaction of the zinc–copper couple and dibromomethane starts (c. 30 minutes). Sonication is continued for an additional 60 minutes and stirring without sonication for a further 60 minutes.

After the reaction is complete, the ultrasonic bath is removed, and the reaction mixture cooled in an ice bath, diluted with pentane (200 ml), and, while being stirred, treated by dropwise addition of saturated ammonium chloride solution (150 ml). The organic layer is separated and the aqueous layer washed with pentane (1 x 50 ml). The combined organic layer is washed with 10 per cent sodium hydroxide solution (1 x 100 ml) and dried over magnesium sulphate. The solvents are removed by distillation on a steam bath through a Vigreux column, and the remaining oil fractionally distilled.

This procedure has been used for the cyclopropanation of cyclohexene, cyclooctene, α-pinene, β-pinene, hex-1-ene, oct-1-ene, (E)-but-2-en-1-ol, and 2,3-dihydropyran.
Experiment 7.15 7,7-DICHLOOROBICYCLO[4.1.0]HEPTANE

\[
\text{Cyclohexene} + \text{CHCl}_3 \overset{\text{NaOH}}{\longrightarrow} \text{7,7-Dichlorobicyclo[4.1.0]heptane}
\]

Place 8.2 g (10.1 ml, 0.1 mol) of freshly distilled cyclohexene, 36 g (24 ml, 0.3 mol) of chloroform (1) and 0.4 g (0.0017 mol) of triethylbenzylammonium chloride in a two-necked, round-bottomed 100-ml flask fitted with a sealed stirrer unit and a reflux condenser. Stir the solution vigorously and add to it a solution of 16 g (0.4 mol) of sodium hydroxide in 16 ml of water in portions down the condenser during 5 minutes. Within 10 minutes an emulsion is formed, and the temperature of the mixture increases slowly during 25 minutes to a maximum of about 50–55 °C; thereafter the temperature decreases while the colour changes from white to pale brown. After stirring for 2.5 hours add 40 ml of ice-cold water to the reaction mixture, transfer to a separating funnel and collect the lower chloroform layer. Extract the aqueous alkaline solution with 30 ml of ether and combine the ether extract with the chloroform solution and wash with 25 ml of 2 M hydrochloric acid followed by two 25 ml portions of water. Dry the organic solution over magnesium sulphate, filter and remove the solvents on a rotary evaporator (water bath at 35–40 °C). Transfer the residual deep golden-coloured liquid to a 25-ml flask to which is attached a short (7 cm) fractionating column, and distil under reduced pressure. Collect the 7,7-dichlorobicyclo[4.1.0]heptane at 80–82 °C/16 mmHg; the yield is 10.2 g (62%). The purity may be checked by g.l.c. using a 5-ft column of Silicone oil on Chromosorb W held at 110 °C and with a nitrogen flow rate of 40 ml/minute; the retention time is 6 minutes.

Note. (1) Ethanol-free chloroform should be used (CAUTION). Ethanol present in chloroform (as stabiliser) can be removed by shaking chloroform several times with an equal volume of water, followed by drying over anhydrous calcium chloride and distilling. Alternatively stand the chloroform over a few grams of the molecular sieve 4A.

Experiment 7.16 ETHYL TRANS-2-METHYLCYCLOPROPANE-1-CARBOXYLATE\(^{12}\)

\[
\text{Me} = \text{OEt} \overset{\text{Me}_2\text{SO}-\text{CH}_2}{\longrightarrow} \text{Me} = \text{CO}_2\text{Et}
\]

CAUTION: This experiment should be conducted in a well-ventilated fume cupboard owing to the volume of hydrogen gas which is evolved.

To a suspension of sodium hydride (1.2 g, 0.05 mol) in dimethylformamide (100 ml) is added in one portion solid trimethylsulphoxonium iodide (11.05 g, 0.052 mol) (1). An exothermic reaction takes place with copious evolution of hydrogen. After all the hydrogen has been evolved (5 minutes), the mixture is stirred for another 15 minutes, and ethyl crotonate (5.7 g, 0.05 mol) in dimethylformamide (15 ml) is added to the methylide in one portion. An exothermic reaction takes place and the mixture turns slightly yellow. Stirring is continued for another hour. The mixture is poured into hydrochloric acid–ice-water (100 ml, 3%), extracted with ether (3 × 50 ml), the ether extract
washed with water (4 × 50 ml) and the aqueous phase counter-extracted with ether (2 × 25 ml). The combined ether layer is dried (magnesium sulphate) and distilled giving ethyl trans-2-methylcyclopropane-1-carboxylate (4.0 g, 63%), b.p. 74–76°C 70 mmHg; i.r. 1740 (C=O), 1020 cm⁻¹ (cyclopropane); g.l.c. analysis shows a single peak (t_R 17 minutes) on a 10 per cent dinonyl phthalate column held at 70°C.

Note. (1) N,N-Dimethylformamide is azeotropically distilled from toluene (Section 4.1.26, p. 409).

Trimethylsulphonium iodide is prepared by refluxing methyl iodide with dimethyl sulphoxide according to the method of Kuhn and Trichmann, and washed with acetone to remove traces of iodine, dried in an oven at 110°C for 2 hours, and kept in a vacuum desiccator before use; it may also be obtained commercially (Aldrich). All reactions are carried out under dry, oxygen-free nitrogen; calcium chloride guard-tubes are used to ensure anhydrous conditions. A magnetic stirrer is used to maintain brisk stirring.

### 7.4 Ring Expansion and Ring Contraction Reactions

Cyclohexanone and pulegone provide useful examples to illustrate ring expansion and ring contraction procedures.

Ring expansion of cyclohexanone to cycloheptanone may be effected by reaction with diazomethane (Expt 7.17). The ring-expanded ketone is obtained in about 60 per cent yield and is accompanied by some epoxide and some cyclooctanone which results from further ring expansion of the cycloheptanone. Mechanistically the reaction may be represented in the following manner.

![Diagram](https://example.com/diagram)

The cycloheptanone is readily separated by taking advantage of the fact that it alone forms a solid bisulphite compound.

The Favorskii rearrangement results from the action of base on an α-halo ketone. When applied to cyclic ketones, ring contraction results, as shown in the classic case of cyclohexanone formulated below.

![Diagram](https://example.com/diagram)
It should be noted that in this case either of the carbonyl-carbon bonds in the symmetrical intermediate cyclopropanone system could be cleaved. With unsymmetrically substituted cyclic ketones (or indeed open chain ketones), the direction of cleavage is that which would lead to the more stable carbanion.

The example given in Expt 7.18 is the formation of a mixture of cis and trans ethyl pulegenates (ethyl 5-methyl-2-isopropylidene-cyclopentanecarboxylate) from pulegone by reaction with bromine to give the dibromide, followed by treatment with sodium ethoxide.\(^\text{14}\)

\[
\text{Me} \quad \overset{(i) \text{Br}_2}{\text{Me}} \quad \overset{(ii) \text{EtO}^-}{\text{Me}} \\
\text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me}
\]

In this case the cleavage of the cyclopropanone system is directed by the concerted loss of the second bromine. The cis/trans ratio appears to be determined by a subsequent epimerisation in which the thermodynamically more stable trans isomer predominates. Hydrolysis of the mixed isomers with aqueous alkali leads to the exclusive formation of trans-pulgenic acid, resulting from the rapid base catalysed equilibration of the cis/trans esters and the retarded rate of hydrolysis of the sterically hindered cis ester.

**Experiment 7.17 CYCLOHEPTANONE**

\[
\begin{align*}
\text{O} & \quad \text{CH}_2\text{N}_2 \quad \longrightarrow \quad \begin{array}{c}
\text{O} \\
\text{O}
\end{array} \\
\text{O} & \quad \text{O} \quad + \quad \begin{array}{c}
\text{O} \\
\text{O}
\end{array}
\end{align*}
\]

**CAUTION:** *This preparation must be carried out in an efficient fume cupboard (see Section 4.2.25, p. 430).*

In a 1-litre three-necked flask equipped with a thermometer, a mechanical stirrer and a dropping funnel, place 49 g (0.5 mol) of redistilled cyclohexanone, 125 g (0.585 mol) of N-methyl-N-nitrosotoluene-p-sulphonamide, 150 ml of 95 per cent ethanol and 10 ml of water. The nitrosamide is largely undissolved. Adjust the height of the stirrer so that only the upper part of the solution is stirred and the precipitate moves slightly; place the thermometer so that the bulb is in the liquid. Cool the mixture to about 0°C in an ice–salt bath. While stirring gently, add a solution of 15 g of potassium hydroxide in 50 ml of 50 per cent aqueous ethanol dropwise very slowly from the dropping funnel: after 0.5–1 ml of the solution has been added, a vigorous evolution of
nitrogen commences and the temperature rises (1). Adjust the rate of addition so that the temperature is maintained at 10–20°C; the duration of the addition of alkali is about 2 hours and the nitroso compound ultimately disappears. Stir the orange-yellow solution for a further 30 minutes, and then add 2 m hydrochloric acid until the solution is acidic to litmus paper (c. 50 ml).

Introduce a solution of 100 g of sodium metabisulphite in 200 ml of water and continue the stirring, preferably for 10 hours with exclusion of air. A thick precipitate separates after a few minutes. Collect the bisulphite compound by suction filtration, wash it with ether until colourless and then decompose it in a flask with a lukewarm solution of 125 g of sodium carbonate in 150 ml of water. Separate the ketone layer, extract the aqueous layer with four 30 ml portions of ether, dry the combined organic layers over magnesium sulphate, remove the ether at atmospheric pressure and distil the residual oil under reduced pressure through a short fractionating side-arm. Collect the cycloheptanone at 64–65 °C/12 mmHg; the yield is 17 g (31%).

Note. (1) If the reaction does not start at this stage remove the flask from the cooling bath and allow the mixture to warm to 10°C; do not add any further alkali until the reaction has started.

Experiment 7.18 ETHYL CIS- AND TRANS-PULEGENATES AND TRANS-PULEGENIC ACID

Pulegone dibromide. To a stirred and cooled solution of (±)-pulegone (21.6 g, 0.14 mol) in glacial acetic acid (30 ml) is added, dropwise, bromine (20 g, 0.125 mol). After the addition is complete (c. 0.5 hour) the solution is stirred for another 30 minutes and then poured on to crushed ice. The resulting oily mixture is extracted with eight 20 ml portions of light petroleum (b.p. 35–37°C). The combined organic extracts (160 ml) are washed with dilute sodium hydrogen carbonate solution and dried over magnesium sulphate. No further attempt is made to purify the unstable dibromide.

Ethyl cis- and trans-pulegenates. The foregoing dried light petroleum solution of pulegone dibromide is added dropwise to a heated and stirred solution of sodium ethoxide [from sodium (9.5 g)] in carefully dried ethanol (200 ml). As the addition proceeds the light petroleum is distilled from the reaction mixture. After the addition is complete and the hydrocarbon has been distilled, the mixture is kept at reflux for 2 hours. The mixture is cooled and poured rapidly into 10 per cent hydrochloric acid (300 ml). The heavy oil which separates is taken up in ether and the aqueous phase is extracted thoroughly with ether. The combined ether extracts are washed successively with water, sodium hydrogen carbonate solution, and water and finally dried. Distillation gives after a forerun of pulegone, b.p. 54–56°C/0.60–0.65 mmHg, the mixture of isomeric ethyl pulegenates, b.p. 56–62°C/0.60–0.65 mmHg (13.8 g,
7.5 PRACTICAL ORGANIC CHEMISTRY

64%). Gas–liquid chromatography analysis on a Carbowax 20M column indicates the presence of 26 per cent of the cis isomer and 74 per cent of the trans isomer.

**trans-Pulegenic acid.** To a solution of the ethyl esters (10.0 g, 51 mol) in absolute ethanol (50 ml) is added potassium hydroxide (5.71 g, 102 mmol) in water (20 ml). The resulting solution is kept at reflux for 3 hours. After dilution with water the solution is extracted with ether to remove neutral products. The alkaline solution is acidified with dilute hydrochloric acid and the mixture extracted with ether. trans-Pulegenic acid may be isolated from this extract by drying, evaporation and distillation; the product may be isolated as a colourless liquid, b.p. 124–128 °C/3 mmHg, or b.p. 95–97 °C/0.45 mmHg. A portion of the ethereal extract is treated with an ethereal solution of diazo-methane (Section 4.2.25, p. 430) and converted into the corresponding methyl ester; g.l.c. analysis indicates the exclusive presence of methyl trans-pulegenate.

### 7.5 REDUCTION OF AROMATIC COMPOUNDS

A convenient route to the preparation of substituted cyclohexanes is the reduction of appropriately substituted benzenes. Total reduction is effected by heterogeneous catalytic hydrogenation at temperatures in the region of 100–200 °C and usually under pressure. Under these conditions functional side-chain substituents may be variously affected (as a result of reduction or hydrogenolysis), and specialised texts should be consulted for coverage of this vast field.\(^\text{15}\)

Reduction of substituted benzenes with sodium (or lithium) in liquid ammonia in the presence of a *proton source* (such as methanol, ethanol, etc.) leads to a substituted, non-conjugated cyclohexadiene as a result of 1,4-addition of hydrogen (*the Birch reduction*).\(^\text{16}\) With benzene the product is cyclohexa-1,4-diene as a result of the following mechanistic pathway.

\[
\begin{array}{c}
\text{C}_6\text{H}_6 \xrightarrow{\text{e}} \text{C}_6\text{H}_5\text{H} \xrightarrow{+\text{H}^+} \text{C}_6\text{H}_5\text{H} \xrightarrow{+\text{e.} +\text{H}^+} \end{array}
\]

With substituted benzenes the regioselectivity and the rate of the reduction are crucially dependent on the electron-donating or electron-withdrawing characteristics of the substituent. Thus with anisole, the rate of reaction is decreased and the product is 1-methoxycyclohexa-1,4-diene (2,5-dihydroanisole) (42); with benzoic acid the rate of reaction is increased and the product is cyclohexa-2,5-dienecarboxylic acid (1,4-dihydrobenzoic acid) (43).

\[
\begin{array}{cc}
\text{OMe} & \text{OMe} \\
\text{(42)} & \text{(43)}
\end{array}
\]
The reaction rate differences are readily rationalised from a consideration of fundamental reaction mechanism principles (e.g. electron-donating groups increase electron density in the aromatic ring and thus hinder acceptance of an electron); the regioselectivity of the reduction is explained from a consideration of the relative stabilities of the possible alternative mesomeric intermediates, these being (44) in the case of anisole and (45) in the case of benzoic acid.

![Chemical structures of anisole and benzoic acid](image)

The Birch reduction of 3,4,5-trimethoxybenzoic acid \(^{17a, b}\) (cognate preparation in Expt 7.19) is of interest in that the product is 1,4-dihydro-3,5-dimethoxybenzoic acid (46) thus revealing that in this reduction the 4-methoxy group is removed by hydrogenolysis. The product possesses two methyl vinyl ether residues which are labile under aqueous acidic conditions to yield the saturated diketone, 3,5-diketocyclohexanecarboxylic acid (47).

![Chemical reaction with structures of 3,4,5-trimethoxybenzoic acid, its Birch reduction product (46), and the subsequent dehydration to give 3,5-diketocyclohexanecarboxylic acid (47)](image)

There is no standard, universal, procedure for the Birch reduction. Experiment 7.19 illustrates some of the variants which have been reported in the literature. The original Birch procedure is to add small pieces of sodium metal to a solution of the aromatic compound in a mixture of liquid ammonia and the proton source (ethanol).\(^{18}\) After completion of the reaction, which is usually indicated by the disappearance of the blue colour, it is quenched by the addition of ammonium chloride and the ammonia allowed to evaporate before the cautious addition of water, and isolation of the product by ether extraction. In a modified procedure a co-solvent (ether, tetrahydrofuran, etc.) is initially added to the solution of aromatic compound/liquid ammonia prior to the addition of metal; lithium metal is often used in place of sodium.\(^{19a, b}\) In general these latter procedures are used for substrates which are more difficult to reduce. Redistilled liquid ammonia is found to be beneficial since the common contaminant iron, in colloidal form or in the form of its salts, has a deleterious effect on the reaction.\(^{20}\) A representative selection of procedures is given in Expt 7.19 for the reduction of \(\sigma\)-xylene, anisole, benzoic acid, and 3,4,5-trimethoxybenzoic acid.

**Experiment 7.19 1,2-DIMETHYLCYCLOHEXA-1,4-Diene\(^{21}\)**

![Chemical reaction with structures of 1,2-dimethyldicyclohexa-1,4-diene](image)
CAUTION: This experiment must be conducted in an efficient fume cupboard and the precautions and techniques for handling liquid ammonia described in Section 2.17.7, p. 116, must be noted.

To liquid ammonia (400 ml) (1) held at −70 °C is added with brisk stirring o-xylene (53 g, 0.5 mol) followed by small pieces of sodium metal (23 g, 1 g-atom) (2). Stirring is continued until all the sodium has dissolved and a blue coloured solution is obtained. Dry methanol (32 ml, 1 mol) is cautiously added dropwise at −70 °C, when a vigorous reaction ensues. When the solution is colourless the ammonia is allowed to evaporate, and water cautiously added. The organic layer is separated (3), dried and distilled to give 1,2-dimethylcyclohexa-1,4-diene (49 g, 92.5%), b.p. 141.5–143 °C (4).

Note. (1) In general the apparatus used in these metal–liquid ammonia reductions is essentially that shown in Fig. 2.69 (d), but without the dropping funnel tube extension. The dropping funnel is replaced with the soda-lime guard-tube, which may then be removed at appropriate intervals for the periodic addition of metal fragments. After the flask has been charged with liquid ammonia, the inlet tube is replaced with a suitable thermometer, the bulb of which should be immersed in the reaction solution. A dry ice–acetone cooling bath should be used.
(2) Details of a large-scale preparation of 1,2-cyclohexa-1,4-diene have been published. 22
(3) The quenched reaction solution may alternatively be extracted with ether to facilitate the isolation of the reduction product.
(4) Gas–liquid chromatography analysis of the product may be effected using didecyl phthalate as the stationary phase. 19a

Cognate preparations. Cyclohexa-2,5-dienecarboxylic acid (1,4-dihydrobenzoic acid). 17a A solution of benzoic acid (10 g, 0.082 mol) in ethanol (100 ml) and liquid ammonia (600 ml) is stirred and sodium (6.2 g, 0.27 g-atom) added in small pieces, followed by ammonium chloride (14.6 g, 0.27 mol). The ammonia is evaporated and the residual material dissolved in ice-water (500 ml). After acidification with 10 per cent hydrochloric acid the solution is extracted with four 100 ml portions of ether, the ether washed once with saturated sodium chloride solution, dried over magnesium sulphate and concentrated in vacuo. The remaining pale yellow oil is distilled at 96–98 °C (0.01 mmHg) to give 9.0 g (89%) of 1,4-dihydrobenzoic acid; this product shows no u.v. absorption above 220 nm.

1,4-Dihydro-3,5-dimethoxybenzoic acid. 17a To solution of 3,4,5-trimethoxybenzoic acid (31.8 g, 0.15 mol) in ethanol (225 ml) and liquid ammonia (1.5 litres) is added sodium (18.0 g, 0.78 mol) in small pieces, followed by ammonium chloride (75 g, 1.45 mol). The ammonia is evaporated and the residue taken up in 2 litres of ice-water. Alternate additions of small portions of 10 per cent hydrochloric acid and immediate extractions with dichloromethane are carried out until the solution becomes acidic to Congo red. The combined extracts are washed several times with water, dried over magnesium sulphate, filtered and concentrated in vacuo at room temperature. Trituration of the residue with a small amount of ether and filtration gives 17.7 g of product. Concentration of the ether filtrate yields an additional 6.3 g of white crystalline product. The crude material, m.p. 100–105 °C (87%), could be recrystallised from ether–hexane. A sample prepared for elemental analysis shows m.p. 105 °C (decomp) or 118 °C (decomp) depending on the rate of heating.
Conversion to 3,5-diketocyclohexanecarboxlic acid.\textsuperscript{17a} A suspension of 1,4-dihydro-3,5-dimethoxybenzoic acid (80 g, 0.43 mol) in 2 per cent hydrochloric acid (800 ml) is heated on a steam bath for 15 minutes. The clear solution is then concentrated to dryness in vacuo, the residue is triturated with a small amount of ether and filtered, giving the diketone (66 g, 97\%) as a white crystalline compound, m.p. 182\°C.

**General procedure for reduction with lithium.\textsuperscript{19b}** The apparatus used for all these reductions in liquid ammonia is a three-necked flask equipped with a stirrer, dropping funnel and soda-lime guard-tube. The flask is placed in a box stuffed with insulating wool or cotton. At the front of the box is a sealed double window with a cork spacer ring and rubber gasket against which the flask is placed. This arrangement prevents condensation of moisture on the flask or window, and with illumination from the top permits observation of the reaction mixture at all times. The flask is filled from one-third to no more than one-half of its capacity, to aid in control of foaming which occurs in some instances towards the end of alcohol addition.

To a solution of the compound to be reduced in dry ether or 1,2-dimethoxyethane is added liquid ammonia with stirring, and to the homogeneous solution is added lithium wire in small pieces over a period of 1 to 10 minutes, depending on the quantity of metal. After stirring for 10 minutes, absolute ethanol is added dropwise over a period of about 20 minutes. In some cases there is a tendency for foaming to occur near the end of this addition. This is easily controlled by stopping the stirrer momentarily. When the blue colour has disappeared the ammonia is evaporated, ether and water are added, separated and the aqueous layer re-extracted. After washing the combined extract with saturated salt solution and drying over potassium carbonate, the ether is removed and the product isolated by crystallisation or distillation as appropriate.

1-Methoxycyclohexa-1,4-diene (2,5-dihydroanisole). A solution of anisole (15 g) in ether (50 ml) and liquid ammonia is treated by the general procedure outlined above with lithium (4.5 g, 4.6 equivalents per mol) and finally with absolute ethanol (35 g) (30 minute addition). After ether extractions, the concentrated aqueous layer (75 ml) is acidified and treated with bromine, giving tribromophenol (0.90 g), m.p. 93–94.5\°C, which indicates only 2 per cent demethylation. From the ether extracts is obtained the product (12.8 g, 84\%), b.p. 148–149\°C, $n_\text{D}^{25}$ 1.4782. The u.v. absorption spectrum (95\% ethanol), $\lambda_{\text{max}}$ 268–269 nm ($\epsilon$ 800) indicates the presence of about 20 per cent of 2,3-dihydroanisole in the 2,5-dihydroanisole \[2,3-dihydroanisole is reported\textsuperscript{23} as having $\lambda_{\text{max}}$ 268 nm ($\epsilon$ 4270); see also Fieser–Woodward rules for conjugated diene absorption, p. 390].

**7.6 CYCLOADDITION REACTIONS**

Cycloaddition reactions represent a very versatile route to alicyclic compounds. The most important for six-membered rings is the Diels–Alder reaction, and its great utility lies in the fact that it is both regioselective and stereospecific. The reaction involves compounds containing a double or triple bond, usually activated by conjugation with additional multiply-bonded systems (carbonyl, cyano,
nitro, phenyl, etc.), which add to the 1,4-positions of a conjugated diene system (e.g. buta-1,3-diene) with the formation of a six-membered ring. The ethylenic or acetylenic compound is known as the dienophile and the second reactant as the diene; the product is the adduct. The product in the case of an ethylenic dienophile is a substituted cyclohexene, and in that of an ethynyl dienophile it is a substituted cyclohexa-1,4-diene. The active unsaturated portion of the dienophile, or that of the diene, or those in both, may be involved in rings; the adduct is then polycyclic.

This formulation emphasises that the Diels–Alder reaction may be represented in the retrosynthetic sense as a two-group disconnection (p. 22).

The Diels–Alder reaction is a concerted reaction in which four $\pi$-electrons from the diene and two $\pi$-electrons from the dienophile participate in the transition state. The Woodward–Hoffmann Rules provide a theoretical framework for these reactions. They suggest that those reactions are thermally allowed which have $4n + 2$ pericyclic electrons, i.e. 6, 10, 14, etc. The Diels–Alder reaction is an example where $n = 1$, i.e. $(4 + 2) \pi$-electrons.

The Woodward–Hoffmann rules also allow the prediction of the stereochemistry of pericyclic reactions. The Diels–Alder reaction is an example of $(\pi 4_s + \pi 2_s)$ cycloaddition. The subscript s, meaning suprafacial, indicates that both elements of the addition take place on the same side of the $\pi$-system. Addition to opposite sides is termed antarafacial. The Woodward–Hoffmann rules apply only to concerted reactions and are derived from the symmetry properties of the orbitals involved in the transition state. These rules may be summarised as shown in Table 7.1.

The number of electrons in the dienophile and diene are represented by the letters p and q respectively.
For a more detailed treatment of the theory of pericyclic reactions the reader is referred to modern texts on reaction mechanism.

The preparative procedure for the Diels–Alder reaction is extremely simple and the cycloaddition usually merely requires warming the reactants together either alone, or in the presence of a suitable solvent.

The reaction has been shown to involve a stereospecific syn-addition with respect to the dienophile. For example, the reaction of 2,3-dimethylbuta-1,3-diene with maleic anhydride gives cis-1,2,3,6-tetrahydro-4,5-dimethylphthalic anhydride (Expt 7.20). An example of the use of a quinone as the dienophile is provided by the synthesis of cis-1,4,4a,9a-tetrahydro-2,3-dimethyl-9,10-anthraquinone which upon dehydrogenation (most simply by the action of oxygen upon its solution in alcoholic potassium hydroxide) yields 2,3-dimethylanthraquinone (Expt 7.21). Tetraphenylcyclopentadieneone (tetracyclone) readily undergoes the addition of dienophiles, such as maleic anhydride, to give an adduct, which then extrudes a molecule of carbon monoxide on heating, as in the preparation of 3,4,5,6-tetraphenyldihydropthalic anhydride (Expt 7.22).

With less reactive dienophiles more extensive heating may be required in which case the reaction is best carried out in a suitable pressure vessel (e.g. the preparation of 4-nitro-5-phenylcyclohexene, Expt 7.23).

Four-membered rings can be synthesised by [2 + 2] cycloadditions. However, thermal [2 + 2] cycloadditions occur only with difficulty; they are not concerted but involve diradicals. Photochemical [2 + 2] reactions are common and although some of these may occur by a stepwise mechanism many are concerted. An example of a [2 + 2] reaction is the photodimerisation of cyclopent-2-ene. This compound, as the neat liquid, or in a variety of solvents, on irradiation with light of wavelength greater than 300 nm (the n → π* excited state is involved) is converted to a mixture of the 'head-to-head' (48) and 'head-to-tail' (49) dimers, both having the cis,anti,cis stereochemistry as shown. It is believed that the reaction proceeds by attack of an n → π* triplet excited species on a ground state molecule of the unsaturated ketone (Section 2.17.5, p. 106). In the reaction described (Expt 7.24) the cyclopent-2-ene is irradiated in methanol and the 'head-to-tail' dimer further reacts with the solvent to form the di-acetal which conveniently crystallises from the reaction medium as the irradiation proceeds; the other dimer (the minor product under these conditions) remains in solution. The di-acetal is converted to the diketone by treatment with the two-phase dilute hydrochloric acid-dichloromethane system.

\end{align*}
\]

The cyclopent-2-ene required for the photodimerisation is prepared by the hydrolysis and oxidation of 3-chlorocyclopentene, which is obtained by the low temperature addition of hydrogen chloride to cyclopentadiene. The latter is obtained by heating dicyclopentadiene. This depolymerisation is an example of a reverse (or retro) Diels–Alder cycloaddition reaction; the diene readily reforms the dicyclopentadiene on standing at room temperature.
The $(2 + 2)$ cycloaddition reactions of ketenes with alkenes are synthetically useful routes to cyclobutanones. Ketenes are particularly useful due to the low steric hindrance at the carbonyl carbon. An example is the reaction of dichloroketene with cyclopentadiene which, after reductive dechlorination of the product, gives bicyclo[3.2.0]hept-2-en-6-one (Expt 7.25).

A further example of a photodimerisation reaction is provided by the formation, in poor yield, of '1,4-naphthoquinone photodimer' (50) on irradiation of 1,4-naphthoquinone in benzene solution (Expt 7.26). The dimerisation may be effected by sunlight or by means of a mercury arc lamp.

![Chemical structure](image)

**Experiment 7.20** Cis-1,2,3,6-tetrahydro-4,5-dimethylphthalic anhydride

Add 4.1 g (0.05 mol) of freshly distilled 2,3-dimethylbuta-1,3-diene (Expt 5.12) to 4.9 g (0.05 mol) of finely powdered maleic anhydride (Expt 5.218) contained in a small conical flask. Reaction occurs in a few minutes (indicated by evolution of heat). Allow to stand until the mixture attains room temperature. Remove the excess of maleic anhydride by extraction with cold water until the aqueous extract no longer gives an acid reaction to Congo red paper. Dry the residual white crystals upon filter paper in the air, and then recrystallise from light petroleum (b.p. 40–60°C). The yield of the tetrahydrophthalic anhydride, m.p. 78–79°C, is almost quantitative.

**Experiment 7.21** Cis-1,4,4a,9a-tetrahydro-2,3-dimethyl-9,10-anthraquinone

In a small round-bottomed flask, fitted with a reflux condenser, place a solution of 8.2 g (0.1 mol) of freshly distilled 2,3-dimethylbuta-1,3-diene (Expt 5.12) and 7.9 g (0.05 mol) of 1,4-naphthoquinone (Expt 6.128) in 30 ml of ethanol, and reflux for 5 hours. Keep the resulting solution in a refrigerator for 12 hours: break up the crystalline mass, filter and wash with 5 ml of ethanol.
The yield of crude adduct, m.p. 147–149 °C, is 11.5 g (91%); recrystallisation from methanol raises the m.p. to 150 °C.

Conversion into 2,3-dimethylantraquinone. Dissolve 10 g (0.0417 mol) of the adduct in 150 ml of 5 per cent potassium hydroxide solution (prepared by dissolving 7.5 g of potassium hydroxide pellets in 142.5 g of 95% ethanol) in a 250-ml three-necked flask equipped with a reflux condenser, gas inlet tube and a take-off adapter leading to a water pump. Bubble a current of air through the solution by means of gentle suction for 24 hours; the initial green colour changes to yellow and much heat is generated. Filter the yellow solid at the pump, wash successively with 50 ml of water, 25 ml of ethanol and 10 ml of ether and dry in the air. The yield of 2,3-dimethylantraquinone, m.p. 209–210 °C, is 7.5 g (76%).

Experiment 7.22 3,4,5,6-TETRAPHENYLDIHYDROPHTHALIC ANHYDRIDE

Place a mixture of 7.0 g (0.018 mol) of tetraphenylcyclopentadienone (Expt 7.7) 1.9 g (0.019 mol) of maleic anhydride (Expt 5.218) and 5 ml of bromobenzene in a 100-ml round-bottomed flask fitted with a reflux condenser. Re- flux gently in a fume cupboard (carbon monoxide is evolved) for 1.5 hours; during this period the dark brown colour of the cyclic ketone disappears. Cool to room temperature, add about 15 ml of light petroleum, b.p. 60–80 °C, break up the solid and filter. Wash with light petroleum and dry. The yield of crude product, m.p. 237–240 °C, is 7.5 g (90%). Dissolve the solid in hot benzene (120 ml), filter and add light petroleum, b.p. 60–80 °C (120 ml), to the hot filtrate and cool. Collect the solid which separates, wash with light petroleum and dry. The yield of pure tetraphenyldihydrophthalic anhydride, m.p. 235–240 °C, is 6.2 g (75%). The m.p. depends on the rate of heating.

Experiment 7.23 4-NITRO-5-PHENYLCYCLOHEXENE

This reaction is carried out using the steel pressure vessel and techniques described in Section 2.17.2, p. 97. To the dry pressure vessel add 7.46 g (0.05 mol) of Ω-nitrostyrene (Expt 6.136), about 0.1 g of hydroquinone (a polymerisation inhibitor) and 15 ml of dry toluene. Fit a rubber bung carrying a calcium chloride guard-tube and cool the vessel to −78 °C in an acetone–Cardice bath. During the cooling process set up the acetone–Cardice
condenser assembly (see p. 98) and charge the receiving flask with about 100 g of fresh potassium hydroxide pellets. Condense into the flask about 45 ml (27 g, 0.5 ml) of buta-1-3-diene from a cylinder, swirl well with the potassium hydroxide pellets and transfer the dried diene directly to the pressure vessel following the procedure described in Section 2.17.2, p. 98. Assemble the vessel, evacuate with an oil pump until a constant pressure is obtained (a few minutes only) and close the exit valve. Allow the apparatus to reach room temperature, wrap with heating tape and heat to 120–125 °C behind a safety screen for 48 hours. After allowing the vessel to cool to room temperature, cool further to about −15 °C and open the valve to the atmosphere. Remove the vessel cap and wash the contents of the vessel into a 1-litre round-bottomed flask with the aid of a little acetone. Remove the solvent on a rotary evaporator and crystallise the semi-solid residue from industrial spirit. The total yield (three crops) of crystallised material, m.p. 102–104 °C, is about 9 g (88%) and a pure colourless sample, m.p. 103 °C, may be obtained by further recrystallisation from industrial spirit.

**Experiment 7.24 PHOTODIMERS OF CYCLOPENT-2-ENONE**

\[
\begin{align*}
\text{Cyclopentadiene.} & \quad \text{Place 200 ml of liquid paraffin in a 500-ml, three-necked round-bottomed flask fitted with a large (30-cm) Vigreux column, a dropping funnel and a thermometer dipping into the paraffin. Attach a distillation head carrying a thermometer and a double surface condenser arranged for distillation. Heat the liquid paraffin to 200–240 °C (electric heating mantle) and add dicyclopentadiene portionwise, from the dropping funnel, and collect the cyclopentadiene, b.p. 40–42 °C, which distils over in a cooled receiver, protected from moisture. The dicyclopentadiene must be added slowly to ensure complete breakdown of the dimer; the temperature at the top of the still-head rises above 42 °C when addition is too rapid. Continue adding dicyclopentadiene (c. 300 ml) until 230 g of cyclopentadiene is obtained. The diene dimerises readily at room temperature, hence it should be used immediately or stored in the ice compartment of a refrigerator overnight.}
\end{align*}
\]
3-Chlorocyclopentene. Place 230 g (c. 285 ml) of cyclopentadiene in a 500-ml measuring cylinder which is fitted with a rubber bung through which passes two glass tubes. One of the tubes (for introducing hydrogen chloride) should reach to near the bottom of the cylinder, but the other (outlet) tube should terminate just below the bung with its other end attached to a calcium chloride guard-tube. Cool the cylinder and contents in a Cardice–acetone bath maintained at −15 to −20 °C (note the volume of the liquid), and pass in a rapid stream of hydrogen chloride gas until the volume of the reaction mixture increases by 42 ml. This takes about 4 hours when a Kipp’s apparatus is used to generate the hydrogen chloride gas. Transfer the reaction mixture to a distillation flask and distil under reduced pressure, collecting in a receiver cooled in Cardice–acetone the 3-chlorocyclopentene as a colourless liquid of b.p. 30 °C/20 mmHg. The yield is 222 g (62%). The compound is unstable at room temperature, polymerising slowly to a black tar. It should be used immediately for the next stage although it may be kept overnight in a Dewar flask packed with Cardice.

Cyclopent-2-enone. Place a solution of 180 g (0.6 mol) of sodium dichromate dihydrate in 630 ml of water in a 3-litre, three-necked round-bottomed flask equipped with an efficient stirrer, a dropping funnel and a thermometer. Cool the solution to 0 °C in an ice–salt bath and slowly add, in portions over about 1 hour, 157 g (1.53 mol) of 3-chlorocyclopentene to the rapidly stirred solution while keeping the temperature at 0–10 °C. Stir the reaction mixture at 0 °C for 0.5 hour then add 300 ml of 50 per cent sulphuric acid dropwise while maintaining the temperature at 0–10 °C by cooling. Saturate the dark brown mixture with sodium chloride and extract with five 250 ml portions of ether. Wash the combined extracts with two 150 ml portions of saturated sodium chloride, dry over magnesium sulphate and remove the ether by flash distillation. Distil the residual yellow oil under nitrogen under reduced pressure and collect the cyclopent-2-enone as a colourless liquid of b.p. 42–44 °C/13 mmHg. The yield is 58.8 g (47%). The compound has a retention time of 4.1 minutes on a 1.5-m column of Carbowax 20M on Chromosorb W maintained at 80 °C and with a nitrogen flow rate of 40 ml/minute.

Photodimerisation of cyclopent-2-enone. cis,trans,cis-3,3,8,8-Tetramethoxytricyclo[5.3.0.02,6]decane and cis,trans,cis-tricyclo[5.3.0.02,6]decane-3,10-dione. Place a solution of 49.9 g (0.61 mol) of cyclopent-2-enone in 800 ml of methanol (distilled from solid potassium hydroxide) in a photochemical reactor vessel of 1-litre capacity equipped with a 100-W medium pressure mercury arc lamp surrounded by a Pyrex cooling jacket (Section 2.17.5, p. 111), flush the magnetically stirred solution with nitrogen for 10 minutes and then irradiate under nitrogen overnight. Filter the white crystalline solid which separates and continue irradiating until no further crystalline material separates from the methanol solution. About 21.5 g of material is obtained after approximately 40 hours’ irradiation. Crystallisation from methanol gives cis,trans,cis-3,3,8,8-tetramethoxytricyclo[5.3.0.02,6]decane as white plates, m.p. 173–174 °C. The yield is 19.3 g (30%).

Remove the methanol from the filtrate remaining from the photolysis using a rotary evaporator and remove any cyclopent-2-enone which remains (c. 8.6 g) by distillation under reduced pressure. Several recrystallisations of the residual gum from carbon tetrachloride-hexane followed by a final crys-
tallisation from hexane gives cis,trans,cis-tricyclo[5.3.0.0^2.6]decane-3,10-dione, m.p. 66–67 °C. The yield is about 2.24 g (5.5%).

**Cis, trans,cis—tricyclo[5.3.0.0^2.6]decane-3,8-dione.** Dissolve 15 g (0.058 mol) of cis,trans,cis-3,8,8-tetramethoxytricyclo[5.3.0.0^2.6]decane-225 mL of dichloromethane in a 500-ml two-necked flask equipped with a sealed stirrer unit and reflux condenser. Add 30 mL of 2 M hydrochloric acid and heat the stirred mixture under reflux for 1 hour. Cool, separate the organic layer and extract the acid solution with two 40 mL portions of dichloromethane. Combine the dichloromethane solutions and wash with 50 mL of 10 per cent aqueous sodium hydrogen carbonate and then 50 mL of water. Dry over magnesium sulphate, filter and remove the solvent on a rotary evaporator. Crystallise the residual solid from carbon tetrachloride; cis,trans,cis-tricyclo[5.3.0.0^2.6]decane-3,8-dione is obtained as white plates, m.p. 125–126.5 °C. The yield is about 9.1 g (95%).

**Experiment 7.25 BICYCLO[3.2.0]HEPT-2-EN-6-ONE**

\[
\begin{align*}
\text{Cyclopentadiene} & \quad + \quad \text{Acetyl chloride} & \quad \rightarrow \quad \text{Bicyclo[3.2.0]hept-2-en-6-one} \\
& & \quad + \quad \text{Butyltin hydride}
\end{align*}
\]

*All solvents and reagents should be dried before use*

**7,7-Dichlorobicyclo[3.2.0]hept-2-en-6-one.** The reaction is conducted in a three-necked round-bottomed flask fitted with a mechanical stirrer, a condenser and a pressure-equalising dropping funnel. A solution of triethylamine (96 g, 0.95 mol) in pentane (500 mL) is added over a period of 3.5 hours to a refluxing solution of dichloroacetyl chloride (129 g, 0.875 mol) and freshly distilled cyclopentadiene (216 mL, 2.62 mol) (Expt 7.24) in pentane (1 litre). The reaction is exothermic and precipitation of triethylamine hydrochloride is instantaneous. The mixture is refluxed for an additional 2 hours and then allowed to stand overnight at room temperature. The mixture is treated with cold water and the organic phase extracted successively with 5 per cent aqueous hydrochloric acid and with several portions of 5 per cent aqueous sodium hydrogen carbonate and then dried over anydrous sodium sulphate. After removal of the solvent *in vacuo*, distillation gives 150.6 g of a fraction boiling between 50 and 65 °C/2 mmHg which still contains an appreciable amount of dicyclopentadiene. Redistillation gives 119.2 g (77%) of 7,7-dichlorobicyclo[3.2.0]hept-2-en-6-one (b.p. 67–68 °C/2 mmHg, n_25^D 1.5136) which appears homogeneous on t.l.c. and on three different g.l.c. columns (SE-30, QF-1 and 1500-Carbowax); i.r. 3050(w), 2955(m), 2855(m), 1807(s), 1608(w), 752(s) and 728(s) cm⁻¹.

**Bicyclo[3.2.0]hept-2-en-6-one.** A solution of freshly distilled tributyltin hydride (31 g, 0.108 mol) (1) in cyclohexane (30 mL) is placed in a three-necked flask equipped with a reflux condenser, a nitrogen inlet tube and a dropping funnel. The flask is flushed with nitrogen. The solution is refluxed while a solution of 7,7-dichlorobicyclo[3.2.0]hept-2-en-6-one (5.83 g, 0.054 mol) in cyclohexane containing *α,α*'-azobisisobutyronitrile (AIBN) (0.1 g, 0.6 mmol) is gradually added. After completion of the addition the mixture is distilled to give 4.38 g (75%) of bicyclo[3.2.0]hept-2-en-6-one (b.p. 62 °C/20 mmHg), n_25^D
1.4800; i.r. 3060(w), 2950(m), 2920(m), 2860(w), 1786 (s), 1608(w), 746(m) and 702(m) cm\(^{-1}\). The semicarbazone recrystallises from a mixture of methanol–water, m.p. 218–219 °C.

**Note.** (1) Tributyltin hydride is prepared according to a slight modification of the literature procedure. A solution of lithium aluminium hydride (4.75 g, 0.136 mol) in anhydrous ether (400 ml) is placed in a three-necked round-bottomed flask equipped with a mechanical stirrer, a condenser, a nitrogen inlet tube and a pressure-equalising dropping funnel containing tributyltin chloride (100 g, 0.308 mol). The system is flushed with nitrogen and then tributyltin chloride is added dropwise at a rate which maintains a gentle reflux of ether. The resulting mixture is stirred for 7 hours. Careful addition of water to the cooled mixture destroys the excess lithium aluminium hydride. The ether solution is decanted, washed with three 100 ml portions of water and dried over calcium sulphate. Evaporation of the solvent and distillation under high vacuum gives 68 g (78%) of tributyltin hydride (b.p. 68–69 °C/0.3 mmHg, \(n_D^5\) 1.4688) which is kept under an argon atmosphere.

**Experiment 7.26 1,4-NAPHTHOQUINONE PHOTODIMER**

![Diagram of 1,4-Naphthoquinone Photodimer]

**Method A.** Place a solution of 5 g of pure, 1,4-naphthoquinone (1) in 115 ml of dry thiophene-free benzene (CAUTION) in the appropriate sized photochemical reactor vessel (Section 2.17.5, p. 111; note also the precautions to be observed for photochemical reactions) fitted with a 100-W medium pressure mercury arc lamp surrounded by Pyrex cooling jackets. Stir the solution by means of a magnetic follower bar and pass dry nitrogen through the solution for 10 minutes before switching on the lamp; adjust the nitrogen flow to a slow trickle and continue irradiation for about 6 hours, by which time a quantity of the solid dimer will have separated from the solution. Switch off the lamp, remove the lamp insert and collect the solid by suction filtration and wash with a little benzene. Gently remove and collect any of the solid which may have separated on the surface of the lamp insert and thoroughly clean the latter with a little acetone on a paper tissue before replacing the benzene filtrate in the reactor and continuing the irradiation process. Repeat these operations as appropriate and collect the dimer over a total irradiation period of about 28 hours; about 0.84 g of solid, m.p. 243–246 °C (decomp.) (2), is obtained. Recrystallise from 150–160 ml of glacial acetic acid with the aid of a little decolourising carbon and dry the pale straw-coloured crystals in a desiccator over solid sodium hydroxide pellets; the yield of pure naphthoquinone dimer, m.p. 245–249 °C (decomp.), is 0.62 g (12%).

**Method B.** Place a solution of 2.5 g of pure 1,4-naphthoquinone (1) in 50 ml of dry thiophene-free benzene in a 50-ml round-bottomed flask and pass a slow stream of dry nitrogen through the solution for 5 minutes. Insert a lightly greased stopper in the flask taking care that the solution does not penetrate the joint. Place the flask in a sunny position – if situated in the open air wrap some aluminium foil around the stopper to prevent the possibility of rainwater seeping through the joint into the reaction mixture. Solid slowly
separates from the solution over a period of days; collect the product by suction filtration, wash with a little benzene and dry. Return the filtrate to the flask, flush with dry nitrogen and place in the sunlight until a further portion of solid is ready for collection. The amount of material obtained in a given period is dependent on light conditions; typically, a total of 0.33 g (13%) of crude naphthoquinone photodimer, m.p. 241–246°C (decomp.), has been obtained during a 31-day irradiation period (April–May).

Notes. (1) Technical grade naphthoquinone may be purified as described in Expt 6128.

(2) The melting point is best observed on a microscope–hot stage apparatus.

REFERENCES

25. See references 3(a), 3(c) and 3(d) in Chapter 1 of this volume.
The methods of preparation which are considered in this chapter involve, principally, ring-forming reactions leading to a restricted and subjective selection of various typical and interesting heterocyclic systems. These cyclic systems may be classified as (a) saturated or partly unsaturated heterocyclic, or (b) heteroaromatic, according to their physical, chemical and spectroscopic properties and to the reactivity of the functional groups attached to the ring atoms. In this way such properties and reactivity are broadly related to those of alicyclic and aromatic compounds.

In this chapter the material is subdivided first on the basis of ring size (8.1, three-membered; 8.2, four-membered; etc.) and thence according to the ring-forming reaction type. Where appropriate, routes to selected target molecules are analysed in a retrosynthetic sense. The reader’s attention is drawn to a book on heterocyclic chemistry¹ which includes a more detailed theoretical treatment of the kinetic and thermodynamic factors of these ring-forming reactions; this book also cites many examples of heterocyclic compounds which play an important role in biological systems.

The spectroscopic features of the heterocyclic ring systems may be inferred from the data noted in the correlation tables (Appendices 2, 3 and 4). Since the range of one- and multi-heteroatom systems is so diverse, a generalised discussion of these features would be too extensive for the scope of this book. Illustrative and descriptive accounts are included in appropriate preparative sections.

8.1 THREE-MEMBERED HETEROCYCLES

The parent saturated three-membered ring systems containing nitrogen, or oxygen, or sulphur as the heteroatom are known as aziridine (1), oxirane (2) and thirane (3).

\[
\begin{align*}
\text{(1)} & \quad \text{(2)} & \quad \text{(3)} \\
\text{NH} & \quad \text{O} & \quad \text{S}
\end{align*}
\]

Four illustrative methods for the synthesis of these systems or their substituted analogues are as follows.

1. Intramolecular cyclisation of a 1,2-bifunctional compound.
2. Insertion of a methylene group into a carbon–heteroatom double bond.
3. Insertion of a heteroatom into a carbon–carbon double bond.
8.1.1 INTRAMOLECULAR CYCLISATION OF A 1,2-BIFUNCTIONAL COMPOUND

A generalised retrosynthetic analysis involving disconnection of the carbon–heteroatom bond may be depicted as follows.

\[
\begin{array}{c}
\text{X} \\
\text{X}^{\ominus}
\end{array}
\rightarrow
\begin{array}{c}
\text{X}^{\ominus} \\
\text{Y}
\end{array}
\]

The reagent equivalent therefore requires an anionic site at the heteroatom, and a good leaving group at the vicinal position.

An illustrative example of oxirane formation by the action of alkali on a \( \beta \)-halohydrin is to be found in the reaction sequence involved in the Darzens glycidic ester synthesis (Section 5.7.6, p. 598). Three target molecules, namely 2-phenylaziridine (4), methyl (S)-thiiranecarboxylate (5) and cyclooctene sulphide (6), are selected here to exemplify this intramolecular cyclisation reaction type.

In the case of 2-phenylaziridine (4) the leaving group may originate from the hydroxyl function of 2-amino-1-phenylethanol by treatment with sulphuric acid to convert it into a sulphate ester which is then cyclised by treatment with base\(^2\) (Expt 8.1).

\[
\begin{array}{c}
\text{Ph} \\
\text{NH}_2
\end{array}
\rightarrow
\begin{array}{c}
\text{Ph} \\
\text{O} \cdot \text{SO}_{3}^{\ominus}
\end{array}
\rightarrow
\begin{array}{c}
\text{Ph} \\
\text{NH}
\end{array}
\]

This method is generally useful for the formation of various substituted aziridines by suitable selection from a range of readily available alkanolamines.

The formation of methyl (S)-thiiranecarboxylate (5) is of interest,\(^3\) since in this case the leaving group is a diazo residue originating from an amino group. The starting material is therefore the chiral amino acid ester, methyl (R)-cysteinate, and the stereoelectronic requirements of the reaction lead to an optically pure product of predictable stereoisomeric form (Expt 8.2).

\end{array}
\]

A further example of this general type of reaction is provided by the synthesis of cyclooctene sulphide (6).\(^4\) Here an alkene is converted into an adduct with succinimide-\(N\)-sulphenyl chloride (reaction formulated in full in Expt 8.3), which is reduced with lithium aluminium hydride at \(-78^\circ\text{C}\) to form the product.
Experiment 8.1 2-PHENYL AZIRIDINE

\[
\text{Ph-CH(OH)} \cdot \text{CH}_2 \text{NH}_2 \xrightleftharpoons{\text{H}_2\text{SO}_4} \text{Ph-CH(O-SO}_3^\ominus) \cdot \text{CH}_2 \text{NH}_3 \quad \text{base} \quad \text{NH}
\]

CAUTION: All three-membered nitrogen heterocycles must be handled with great care as they may be highly toxic, and frequently are foul smelling. All operations therefore should be conducted in an efficient fume cupboard and disposable plastic gloves must be worn.

An aqueous solution of 2-amino-1-phenylethanol (0.5 mol) is neutralised to a methyl red end-point with 50 per cent aqueous sulphuric acid, followed by the addition of a further equal volume of aqueous acid. Water is removed by heating the solution at 10–15 mmHg, finally at 130 °C. The product crystallises and is coarsely ground and heated at 120–130 °C under reduced pressure to constant weight.

The conversion of the sulphate ester (0.5 mol) into the aziridine is carried out by dissolving it in 1 litre of 2 M sodium hydroxide held at 0 °C, and then slowly heating the resulting solution in an oil bath. At approximately 90 °C, the aziridine product separates from the solution as an upper layer. The reaction mixture is then steam distilled until a fresh portion of the distillate gives a neutral reaction. The product is separated from the aqueous distillate and dried over potassium hydroxide pellets. Fractional distillation using a 24-inch Podbielniak tantalum spiral column affords a 90 per cent yield of 2-phenylaziridine, b.p. 94–94 °C/10 mmHg. Gas–liquid chromatography analysis through a 10-ft column of 20 per cent Carbowax 20M reveals a single peak.

Experiment 8.2 METHYL (S)-THIIRANECARBOXYLATE

\[
\begin{align*}
\text{HS} & \quad \text{HCO}_2\text{Me} \xrightarrow{\text{HNO}_2} \text{H} \quad \text{CO}_2\text{Me} \\
\text{NH}_2 & \quad \xrightarrow{\text{S}} \quad \text{S} \\
\end{align*}
\]

Sodium nitrite (2.07 g, 30 mmol) is added in one portion to a solution of methyl (R)-cysteinate (1.35 g, 10 mmol) (1) in 1 M hydrochloric acid (50 ml) at 0 °C. The solution develops a deep red coloration which partly fades within a few minutes. After 5 minutes the mixture is extracted three times with chloroform and the organic layer dried over magnesium sulphate and evaporated. Purification of the product by chromatography on aluminium (Brockmann activity III, light petroleum (b.p. 40–60 °C) as eluant) affords methyl (S)-thiiranecarboxylate (0.555 g, 47%) as a chromatographically homogeneous liquid; \([\alpha]_D -25^\circ\) (c 2.8 in CHCl₃); p.m.r. (CDCl₃, TMS) \(\delta 2.68\) (d of d, 1H, \(J = 1.0\) and 5.9 Hz, SCHHCH), 2.90 (d of d, 1H, \(J = 1.0\) and 4.8 Hz, SCHCH), 3.45 (d of d, 1H, \(J = 5.9\) and 4.8 Hz, SCHCH₂), and 3.80 (s, 3H, Me); m/z 118 (M) and 86 (C₃H₆O₂S®, base peak).
Note. (1) This amino ester is prepared as the corresponding hydrochloride by heating (R)-cysteine hydrochloride in methanol saturated with hydrogen chloride, followed by evaporation (cf. Expt 8.7). The hydrochloride is partitioned between dichloromethane and sodium hydrogen carbonate solution; evaporation of the organic layer affords the pure amino ester which is used immediately.

Experiment 8.3 CYCLOOCTENE SULPHIDE

\[
\text{NH} \quad \rightarrow \quad \text{K}^+ \quad \overset{\text{S}_2\text{Cl}_2}{\rightarrow} \quad \left[ \overset{-}{\text{S}} \right] \quad \text{Cl}_2 \quad \overset{\text{LiAlH}_4}{\rightarrow} \quad \text{S}
\]

CAUTION: The use of sulphur monochloride and of chlorine gas in these reactions makes it imperative that they are carried out in an efficient fume cupboard.

\(N,N^\prime\)-Dithiobis(succinimide). A hot solution of succinimide (100 g) in absolute ethanol (1 litre) is poured into an ice-cold solution of potassium hydroxide (58 g) in absolute ethanol (300 ml). The mixture is stirred and cooled to 0°C. Potassium succinimide crystallises from the mixture as colourless crystals, and is collected by suction filtration. After washing with light petroleum (b.p. 60–80°C) the crystals are dried (110.3 g, 79.1%). A solution of sulphur monochloride (54 g) in dichloromethane (50 ml) is added over 5 minutes to a vigorously stirred suspension of the potassium succinimide (110.3 g) in dichloromethane (400 ml) at 0°C. After the initial exothermic reaction, the mixture is stirred for a further 5 minutes, filtered and the filtrate evaporated in vacuo to leave a solid residue, which is washed three times with light petroleum (b.p. 60–80°C) and once with water. Crystallisation from methanol gives colourless plates of \(N,N^\prime\)-dithiobis(succinimide) (83 g, 79.3%), m.p. 192–193°C; \(m/z\) 260, 162, 134, 102, 99 and 55.

Succinimide-\(N\)-sulphenyl chloride. Chlorine gas (CAUTION) is passed for 8 hours through a stirred solution of the foregoing compound (53.7 g) in chloroform (250 ml) warmed to 50°C. Nitrogen gas is passed through the mixture to remove excess chlorine, followed by evaporation in vacuo to give succinimide-\(N\)-sulphenyl chloride (65.1 g, 93.3%) as yellow crystals, m.p. 65–67°C.

Cyclooctene sulphide. The foregoing imidosulphenyl chloride (6.6 g, 0.04 mol) is dissolved in dichloromethane (25 ml) to form a yellow solution which is added dropwise at room temperature to cyclooctene (4.5 g, 0.041 mol) in dichloromethane (50 ml). The mixture is stirred until no yellow colour persists.
Removal of the solvent under reduced pressure gives the adduct, trans-N-(2-chlorocyclooctylthio)succinimide (9.4 g, 85.3%), m.p. 83–85 °C (from ether); m/z 277, 275, 260, 239, 211, 176, 141, 109 and 99.

The foregoing adduct (9.4 g, 0.034 mol) is dry tetrahydrofuran (25 ml) is added dropwise to a stirred suspension of lithium aluminium hydride (1.1 g) in tetrahydrofuran (10 ml) at −78 °C under nitrogen. After stirring for 10 minutes, the mixture is allowed to warm to room temperature and then quenched with water. The episulphide is extracted with ether and, after drying over magnesium sulphate, the solvent is removed and the residue distilled under reduced pressure to afford cyclooctene sulphide (4.7 g, 97.35%), b.p. 50 °C/2 mmHg.

8.1.2 INSERTION OF A METHYLENE GROUP INTO A CARBON–HETERATOM DOUBLE BOND

This method is illustrated by the synthesis of the target molecules 1,2-diphenyl-aziridine (7) and phenyloxirane (8).

A retrosynthetic disconnection in the case of each of these molecules gives a methylene group synthon, and benzylideneaniline and benzaldehyde from (7) and (8) respectively.

The most convenient reagent equivalent is a methylene transfer reagent which arises from the action of base on either a trimethyloxosulphonium salt (see Section 7.3) or a trimethylsulphonium salt. In this latter case dimethylsulphonium methylide (Me₂S·CH₂) may be generated by the action of sodium hydride or butyllithium. However, a PTC method which is applicable to the synthesis of both target molecules (Expts 8.4 and 8.5) offers a convenient alternative. Here benzylideneaniline⁶ or benzaldehyde⁷ in dichloromethane solution containing the phase transfer catalyst is stirred with a suspension of trimethylsulphonium iodide in aqueous sodium hydroxide. The mechanism of the reaction is illustrated with reference to the aziridine synthesis.
Experiment 8.4 1,2-DIPHENYLAZIRIDINE

\[
\text{Ph-CH=NN-Ph + Me}_3\text{S}^\oplus\text{I}^{\oplus} \xrightarrow{\text{PTC}} \text{Ph-CH=N-Ph}
\]

CAUTION: See cautionary note in Expt 8.1.

Benzyldeneaniline (18.1 g, 0.1 mol) and tetrabutylammonium hydrogen sulphate (0.5 g, 1.35 mol) are dissolved in dichloromethane (100 ml) and a layer of 50 per cent aqueous sodium hydroxide introduced under this solution. Trimethylsulphonium iodide (20.4 g, 0.1 mol) is then added and the whole warmed at 50 °C with vigorous stirring for 2 hours, whereupon the originally undissolved sulphonium salt disappears. The mixture is poured on to ice, the organic phase separated, washed with water and dried. The solvent is evaporated and the residue distilled under reduced pressure to afford 1,2-diphenylaziridine (94%), b.p. 120 °C/0.05 mmHg.

Experiment 8.5 PHENYLOXIRANE (1,2-Epoxyethylbenzene)

\[
\text{Ph}^\text{=C-H + Me}_3\text{S}^\oplus\text{I}^{\oplus} \xrightarrow{\text{PTC}} \text{Ph}^\text{=C-O-Ph}
\]

Dissolve 5.3 g (0.05 mol) of benzaldehyde (previously shaken with sodium hydrogen carbonate solution) and 0.25 g (0.67 mmol) of tetrabutylammonium iodide in 50 ml of dichloromethane. Place this solution in a 250-ml, three-necked round-bottomed flask equipped with an efficient sealed stirrer unit, a reflux condenser and a thermometer sited in a screw-capped adapter, and supported in an oil bath mounted on an electric hot plate. Introduce 50 ml of a 50 per cent (w/v) aqueous solution of sodium hydroxide, and then 10.2 g (0.05 mol) of finely powdered trimethylsulphonium iodide. Adjust the electric hot plate so that the oil bath is maintained at a constant temperature of 55 °C for 60 hours and during this period stir the reaction mixture rapidly (1). Pour the reaction mixture on to ice, separate the organic phase and extract the aqueous solution with one 20 ml portion of dichloromethane. Wash the combined organic phases successively with four 20 ml portions of water, two 10 ml portions of a saturated solution of sodium metabisulphite and finally two 20 ml portions of water. Dry the organic phase over anhydrous calcium sulphate, remove the dichloromethane on a rotary evaporator and distil the residue. Collect the phenyloxirane as a fraction having b.p. 191–192 °C; the yield is 4.7 g (78%).

Note. (1) The reaction may be monitored by observing the diminution of carbonyl absorption in the infrared spectrum of successive samples withdrawn from the organic phase, after allowing the dichloromethane to evaporate from a portion placed on a sodium chloride plate. Alternatively samples of the reaction medium may be analysed by g.l.c. using a 10 per cent Carbowax column on Chromosorb W held at 150 °C with a nitrogen carrier gas flow rate of 40 ml/minute; benzaldehyde has \( t_R \) 2 minutes and phenyloxirane has \( t_R \) 2.75 minutes.

8.1.3 INSERTION OF A HETEROATOM INTO A CARBON–CARBON DOUBLE BOND

The most important example of this method is the epoxidation of an olefinic bond. The reaction is illustrated by the synthesis of the target molecules trans-
1,2-dibutyloxirane (9), phenyloxirane (8) and (2S,3S)-epoxygeraniol (10) formed from trans-dec-5-ene,\textsuperscript{8} styrene, and geraniol [(E)-3,7-dimethylocta-2,6-dien-1-ol]\textsuperscript{10b} respectively (Expt 8.6).

\[
\begin{align*}
\text{(8)} & \quad \text{Bu} \quad \text{O} \\
\text{(9)} & \quad \text{Bu} \quad \text{O} \\
\text{(10)} & \quad \text{Me} \quad \text{Me} \quad \text{OH} \\
\end{align*}
\]

The epoxidation reaction is achieved most conveniently by employing m-chloroperbenzoic acid (or perbenzoic acid) in a solvent such as chloroform. The use of other peracids, such as peracetic acid or pertrifluoroacetic acid, give lower yields of the oxirane since the oxide may be readily cleaved to form the monoester of the diol (e.g. Section 5.4.5, p. 547).

The regioselectivity of this reaction in the case of certain dienes is of interest, since it has been found that the most highly substituted double bond is preferentially attacked, for example as in the mono-epoxidation of 1,2-dimethylcyclohexa-1,4-diene\textsuperscript{9} (formed by the Birch reduction of o-xylene, Section 7.5, p. 1114).

\[
\begin{align*}
\text{Me} & \quad \text{Me} \\
\text{Me} & \quad \text{Me} \\
\text{Me} & \quad \text{Me} \\
\end{align*}
\]

It should be noted that although oxiranes (8) and (9) are chiral, this epoxidation methodology gives the racemate since no chiral inducing agent is present.

However, the asymmetric synthesis of optically active oxiranes has been the subject of much research activity in recent years. This arises from the fact that the synthesis of stereoisomerically pure structural units, required for the total synthesis of a range of biologically active compounds, may be effected by using the many ring-opening reactions of chiral oxiranes (e.g. reduction, acidic hydrolysis, base-catalysed reactions, reaction with organometallic compounds, etc.). In particular the asymmetric epoxidation of allylic alcohols with t-butyl hydroperoxide in the presence of titanium(IV) isopropoxide-diethyl tartrate catalyst is a significant and important step forward in this methodology (the Sharpless epoxidation reaction). A preparative example, for which precise experimental details have been published,\textsuperscript{10a} is the conversion of (E)-hex-2-en-1-ol into (2S,3S)-3-propyloxiranemethanol in 96.8 per cent enantiomeric purity using diethyl (2R,3R)-(+)-tartrate [(R,R)-DET]; the enantiomeric oxirane is obtained by the use of diethyl (−)-tartrate.

\[
\begin{align*}
\text{HO} & \quad \text{H} & \quad \text{Me} & \quad \text{Ti(OR')}_4 & \quad \text{Ti(DET)(OR')}_2 & \quad 2\text{R'}\text{OH} \\
\text{Me} & \quad \text{H} & \quad \text{Ti(OR')}_4 & \quad \text{Ti(DET)(OR')}_2 & \quad 2\text{R'}\text{OH} \\
\end{align*}
\]

This reaction has now been applied to a very great number of substituted allylic alcohols, and the mechanistic and stereoisomeric features of the reaction are becoming clearer.\textsuperscript{11} In broad outline, it would appear that the initial step is an alkoxy-exchange reaction between two alkoxy residues in the titanium complex and the two hydroxy groups in the tartrate ester, thus:

\[
\text{Ti(OR')}_4 + \text{DET} \rightleftharpoons \text{Ti(DET)(OR')}_2 + 2\text{R'}\text{OH}
\]
Subsequently the remaining isopropoxide residues in the resulting complex (11) undergo exchange with the hydroxyl group of the allylic alcohol and the hydroxyl group of the peroxide to give the complex (12); further coordination activates the peroxide and the topography of this complex (13) determines the favourable enantioselective transfer of oxygen to the carbon–carbon double bond to give complex (14). The epoxidised allylic alcohol and the t-butyl alcohol are then released by further exchange reactions with the allylic alcohol and peroxide.

The methodology used for the asymmetric epoxidation of geraniol to give (10), (2S,3S)-epoxygeraniol (Expt 8.6, cognate preparation), illustrates a general procedure which employs 1.5 equivalents of t-butyl hydroperoxide with catalytic amounts (<10%) of titanium(iv) isopropoxide and of diethyl tartrate.\(^{10b}\)

The success of this procedure depends on the presence of 3A or 4A molecular sieves since moisture, from no matter what source, contributes to a lowering of enantioselectivity and a slowing of reaction rate.

**Experiment 8.6 TRANS-1,2-DIBUTYLOXIRANE (trans-Dec-5-ene oxide)^8**

**CAUTION:** All operations, particularly distillations, should be conducted behind a safety screen.

Into a stirred solution of \(m\)-chloroperbenzoic acid (15.0 g, 87 mmol) in chloroform (150 ml) held at 0 °C is added trans-dec-5-ene (10 g, 70 mmol) dissolved in chloroform (50 ml) over a 30-minute period. The mixture is stirred overnight at room temperature, filtered, washed with 10 per cent sodium hydrogen carbonate solution (1) and dried over anhydrous sodium sulphate. The solvent is removed by rotary evaporation and the epoxide distilled under reduced pressure, affording 9.6 g (88%) of product having b.p. 71–72°C/
12 mmHg; p.m.r. (CDCl<sub>3</sub>, TMS) δ 0.97 (t, 6H, 2 Me), 1.45 (m, 12H, 6 CH<sub>2</sub>), 2.63 (m, 2H, 2 CH—O).

**Note.** (1) It is advisable to test for the complete disappearance of peracid (see below) before proceeding.

**Cognate preparations.** **Phenyloxirane** (**styrene oxide**). Use of perbenzoic acid. Use 42 g (0.29 mol) of perbenzoic acid (**CAUTION**, see Section 4.2.56, p. 455), in 350 ml of dichloromethane and 30 g (0.29) of styrene in 100 ml of dichloromethane. Stir the reaction mixture at 0°C for 24 hours. Only a slight excess of peracid remains; confirm this by mixing an aliquot portion with excess of acidified potassium iodide and titrating with standard sodium thiosulphate solution. Work-up as described above and distil the dried dichloromethane solution through an efficient fractionating column. Styrene oxide passes over at 189–192°C (or at 101°C/40 mmHg); the yield is 25 g (72%).

**Catalytic asymmetric epoxidation of (E)-3,7-dimethylocta-2,6-dien-1-ol** (**geraniol**).<sup>10b</sup> Preparation of anhydrous t-butyl hydroperoxide (TBHP) in dichloromethane. **CAUTION** (1). Solutions of TBHP in dichloromethane are prepared as described previously for toluene solutions with minor modifications.<sup>10a</sup> Two litres of aqueous 70 per cent TBHP (2) and 2 litres of dichloromethane are shaken in a separatory funnel. The lower, organic phase is transferred to a 5-litre flask fitted with a heavier-than-water solvent Dean-Stark trap (Ace Glass Co.) with condenser. Although the literature authors report that they have never experienced a problem with this procedure, they advise that all heating should be done behind an adequate blast shield in a well-ventilated fume hood. After addition of a few boiling chips, the mixture is brought to a gentle reflux by using a heating mantle set on a low voltage. Periodically the collected water is removed from the trap. After 10 hours about 50 ml have been removed, and no more water is observed in the azeotrope. The TBHP solution (c. 2.5 litres) is divided into two batches, and each is finally dried in a refrigerator for several hours (usually overnight) over 200–300 g of activated 3A sieve pellets (3) either in a flask covered with cellophane or in a polyethylene bottle. The solutions (about 50% v/v TBHP, 5–6 m) are then transferred to high density polyethylene bottles and stored over activated 3A molecular sieve pellets at 0–5°C. When properly capped, polyethylene bottles develop negative pressure upon cooling in the refrigerator and compress. Such solutions have been stored for months without loss of effectiveness and only slight loss of titre (5–10%, possibly due to constant use, and thus warming). Assay of the solution is effected by iodometric titration as follows. An 0.1 m aqueous sodium thiosulphate solution is prepared (12.4 g of sodium thiosulphate pentahydrate with enough water to make 500 ml suffices for 15 to 20 titrations), and 50 ml of this solution is placed in a 50-ml graduated burette. A 250-ml Erlenmeyer flask is charged with 25 ml of propan-2-ol and 1 ml of glacial acetic acid. To this is added 10 ml of a freshly prepared, cooled solution of 20 g of sodium iodide in 100 ml of warm propan-2-ol. After addition of 0.25 ml of anhydrous TBHP/dichloromethane solution (4), the mixture is heated to reflux (with stirring on a hot plate) and refluxed for 30–45 seconds. Failure to reflux the solution will result in a low titre. After dilution with 100 ml of distilled water, the warm solution is titrated rapidly with the 0.1 m sodium thiosulphate (25–30 ml required) to the disappearance of the
yellow iodine colour. Starch indicator may be used towards the end of the titration to enhance the end-point. The concentration is calculated according to the equation \([(\text{molarity of titrant}) \times (\text{ml of titrant})/(\text{ml of TBHP solution}) \times 2]\), and should be in the range 5–6 M. The active oxygen content of a 5.0 M (45 wt %) TBHP/dichloromethane solution is about 7 wt per cent. Solutions of lower molarity are obtained either by dilution just prior to titration or by addition of less than 70 per cent TBHP at the start of the procedure. In any case, a flask size should be selected which ensures that the liquid remains above the top of the heating mantle throughout the azeotropic process, with the addition of more dichloromethane if necessary.

(2S,3S)-Epoygeraniol. A mixture of powdered, commercially activated 4A molecular sieves (5) (1.8 g, Aldrich, 15–20 wt % based on substrate) and 100 ml of dichloromethane (6) is cooled to \(-10^\circ\text{C}\) (7). (2R,3R)-(+-)-Diethyl tartrate (8) (1.00 g, 4.8 mmol), titanium(IV) isopropoxide (9) (0.91 g, 3.2 mmol), and t-butyl hydroperoxide (4) (15.6 ml, 97 mmol, 6.2 M in dichloromethane) are added sequentially. After 10 minutes, the mixture is cooled to \(-20^\circ\text{C}\) and freshly distilled geraniol (10.0 g, 65 mmol, in 10 ml of dichloromethane) is added dropwise, with vigorous overhead stirring, over a 15 minute period.

After 45 minutes of stirring at \(-20^\circ\text{C}\) to \(-15^\circ\text{C}\), the reaction is warmed to 0°C (5 minutes) and quenched with water [20 ml, c. 20 times the weight of Ti(OPr')₄ used in the reaction]. Upon warming to room temperature (10 minutes), phase separation is apparent (aqueous suspension above a clear to slightly cloudy organic phase). Without separation, hydrolysis of tartrates is effected by adding 4.5 ml of a 30 per cent aqueous solution of sodium hydroxide saturated with sodium chloride. After 10 minutes of vigorous stirring, sudden, dramatic phase separation occurs. The lower (organic) phase is removed and combined with two extractions of the aqueous phase (dichloromethane, 2 x 10 ml) (10). The combined organic phases are dried over magnesium sulphate and filtered through analytical grade Celite to give a clear, colourless solution, which turns bluish (TiO₂) on standing (11). Concentration, followed by Kugelrohr distillation (140°C, 1.0/mmHg) gives (2S,3S)-epoxygeraniol as a colourless oil [10.95 g, 99%, purity c. 95% by n.m.r. (12), [α]D recreational 5 - 5.3° (c 3.0 in CHCl₃)].

Notes. (1) The literature authors note that this procedure has been carried out many times without incident. However, they warn that solutions of oxidants and oxidisable substances are potentially hazardous and possibly subject to violent decomposition by adventitious catalysts. They state that the following rules should be applied when handling solutions of TBHP. The first rule is never to add a strong acid (not even a drop) to high strength TBHP solutions. The second rule is never to add transition-metal salts known to be good autooxidation catalysts to high strength TBHP solutions (Mn, Fe and Co are particularly bad). Alkyl hydroperoxides are sensitive to metal-catalysed radical-chain decomposition. Among other things, this produces oxygen gas. The third rule is never to work with pure TBHP and avoid using high strength solutions of it whenever possible. They do not recommend storing TBHP solutions in glass bottles due to the slight danger of gas evolution. Instead they recommend high density polyethylene bottles, even though there may be some solvent migration through the walls of the bottle.

(2) Aqueous 70 per cent t-butyl hydroperoxide (TBHP) is obtained from Aldrich Chemical Co.
(3) Activation of crushed or pelleted 3A molecular sieves involves heating in a vacuum oven at 160 °C and 0.05 mm pressure for at least 3 hours.

(4) Cold stock solutions of TBHP in dichloromethane should be warmed to room temperature prior to opening (warm water baths are convenient), in order to minimise exposure to moisture. Somewhat more than the required amount of solution should then be dispensed into a small flask or graduated cylinder containing activated 3A or 4A sieve pellets and stoppered. After a few minutes, the desired volume of solution is transferred to the reaction flask, either by syringe, addition funnel, or direct addition. Syringe needles should never be inserted into any stock solution of TBHP which is to be stored.

(5) Preactivated, powdered 4A sieves are available from Aldrich Chemical Co.

(6) Dichloromethane (EM Reagent) is not distilled but is stored over activated 3A molecular sieves. 4A sieves should not be used since pressurisation of bottles of dichloromethane containing 4A sieves has been observed.

(7) The flask used for this reaction is three-necked and round-bottomed, fitted with an overhead mechanical stirrer, thermometer, and either a septum or an addition funnel. The internal temperature is carefully monitored. All equipment is either flame dried under vacuum or cooled under vacuum after storage in an oven at 125 °C. The reaction is carried out under an inert atmosphere (nitrogen or argon) in order to exclude atmospheric moisture. All additions are made either by addition funnel or syringe. Cooling is effected by using a water–ethylene glycol (70:80) dry ice bath.

(8) Diethyl tartrate is used as obtained from Aldrich Chemical Co.

(9) Titanium(iv) isopropoxide is distilled under vacuum and stored under an inert atmosphere. Neither the tartrate ester nor the titanium isopropoxide should be stored over sieves. Reagents handled by syringe are measured by weight rather than by volume.

(10) During any separations, if the phases do not immediately separate, c. 5 per cent v/v methanol should be added. After very brief shaking, clean phase separation generally occurs, leaving an almost clear organic phase below a milky aqueous phase.

(11) If the mixture is allowed to stand for a longer period after the addition of magnesium sulphate, no titanium will be found in solution after filtration.

(12) The c. 5 per cent impurity seen in the n.m.r. is related to an impurity in the geraniol, possibly a double bond isomer.

### 8.1.4 HETEROATOM EXCHANGE

Since the above methods provide a range of procedures for the formation of oxiranes, the exchange reaction of oxygen to sulphur is a convenient method for thiirane synthesis. A simple procedure involves stirring the oxirane in toluene solution with a potassium thiocyanate-on-silica gel reagent. A drawback of this reaction is that the rate is slow in the case of disubstituted oxiranes. The reaction is highly stereospecific in that, for example, trans-oxiranes yield trans-thiiranes. A probable mechanism is given below and involves a double inversion process which explains the high stereospecificity.
8.2 FOUR-MEMBERED HETEROCYCLES

An important group of four-membered heterocyclic compounds are the derivatives of the $\beta$-lactam [azetidin-2-one (15)] system. Many of the compounds are biologically active, for example, the monocyclic nocardicins [e.g. (16)] and the bicyclic penicillin and cephalosporin antibiotics [e.g. (17) and (18) respectively], and the $\beta$-lactamase inhibitors of the clavam group (19).

The numerous methods which are available for the synthesis of substituted $\beta$-lactams involve a variety of ring-forming strategies. Two categories only are selected and exemplified below to illustrate some of the interesting chemistry involved: Cyclisation reactions; and Cycloaddition reactions.

8.2.1 CYCLISATION REACTIONS

The target molecule ethyl $\alpha$-[p-(benzylxoy)phenyl]-2-oxo-1-azetidineacetate (20) (Expt 8.7) is an intermediate in the synthesis of one of the compounds of nocardicin group. It is an interesting example with which to illustrate the application of retrosynthetic analysis in this field.

$$\begin{align*}
\text{CON}=\text{NC}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_2\cdot\text{Ph} & \quad\rightarrow\quad \text{H}_2\text{C}=\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_2\cdot\text{Ph} \\
\text{Br}-\text{CH}^+\text{NH} & \quad\rightarrow\quad \text{Br}_2\text{CH}^+\text{NH} \\
\text{Br}-\text{CO} & \quad\rightarrow\quad \text{Br}_2\text{CO} \\
\text{Br}-\text{Cl} + \text{H}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_2\cdot\text{Ph} & \quad\rightarrow\quad \text{H}_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{OH}(p)
\end{align*}$$
The retrosynthetic analysis given above involves an initial disconnection at the N—C₄ bond, although it should be pointed out that disconnections at some of the other bonds have been variously explored in the literature. The synthesis of the reagent equivalent (22) of the synthon (21) may be seen to require reaction of a doubly protected p-hydroxyphenylglycine derivative with 3-bromopropionaldehyde chloride in the presence of base. The protection sequence (formulated in Expt 8.7) for the amino acid is: (i) esterification of the carboxyl group; (ii) conversion of the amino group into a benzylidene derivative; (iii) benzylolation of the phenolic hydroxyl group; and (iv) deprotection of the amino group by hydrolysis. The protected amino acid is finally isolated as the toluene-p-sulphonate salt.

The cyclisation of (22) to the β-lactam system, which is a thermodynamically unfavourable reaction, is promoted by using sodium hydride as the base in a dichloromethane–dimethylformamide solvent system at high dilution.

**Experiment 8.7 ETHYL α-[p(BENZYLOXY)PHENYL]-2-OXO-1 AZETIDINEACETATE**

![Chemical structure image](image)

2-(p-Hydroxyphenyl)glycine ethyl ester. To a suspension of 2-(p-hydroxyphenyl)glycine (10.0 g, 59.8 mmol) in absolute ethanol (40 ml) is added concentrated sulphuric acid (8 ml). The resulting yellow solution is heated at reflux for 2 hours, cooled to 0°C and neutralised with concentrated aqueous ammonia solution. The precipitated product is then collected by filtration, washed with cold water, and recrystallised from aqueous ethanol to give 4.9 g (42%) of pure amino acid ester, m.p. 160–162°C; i.r. (KBr disc) 3250, 2800–2100, 1700, 1575 cm⁻¹; p.m.r. (Me₄SO-d₆/CDCl₃, TMS) δ 1.14 (t, J = 7 Hz, 2H), 4.05 (q, J = 7 Hz, 2H), 6.68 (d, J = 9 Hz, 2H) and 7.12 (d, J = 9 Hz, 2H).

2-[(p-Benzylxyloxy)phenyl]glycine ethyl ester hydrotosylate. A mixture of 2-(p-hydroxyphenyl)glycine ethyl ester (2.7 g, 14.6 mmol), benzaldehyde (1.6 g, 15.1 mmol), and a catalytic amount of toluene-p-sulphonic acid monohydrate is added to dimethylformamide (25 ml) containing 4 A molecular sieves (5 g). The mixture is stirred at 40°C under nitrogen for 12 hours, decanted to remove the sieves and treated with anhydrous potassium carbonate (2.8 g, 20.3 mmol) followed after 15 minutes by dry benzyl chloride (1.9 g, 15 mmol). After being heated at 60°C for 16 hours, the reaction mixture is poured onto to 10 per cent hydrochloric acid (50 ml), stirred for 15 minutes and then

1139
extracted with ether (2 × 50ml). Following neutralisation with solid sodium carbonate, the aqueous layer is re-extracted with fresh ether (3 × 75 ml), and the combined ethereal portions are washed with water (5 × 100 ml), dried over anhydrous magnesium sulphate and concentrated to a yellow oil (1.3 g). The oily residue is then dissolved in ethyl acetate (10 ml) and treated with toluene-p-sulphonic acid monohydrate (0.9 g, 4.8 mmol) in ethyl acetate (20 ml). The resulting precipitate is collected by filtration and dried under vacuum to give 2.5 g (37%\(^\circ\)) of the amino acid ester hydrolysate, m.p. 174–175 °C; i.r. (KBr disc) 3400, 1740, 1600, 1500, 1380 cm\(^{-1}\); p.m.r. (Me\(_2\)SO-d\(_6\), TMS) \(\delta\) 1.16 (t, \(J = 7\) Hz, 3H), 2.29 (s, 3H), 4.17 (q, \(J = 7\) Hz, 2H), 5.11 (s, 3H), 7.02–7.55 (m, 13H) and 8.75 (broad s, 3H). The product may be recrystallised from ethanol–ether–heptane.

2-[\(\sigma\)-(Benzyloxy)phenyl]-\(N\)-(3-bromopropanoyl)glycine ethyl ester. To a stirred solution of the foregoing hydrolysate (2.5 g, 5.5 mmol) and \(N\)\(,\)N-dimethylaniline (2.4 g, 19.9 mmol) in dry dichloromethane (65 ml) at -20 °C (ice–methanol bath) is added over 20 minutes 3-bromopropanoyl chloride (1.2 g, 6.3 mmol) in dry dichloromethane (5 ml). After completion of the addition, the reaction mixture is allowed to come to room temperature and stirred for 1.5 hours. The clear solution is diluted with dichloromethane–ether (2:1) and washed successively with 1% hydrochloric acid, 5% per cent sodium hydrogen carbonate solution and saturated sodium chloride solution. The organic layer is dried over anhydrous sodium sulphate and concentrated to give 2.5 g of a light blue solid. Following column chromatography over silica gel with ether elution, the product is recrystallised from aqueous ethanol to provide 2.0 g (87%\(^\circ\)) of white crystals, m.p. 98–99 °C; i.r. (CHCl\(_3\)) 3330, 1730, 1660, 1500, 1220 cm\(^{-1}\); p.m.r. (CDCl\(_3\), TMS) \(\delta\) 1.18 (t, \(J = 7\) Hz, 3H), 2.75 (t, \(J = 6\) Hz, 2H), 3.55 (t, \(J = 6\) Hz, 2H), 4.16 (q (split), \(J = 7\) Hz, 2H), 5.00 (s, 2H), 5.46 (d, \(J = 7\) Hz, 2H), 6.58 (d, \(J = 7\) Hz, 1H), 6.88 (d, \(J = 9\) Hz, 2H), 7.26 (d, \(J = 9\) Hz, 2H) and 7.32 (s, 5H). The product may be recrystallised from methyl acetate–heptane–ether.

Ethyl \(\alpha\)-[(\(p\)-benzyloxy)phenyl]-2-oxo-1-azetidinone acetate. To a suspension of 0.375 g (7.8 mmol) of a 50 per cent mineral oil dispersion of sodium hydride (prewashed with pentane) and dry dimethylformamide (15 ml) in dichloromethane (55 ml) is added over 3.5 hours a solution containing the foregoing substituted glycine ethyl ester (2.98 g, 7.1 mmol) and dry dimethylformamide (15 ml) in dry dichloromethane (55 ml). After completion of the addition, the reaction mixture is stirred for 3 hours at room temperature and then quenched with a saturated ammonium chloride solution (10 ml). The resulting mixture is diluted with ether and dichloromethane. The organic phase is separated, washed with water and with saturated aqueous sodium chloride and then dried over anhydrous magnesium sulphate. Removal of the solvent under reduced pressure gives an orange oil which is crystallised from ether–hexane to give 1.9 g (80%\(^\circ\)) of white solid product, m.p. 52–54 °C (1).

Note. (1) This substituted azetidinone was also synthesised by the same workers using a different strategy when the product had m.p. 57–59 °C; i.r. (CHCl\(_3\)) 1740 (split), 1610, 1510 cm\(^{-1}\); p.m.r. (CDCl\(_3\), TMS, 270 MHz) \(\delta\) 1.18 (t, \(J = 6.6\) Hz, 3H), 2.76 (m, 1H), 2.92 (m, 1H), 2.99 (m, 1H), 3.54 (m, 1H), 4.14 (q (split), \(J = 6.6\) Hz, 2H), 4.99 (s, 2H), 5.46 (s, 1H), 6.91 (d, \(J = 8.8\) Hz, 2H), 7.14 (d, \(J = 8.8\) Hz, 2H) and 7.33 (m, 5H).
8.2.2 CYCLOADDITION REACTIONS.

To illustrate the two alternative \((2 + 2)\) cycloaddition processes, three target molecules are selected, namely, 4-acetoxy-3-ethylazetidin-2-one (23), 1-azaspiro[3.5]nonan-2-one (24) and 3-chloro-1-cyclohexyl-4-cyclohexylimino-3-phenylazetidin-2-one (25).

For the synthesis of compounds (23) and (24), bond formation is between N to C\(_4\) and C\(_2\) to C\(_3\); for compound (25) bond formation is between N to C\(_2\) and C\(_3\) to C\(_4\). These reactions may proceed in two steps via a dipolar intermediate (formulated below) rather than in the pericyclic sense.

Compound (23) (Expt 8.8) is formed by the reaction of but-1-enyl acetate with chlorosulphonyl isocyanate (Section 4.2.77, p. 425).\(^{13}\) The reaction intermediate is the N-chlorosulphonyl derivative which is subjected to reduction with alkaline sodium sulphide to yield the product which is isolated as a cis: trans (1:1) mixture. But-1-enyl acetate is readily synthesised by acetylation of the enol form of butanal.

Compound (24) (Expt 8.8, cognate preparation) is similarly prepared from chlorosulphonyl isocyanate and methylenecyclohexane followed by reduction with sodium sulphite.\(^{14}\) Chlorosulphonyl isocyanate has been widely used in cycloaddition reactions of this type to yield \(\beta\)-lactams having a range of functional groups.\(^{15}\) These functional groups enable further structural modifications to be carried out leading to many mono- and bicyclic compounds containing the \(\beta\)-lactam structural feature. A straightforward example is the conversion of 4-acetoxyazetidin-2-one (26) into clavam (28) (Expt 8.9). Compound (26), prepared from vinyl acetate and chlorosulphonyl isocyanate followed by reductive removal of the chlorosulphonyl group,\(^{16}\) or obtained commercially, is submitted to a Lewis-acid-catalysed displacement of the acetox group by reaction with 2-bromoethanol to give 4-(2-bromoethoxy)azetidin-2-one (27). Cyclisation to the bicyclic system is then effected by using the non-nucleophilic base 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).
An illustration of a cycloaddition reaction resulting in the formation of the N—C₂ and C₃—C₄ bonds is the reaction of 2-chlorophenylketene (29) with dicyclohexylcarbodiimide, to give 3-chloro-1-cyclohexyl-4-cyclohexylimino-3-phenylazetidin-2-one (25) (Expt 8.10).¹⁷ The ketene is generated in situ from 2-chloro-2-phenylacetyl chloride by the action of triethylamine (cf. Expt 7.25).

**Experiment 8.8 4-ACETOXY-3-ETHYL AZETIDIN-2-ONE¹³**

**But-1-enyl acetate.** A mixture of butanal (100 g), acetic anhydride (330 g) and sodium acetate (14 g) is heated at 80 °C for 12 hours. After cooling the resulting mixture is diluted with pentane (100 ml), washed with water, saturated aqueous sodium hydrogen carbonate, and water, and dried over anhydrous sodium sulphate. Evaporation of the solvent gives a colourless oil, which is purified by distillation to afford but-1-enyl acetate [(E):(Z) c. 3:2] (56 g, 38%), b.p. 45–55 °C/20 mmHg, i.r. (CHCl₃) 1750 cm⁻¹.

**4-Acetoxy-3-ethylazetidin-2-one.** To a stirred solution of the foregoing enol acetate (10 g) in dry dichloromethane (10 ml) is added dropwise at 0 °C chlorosulphonyl isocyanate (7 ml) (Aldrich) (1) (CAUTION). After stirring for a further 2 hours at 0 °C, the mixture is poured into an aqueous solution (300 ml) of sodium hydrogen carbonate (20 g) and sodium sulphide (10 g) at 0 °C with stirring. Stirring is again continued at 0 °C for 0.5 hour and the mixture extracted with dichloromethane. Evaporation of the solvent gives a yellow oil, which is chromatographed on silica gel using dichloromethane as eluant to afford 4-acetoxy-3-ethylazetidin-2-one (trans:cis 1:1) (5.4 g, 48%) as a yellow oil; i.r. (CHCl₃) 3400 (NH) and 1780 cm⁻¹ (C=O); p.m.r. (CDCl₃, TMS) δ 1.06 (t, J = 7 Hz, 6H,—CH₂—Me), 1.73 (q, J = 7 Hz, —CH₂—Me), 2.10 (s, 6H, O—CO—Me), 3.13 (broad t, J = 7 Hz, 2H, C₃—H), 5.53 (broad s, 1H, C₄—H), 5.85 (d, J = 4 Hz, 1H, C₄—H) and 6.93 (broad s, 2H, NH).

**Note.** (1) See Section 4.2.17, p. 525; CAUTION: it must be emphasised that this reagent is corrosive and lachrymatory and appropriate protective measures are essential.

**Cognate preparation.** 1- Azaspiro[3.5]nonan-2-one. 1-Chlorosulphonyl-1-
azaspiro[3.5]nonan-2-one. Chlorosulphonyl isocyanate (3.5 g, CAUTION: see Note (1) above) is added dropwise to methylenecyclohexane (2.4 g) in ether (10 ml) at 10°C. The reaction mixture becomes semi-solid with fine needles. The product is filtered and recrystallised from ether (yield 5.1 g, 96%), m.p. 88–90°C; i.r. shows the lactam band at 5.53 μm (1810 cm⁻¹).

General procedure for the reduction of N-chlorosulphonyl β-lactams with sodium sulphite. A solution of N-chlorosulphonyl β-lactam dissolved in ether is added slowly to a stirred mixture of about two parts of 25 per cent aqueous sodium sulphite and one part of ether. The aqueous phase is kept slightly basic by addition of 10 per cent potassium hydroxide solution as the reduction proceeds. The reaction course could easily be followed by t.l.c. in which the product has a considerably smaller Rᵣ value than the starting material. At the end of the reaction (usually less than 15 minutes) the ether layer is separated and dried and evaporated. The products are of greater than 95 per cent purity as determined by p.m.r. spectroscopy. The reaction may be carried out at 25°C or at 0°C.

1-Azaspiro[3.5]nonan-2-one is prepared by the above general procedure in 98 per cent yield, and is isolated as a colourless oil, b.p. 123 °C/4.2 mmHg; i.r. (CHCl₃) 5.72 μm (1750 cm⁻¹) p.m.r. (CDCl₃, TMS), δ 1.3–2.0 (m, 10H), 2.61 (d, J = 1.5 Hz, 2H, collapses to a singlet on the addition of D₂O) and 7.3–8.0 (broad s, 1H).

**Experiment 8.9 4-OXA-1-AZABICYCLO[3.2.0]HEPTAN-7-ONE**
*(Clavam)*

4-(2-Bromoethoxy)azetidin-2-one. 4-Acetoxyazetidin-2-one (10 g) and 2-bromoethanol (10 g) are dissolved in dry benzene (150 ml, CAUTION) and finely powdered zinc acetate dihydrate (9 g) is added. The mixture is stirred and refluxed with azeotropic removal of water for 24 hours. The mixture is cooled, diluted with ethyl acetate (200 ml), and washed twice with saturated sodium hydrogen carbonate solution and three times with water. The solution is dried and the solvent removed to yield a yellow oil (4.54 g) which is chromatographed (see below) to give 4-(2-bromoethoxy)azetidin-2-one as a pale yellow gum (2.6 g); i.r. 3390, 3230 and 1780 cm⁻¹; p.m.r. (CDCl₃, TMS) δ 3.10 (m, 2H), 3.60 (m, 2H), 3.95 (m, 2H), 5.27 (d of d, 1H, J = 3 and 2 Hz) and 7.60 (broad s, 1H); m/z 196 (M + 1, RA 0.1%), 194 (M + 1, 0.1), 167 (3), 165 (3), 144 (5), 142 (32), 140 (27), 109 (80), 107 (82) and 43 (100).

4-Oxa-1-azabicyclo[3.2.0]heptan-7-one. DBU (1.8 g) is added dropwise to a stirred solution of the foregoing substituted β-lactam (1.4 g) in ether (15 ml). The mixture is stirred for 18 hours and then concentrated to 5 ml. The concentrated solution is chromatographed (Silica gel 60, ethyl acetate–light petroleum, b.p. 60–80 °C mixture) to give clavam as a colourless oil (270 mg); i.r. 1785 cm⁻¹; p.m.r. (CDCl₃, TMS) δ 2.84 (d, J = 17 Hz, 1H), 2.9–3.6 (m, 2H), 3.7–4.4 (m, 3H) and 5.25 (d, J = 2 Hz, 1H).
Experiment 8.10 3-CHLORO-1-CYCLOHEXYL-4-CYCLOHEXYLIMINO-3-PHENYL AZETIDIN-2-ONE

\[

\end{align*}
\]

A solution of 2-chloro-2-phenylacetyl chloride (13.3 g, 0.070 mol) (1), in hexane (30 ml) (2) is added dropwise to a refluxing solution of dicyclohexylcarbodiimide (14.5 g, 0.070 mol) (CAUTION) and triethylamine (14.2 g, 0.141 mol) in dry hexane (200 ml) (3). After the addition is complete, the mixture is allowed to continue to reflux for 2 hours. The amine salt is removed by filtration and the hexane evaporated to yield 16 g (65%) of the product which is recrystallised from methanol and has a m.p. 86–88 °C; i.r. 1822 (C=O) and 1700 cm\(^{-1}\) (C=N); p.m.r. (CCl\(_4\), TMS) \(\delta\) 1.5 (m, 20H), 3.4 (m, 2H) and 7.42 (m, 5H).

Notes. (1) This compound is available from Aldrich; alternatively it may be prepared from mandelic acid and phosphorus pentachloride according to the method of Walden.  
(2) Dicyclohexylcarbodiimide is toxic and may cause sensitisation and subsequent allergic reactions. The vapour particularly irritates the eyes severely.  
(3) Hexane is dried by refluxing and distilling from calcium hydride.

8.3 FIVE-MEMBERED HETEROCYCLES

The commonest five-membered heteroaromatic compounds containing one heteroatom are pyrrole (30), furan (31) and thiophene (32). Their substituted derivatives and the substituted derivatives of the corresponding benzo analogues [indole (33), benzofuran (34) and benzothiophene (35)] are widespread naturally-occurring compounds.

\[
\begin{align*}
\text{(30)} & \quad \text{(31)} & \quad \text{(32)} \\
\text{(33)} & \quad \text{(34)} & \quad \text{(35)} \\
\end{align*}
\]

Examples of five-membered heterocyclic systems having more than one heteroatom, the derivatives of which have been selected to illustrate some important methods of ring formation, are pyrazole (36), pyrazolone (37), hydantoin (38), oxazoline (39), thiazole (40), benzimidazole (41) and benzotriazole (42).
A useful initial guide to an overall strategy of ring formation is to formulate the ring atoms as various skeletal fragments. For example, in the case of the five-membered heterocyclic system (43), ring construction may be seen to result from the union of the skeletal fragments shown in (44) to (46). With the benzo analogue (47) a limited selection of possibilities is given by (48) and (49).

This time-honoured view of ring construction preceded the retrosynthetic approach; it is still of value since it provides an indication of which bonds could be selected for disconnection. The more rigorous application of the principles of retrosynthetic analysis leads of course to the formulation of synthons and their reagent equivalents.

A selection of cyclisation reactions is detailed below to exemplify these principles. They are conveniently discussed in relation to the synthesis of compounds belonging to the following groups of heterocyclic systems.

1. Pyrroles, furans, thiophenes and pyrazolones from dicarbonyl compounds.
2. Hydantoins from urea, and thiazoles from thiourea or thioamides.
3. Oxazolones (and azlactones) from α-amino acids.
4. Indoles, benzofurans and benzothiophenes.
5. Benzimidazoles and benzotriazole from o-phenylene diamines.
8.3.1 PYRROLES, FURANS, THIOPHENES AND PYRAZOLONES FROM DICARBONYL COMPOUNDS

FROM 1,4-DICARBONYL COMPOUNDS
The first group of illustrative target molecules comprises 2,5-dimethylpyrrole (50), 2,5-dimethylfuran (51) and 2,5-dimethylthiophene (52).

A retrosynthetic analysis of (50) and (52) involving disconnection at both carbon–heteroatom bonds reveals hexane-2,5-dione as the four-carbon fragment needed for ring assembly; ring construction is thus of type (45). The most convenient reagents for the appropriate heteroatom synthons are ammonium carbonate and phosphorus pentasulphide (Expts 8.11 and 8.13).

In the case of 2,5-dimethylfuran (51) the dicarbonyl compound is revealed by the disconnection of one carbon–oxygen bond; ring construction is of type (44). The forward synthetic reaction is a cyclodehydration reaction effected by the action of acetic anhydride in the presence of zinc chloride (Expt 8.12).

These methods [which are known as the Paal–Knorr (pyrrole and furan) or Paal (thiophene) syntheses] are applicable to other 1,4-dicarbonyl compounds, the limitation being the accessibility of the dicarbonyl starting material.

FROM 1,3-DICARBONYL COMPOUNDS
The second group of target molecules selected to illustrate the use of dicarbonyl compounds consists of 3,5-dimethylpyrazole (53), 3-methyl-1-phenylpyrazol-5-one (54) and 3,5-diethoxycarbonyl-2,4-dimethylpyrrole (55).

Disconnection of both carbon–nitrogen bonds in (53) in the manner depicted above, reveals hydrazine and a synthon which is equivalent to pentane-2,4-
dione. In a similar way disconnection of both carbon–nitrogen bonds in (54) reveals phenylhydrazine and ethyl acetoacetate (see also p. 805).

![Chemical structure](image)

Synthesis of (53) and (54) proceeds with ease on mixing the relevant reagents (Expts 8.14 and 8.15). N-Methylation of (54) with dimethyl sulphate in the presence of alkali gives 2,3-dimethyl-1-phenylpyrazol-5-one (antipyrin), which was one of the earliest synthetic antipyretics.

An example of the Knorr pyrrole synthesis is provided by the formation of 3,5-diethoxycarbonyl-2,4-dimethylpyrrole (55). Overall ring construction in this case may be related to (46) above. A retrosynthetic analysis involving disconnection of the N—C$_2$ bond, appropriate prototropic shifts, and finally a retro-aldol reaction to effect disconnection of the C$_3$–C$_4$ bond, reveals ethyl acetoacetate and ethyl α-aminoacetoacetate (ethyl 2-amino-3-oxo-butanoate) (56) as reagents. An FGI transform on this latter compound generates the corresponding nitroso (oximino) compound which may also be derived from ethyl acetoacetate.

![Chemical structure](image)

In practice the synthesis (Expt 8.16) is a one-pot reaction in which one-half of the ethyl acetoacetate is converted to the oximino compound by treatment with
nitrous acid in acetic acid, which is then reduced by the addition of zinc dust. The resulting amino compound spontaneously reacts with the remaining ethyl acetoacetate to yield the pyrrole derivative (55).

The Knorr synthesis is generally suitable for the synthesis of a range of substituted pyroles utilising $\alpha$-aminoketones (or keto esters as illustrated above) with carbonyl compounds containing an active methylene group.

![Chemical reaction]

**Experiment 8.11 2,5-DIMETHYL PYRROLE**

In a 250-ml flask, fitted with an air condenser of wide bore, place 50 g (51.5 ml, 0.44 mol) of hexane-2,5-dione (Expt 5.104) and 100 g of ammonium carbonate (lump form). Heat the mixture in an oil bath at 100 °C until effervescence stops (60–90 minutes); some ammonium carbonate (or carbamate) sublimes into the condenser and this must be pushed back into the reaction mixture by means of a stout glass rod. Replace the air condenser by a Liebig condenser with wide bore inner tube and reflux the mixture gently (bath temperature, 115 °C) for a further 30 minutes; dissolve the solid which has sublimed into the condenser in about 5 ml of hot water and return the solution to the reaction mixture. Cool and separate the upper yellow layer of crude dimethylpyrrole, extract the lower layer with 10 ml of dichloromethane and combine it with the crude dimethylpyrrole; carry out the foregoing operations in apparatus which has been flushed with nitrogen. Dry over anhydrous sodium sulphate in a tightly stoppered flask filled with nitrogen. Transfer to a flask fitted with a fractionating column. Displace the air from the apparatus by nitrogen and distil under reduced pressure, preferably in a stream of nitrogen. Collect the 2,5-dimethylpyrrole at 78–80 °C/25 mmHg. The yield is 36 g (86%). Store the product in an inert atmosphere in a sealed, dark glass container. Record the p.m.r. spectrum (CDCl$_3$) and assign the signals that occur at δ 2.20 (s, 6H), 5.71 (d, 2H) and 7.49 (broad s, 1H).

**Experiment 8.12 2,5-DIMETHYL FURAN**

Dissolve 0.5 g of anhydrous zinc chloride in 16.8 g (15.5 ml, 0.165 mol) of acetic anhydride contained in a 50-ml round-bottomed flask, and to this solution add 17.1 g (17.6 ml, 0.15 mol) of redistilled hexane-2,5-dione (Expt 5.104). Attach a reflux condenser fitted with a calcium chloride drying tube and warm the mixture carefully. When a vigorous reaction commences remove
the source of heat until the reaction subsides and then boil the mixture under gentle reflux for 2 hours. Transfer the cooled dark brown mixture to a 250-ml round-bottomed flask and add 6 m aqueous sodium hydroxide until alkaline (c. 50 ml), keeping the temperature below 50 °C by cooling in an ice-water bath. Steam distil the mixture until no more oily drops appear in the distillate (about 100 ml). Transfer the distillate to a separating funnel, collect the upper layer of product and dry over anhydrous calcium chloride. Filter the straw-coloured crude product into a 25-ml pear-shaped flask and distil. Collect the colourless 2,5-dimethylfuran (1) as a fraction, b.p. 93–95 °C. The yield is 8.9 g (62%). Record the p.m.r. spectrum and compare it with that of 2,5-dimethylpyrrole.

Note. (1) The purity of the product may be checked by g.l.c. on a 1.5-m Silicone oil column held at 105 °C. At this temperature and with a nitrogen flow rate of 40 ml/minute, 2,5-dimethylfuran has a retention time of 48 seconds.

Experiment 8.13 2,5-DIMETHYLTHIOPHENE

\[
\text{Me} \quad \text{O} \quad \text{O} \quad \text{Me} \quad \xrightarrow{\text{P}_{2} \text{S}_{5}} \quad \text{Me} \quad \text{S} \quad \text{Me}
\]

CAUTION: This preparation should be carried out in an efficient fume cupboard.

Place 55 g (0.25 mol) of phosphorus pentasulphide in a 500-ml three-necked flask equipped with a long Leibig-type condenser, a dropping funnel and a stopper. Add from the dropping funnel 23 g (24 ml) of hexane-2,5-dione (Expt 5.104) and heat the reaction mixture with a small luminous flame until the exothermic reaction commences. Remove the flame and add dropwise 91 g (94 ml, total 1 mol) of hexane-2,5-dione over a period of about 45 minutes so that the mixture refluxes gently. A bath of cold water should be to hand should the reaction show signs of becoming too vigorous. When the addition is complete, and the reaction has subsided, heat the mixture under reflux for a further 1 hour, cool to room temperature and pour into 200 ml of ice-water (fume cupboard). Extract the aqueous mixture with four 40 ml portions of ether and wash the combined ethereal extracts with aqueous sodium carbonate solution and then with water. Dry the ether solution over magnesium sulphate, remove the ether by flash distillation and distil the residue. 2,5-Dimethylthiophene is obtained after redistillation as a very unpleasant-smelling colourless liquid, b.p. 135–136 °C; the yield is 52 g (46%).

Experiment 8.14 3,5-DIMETHYLPYRAZOLE

\[
\text{Me} \quad \text{O} \quad \xrightarrow{\text{H}_{2}\text{N-} \text{NH}_{2}} \quad \text{Me} \quad \text{N}
\]

Dissolve 65 g (0.5 mol) of hydrazine sulphate in 400 ml of 2.5 M sodium hydroxide solution contained in a 1-litre three-necked flask, equipped with a thermometer, mechanical stirrer and dropping funnel. Immerse the flask in an ice bath and when the temperature reaches 15 °C (some sodium sulphate
may separate at this point), add 50 g (51.5 ml, 0.5 mol) of pentane-2,4-dione (Expt 5.102) dropwise, with stirring, while maintaining the temperature at 15 °C. When the addition is complete (after about 30 minutes), stir for 1 hour at 15 °C; the dimethylpyrazole separates during this period. Add 200 ml of water, stir to dissolve inorganic salts, transfer the contents of the flask to a separatory funnel and shake with 100 ml of ether. Separate the layers and extract the aqueous layer with four 40 ml portions of ether. Wash the combined ethereal extracts with saturated sodium chloride solution, dry over anhydrous potassium carbonate and remove the ether on a rotary evaporator. The yield of pale yellow solid, m.p. 107–108 °C, is 38 g. Recrystallise from about 250 ml of light petroleum, b.p. 80–100 °C; the yield of 3,5-dimethylpyrazole, of unchanged m.p., is 36 g (75%). Record and interpret the p.m.r. spectrum.

**Experiment 8.15 3-METHYL-1-PHENYLPYRAZOL-5-ONE**

(antipyrine)

\[
\begin{align*}
\text{Me} & \quad \text{Me} \\
\text{O} & \quad \text{O} \\
\text{Et} & \quad \text{Ph} \\
\text{N} & \quad \text{Me}
\end{align*}
\]

Mix together 50 g (49 ml, 0.384 mol) of redistilled ethyl acetoacetate and 40 g (36.5 ml, 0.37 mol) of phenylhydrazine (CAUTION in handling) in a large evaporating dish. Heat the mixture on a boiling water bath in the fume cupboard for about 2 hours and stir from time to time with a glass rod (1). Allow the heavy reddish syrup to cool somewhat (2), add about 100 ml of ether and stir the mixture vigorously. The syrup, which is insoluble in ether, will solidify within 15 minutes. Filter the solid at the pump and wash it thoroughly with ether to remove coloured impurities. Recrystallise it from hot water or from a mixture of equal volumes of ethanol and water. The yield of methylphenylpyrazolone (colourless crystals, m.p. 127 °C) is 52 g (80%). Record and interpret the p.m.r. spectrum.

**Formation of 2,3-dimethyl-1-phenylpyrazol-5-one by N-methylation.** In a 500-ml three-necked flask, equipped with a dropping funnel, a sealed stirrer unit and a double surface condenser and set up in the fume cupboard, place a solution of 10 g of sodium hydroxide in a small volume of water and also a solution of 43.5 g (0.25 mol) of 3-methyl-1-phenylpyrazol-5-one in 20 ml of methanol. Warm up the solution on a water bath and add 36 g (27 ml, 0.285 mol) of dimethyl sulphate (CAUTION: toxic, see discussion in Section 4.2.24, p. 430). Reflux the mixture for 1 hour and allow to cool, with continuous stirring. Distil off the methanol. Add hot water to the residue, filter from impurities, extract the antipyryl with benzene (fume cupboard) and evaporate the solvent. Recrystallise the crude product from benzene (CAUTION) or benzene–light petroleum, or from hot water with the addition of a little decolourising carbon. The yield of antipyryl (white crystalline solid, m.p. 113 °C) is 35 g (74%).

**Notes.** (1) The heating should be continued until a test portion solidifies completely when it is rubbed with a little ether; when freshly redistilled phenylhydrazine is used, a
period of 1 hour's heating may be adequate. If the product is reluctant to crystallise
inoculation with seeds of previously prepared material is advantageous.
(2) If the product is already solid at this stage it should be ground thoroughly with the
100 ml portion of ether and filtered.

**Experiment 8.16 3,5-DIETHOXYCARBONYL-2,4-DIMETHYL-
PYRROLE**

In a 1500-ml three-necked flask, fitted with a dropping funnel and a sealed
mechanical stirrer, place 195 g (190 ml, 1.5 mol) of ethyl acetoacetate and
450 ml of glacial acetic acid. Cool the solution in an ice–salt mixture to 5 °C;
add a cold solution of 52 g (0.75 mol) of sodium nitrite in 75 ml of water drop-
wise and with vigorous stirring at such a rate that the temperature remains
between 5 and 7 °C (about 30 minutes), stir for a further 30 minutes, and keep
at room temperature for 4 hours. Replace the dropping funnel by a wide-bore
condenser: close the third neck with a stopper. Stir the solution vigorously
and add 100 g (1.5 mol) of zinc powder (Section 4.2.80, p. 467) via the third
neck in portions of about 10 g; introduce the first 3 or 4 portions quickly so
that the liquid boils. Keep a bath of ice-water and also wet towels at hand to
control the reaction should it become violent or foam badly. When all the
zinc has been added (about 45 minutes), reflux the mixture for 1 hour; if stir-
ing becomes difficult, add some acetic acid. While still hot, decant the con-
tents of the flask into 5 litres of water in a large beaker with vigorous stirring.
Wash the zinc residue with two 25 ml portions of hot glacial acetic acid and
decant the washings into the water also. Keep overnight, collect the crude
product by suction filtration, wash with two 250 ml portions of water and dry
in the air to constant weight. The yield of crude product is 114 g (64%), m.p.
127–130 °C. Recrystallisation from hot 95 per cent ethanol gives pure 3,5-
diethoxycarbonyl-2,4-dimethylpyrrole as pale yellow crystals, m.p. 136–
137 °C; the recovery is about 80 per cent. Record the p.m.r. spectrum (CDCl₃,
TMS) and assign the signals which occur at δ 1.38 (t, 6H), 2.52 (s, 3H), 2.57 (s,
3H), 4.29 (q, 2H) and 4.32 (q, 2H).

### 8.3.2 HYDANTOINS FROM UREA, AND THIAZOLES FROM THIOUREA OR THIOAMIDES

The illustrative target molecules are 5,5-diphenylhydantoin (57), 2-amino-4-
methylthiazole (58), 2-aminothiazole (59) and 2,4-dimethylthiazole (60).
Urea may be recognised as a structural unit in 5,5-diphenylhydantoin (57) and it constitutes one of the reagents in the synthesis. Although it is not obvious, the appropriate reagent equivalent corresponding to the accompanying synthon is in fact benzil.

The base-catalysed reaction sequence (formulated in Expt 8.17) is thought to proceed via an intermediate heterocyclic pinacol which on acidification yields the required hydantoin as a result of a pinacolic rearrangement. The procedure is applicable in general to diaryl-1,2-diketones.

The thiourea fragment may be readily recognised in (58); appropriate disconnection thus reveals a chloroacetone as the other reagent; the synthesis is readily effected by heating the two reagents together (Expt 8.18). In a similar manner disconnection of 2-aminothiazole (59) reveals thiourea and chloroacetaldehyde; in this case the carbonyl reagent is generated \textit{in situ} from \(\alpha,\beta\)-dichloroethyl ethyl ether (formulated in Expt 8.19).

Chloroacetone is also a recognisable reagent equivalent following disconnection of 2,4-dimethylthiazole (60); the reagent equivalent of the other synthon is thioacetamide, which is formed \textit{in situ} from acetamide and phosphorus pentasulphide (Expt 8.20).
Experiment 8.17 5,5-DIPHENYLHYDANTOIN

\[
\begin{align*}
\text{Ph} & \quad \text{H}_2\text{N} \quad \text{O} \\
\text{O} & \quad \text{H}_2\text{N} \quad \text{Ph}
\end{align*}
\]

(i) \text{NaOH/EtOH}  \quad (ii) \text{H}_2\text{O}

Place 5.3 g (0.025 mol) of benzil (Expt 6.143), 3.0 g (0.05 mol) of urea, 15 ml of 30 per cent aqueous sodium hydroxide solution and 75 ml of ethanol in a 100-ml round-bottomed flask. Attach a reflux condenser and boil under reflux using an electric heating mantle for at least 2 hours. Cool to room temperature, pour the reaction product into 125 ml of water and mix thoroughly. Allow to stand for 15 minutes and then filter under suction to remove an insoluble by-product. Render the filtrate strongly acidic with concentrated hydrochloric acid, cool in ice-water and immediately filter off the precipitated product under suction. Recrystallise at least once from industrial spirit to obtain about 2.8 g (44%) of pure 5,5-diphenylhydantoin, m.p. 297-298°C.

Experiment 8.18 2-AMINO-4-METHYLTHIAZOLE

\[
\begin{align*}
\text{Me} & \quad \text{O} \\
\text{Cl} & \quad \text{NH}_2 \quad \text{S} \quad \text{NH}_2
\end{align*}
\]

Suspend 76 g (1 mol) of thiourea (CAUTION: see Section 2.3.4, p. 50) in 200 ml of water in a 500-ml three-necked flask sited in a fume cupboard and equipped with a sealed stirrer unit, a reflux condenser and a dropping funnel. Stir and add 92.5 g (80 ml, 1 mol) of chloroacetone (1) over a period of 30 minutes. The thiourea dissolves as the reaction proceeds and the temperature rises. Reflux the yellow solution for 2 hours. To the cold solution immersed in an ice bath add, with stirring, 200 g of solid sodium hydroxide. Transfer to a separatory funnel, add a little ice-water, separate the upper oil layer and extract the aqueous layer with three 100 ml portions of ether. Dry the combined oil and ether extracts with anhydrous sodium sulphate, remove the ether using a rotary evaporator and distil the residual oil under diminished pressure. Collect the 2-amino-4-methylthiazole at 130–133°C/18 mmHg; it solidifies on cooling in ice to a solid, m.p. 44–45°C. The yield is 84 g (74%).

Note. (1) See Expt 8.20, Note (1).

Experiment 8.19 2-AMINOTHIAZOLE

\[
\begin{align*}
\text{Cl} & \quad \text{Cl} \quad \text{Et} \\
\text{O} & \quad \text{Cl} \quad \text{O} \quad \text{Et}
\end{align*}
\]

Place a solution of 76 g (1 mol) of thiourea (CAUTION: see Section 2.3.4, p. 50) in 200 ml of warm water in a 500-ml three-necked flask equipped with
a dropping funnel, sealed mechanical stirrer and reflux condenser. Add 143 g (122 ml, 1 mol) of \( \alpha, \beta \)-dichloroethyl ethyl ether, and heat the mixture under gentle reflux with stirring for 2 hours. As the reaction proceeds, the two layers gradually merge. To the cold solution add sufficient solid sodium hydroxide to liberate the 2-aminothiazole from its salt. Add ether to dissolve the product, dry the ethereal extract with anhydrous sodium sulphate and evaporate the ether. Recrystallise the crude 2-aminothiazole from ethanol; the resulting yellow crystalline solid has m.p. 90 °C. The yield is 80 g (80%).

**Experiment 8.20 2,4-DIMETHYLTHIAZOLE**

\[
\text{Me} \cdot \text{CONH}_2 \xrightarrow{\text{PS_5}} \text{Me} \cdot \text{CSNH}_2
\]

\[
\text{Me} \quad \text{O} \quad + \quad \text{S} \quad \text{NH}_2 \quad \xrightarrow{\text{Me}} \quad \text{Me} \quad \text{N} \quad \text{Me} \quad \text{S}
\]

Equip a 1-litre, two-necked round-bottomed flask with a reflux condenser and a dropping funnel. Prepare a mixture of 150 g (2.54 mol) of finely powdered acetamide and 100 g of powdered phosphorus pentasulphide quickly, transfer it rapidly into the flask and immediately add 100 ml of dry benzene (CAUTION). Set up the apparatus in a fume cupboard. Prepare a mixture of 232 g (200 ml, 2.5 mol) of chloroacetone (1) (CAUTION: the compound is lachrymatory) and 75 ml of dry benzene; place it in the dropping funnel and insert a calcium chloride drying tube in the mouth. Add about 10 ml of the chloroacetone-benzene mixture to the contents of the flask and warm gently on a water bath: remove the water bath immediately the exothermic reaction commences. Introduce the remainder of the chloroacetone in c.10 ml portions at such intervals that the reaction is under control. When all the chloroacetone has been added, reflux the mixture on a water bath for 30 minutes. Then add 400 ml of water to the reaction mixture with shaking; after 20 minutes, transfer the contents of the flask to a separatory funnel, run off the lower layer into a beaker and discard the reddish upper layer containing the benzene. Make the lower layer alkaline by the addition of 20 per cent sodium hydroxide solution: test the highly coloured aqueous solution (and not the dark dimethylthiazole floating on top of the liquid) with universal indicator paper. Separate the black upper layer of crude dimethylthiazole with 50 ml of ether, and extract the aqueous layer with five 60 ml portions of ether. Dry the combined ethereal extracts over magnesium sulphate, and filter through glass wool. Remove the ether by flash distillation through a short fractionating column; insert a calcium chloride drying tube into the dropping funnel since the thiazole is hygroscopic and fractionate the residue. Collect the fraction boiling at 140–150 °C and redistil. The yield of 2,4-dimethylthiazole, b.p. 143–145 °C, is 115 g (40%). Record and interpret the p.m.r. spectrum (CDCl_3).

**Note.** (1) Distil and store commercial chloroacetone, b.p. 118–120 °C over calcium carbonate. It is prepared inter alia by the chlorination of acetone in the cold.
8.3.3 Oxazolones (And Azlactones) from α-Amino Acids

The retrosynthetic analysis outlined below for 4-benzylidene-2-methyloxazol-5-one (61) follows familiar general principles.

\[
\text{Ph-CHO} \quad \text{Ph-CO} \quad \text{HO}_2\text{C-CH}_2\cdot\text{NH-CO-Me} \quad \text{HO}_2\text{C-CH}_2\cdot\text{NH-CO-Me} \quad \text{HO}_2\text{C-CH}_2\cdot\text{NH-CO-Me}
\]

The synthetic steps are thus the conversion of N-acetylglycine with acetic anhydride into 2-methyloxazol-5-one (62), followed by reaction of the active methylene group with benzaldehyde to afford the corresponding benzylidene derivative (61) (Expt 8.24; see also Section 5.14.3, p. 736). In a similar manner N-benzoylglycine gives 4-benzylidene-2-phenyloxazol-5-one. These azlactones have been used as starting materials for the preparation of phenylpyruvic acid and phenylalanine (Expts 5.175 and 5.182 respectively).

**Experiment 8.21 4-Benzylidene-2-Methyloxazol-5-One**

Acetylglycine. Place 37.5 g (0.5 mol) of glycine (Expt 5.180) and 150 ml of water in a 500-ml conical flask. Introduce a mechanical stirrer and stir vigorously until the solid has almost completely dissolved. Add 102 g (95 ml, 1 mol) of acetic anhydride in one portion and stir vigorously for 15–20 minutes; the solution becomes hot and some acetylglycine may crystallise. Cool in a refrigerator, preferably overnight; collect the precipitate on a Buchner funnel, wash with ice-cold water and dry at 100°C. The product weighs 40 g and melts at 207–208°C. Evaporate the combined filtrate and washings to dryness under reduced pressure on a water bath at 50–60°C, and recrystallise the residue from 40 ml of boiling water: collect the solid which separates, wash and dry it as before. The second fraction of acetylglycine weighs 15 g (total yield 55 g, 94%) and melts at 207–208°C.

4-Benzylidene-2-methyloxazol-5-one. Warm a mixture of 29 g (0.25 mol) of acetylglycine, 39.5 g (37.5 ml, 0.37 mol) of redistilled benzaldehyde [Expt 6.133, Note (1)], 15 g (0.183 mol) of anhydrous sodium acetate and 63.5 g (59 ml, 0.62 mol) of acetic anhydride in a 500-ml flask (equipped with a reflux condenser) on a water bath with occasional stirring until solution is complete (10–20 minutes). Boil the resulting solution for 1 hour, cool and leave in a refrigerator overnight. Stir the solid mass of yellow crystals with 60 ml of cold water, transfer to a Buchner funnel and wash well with cold water. (If the odour of benzaldehyde is still apparent, wash with a little ether.) Recrystallise from carbon tetrachloride or from ethyl acetate–light petroleum. The yield of the oxazolone, m.p. 150°C, is 35 g (76%).

1155
Hydrolysis to \(\alpha\)-acetamidocinnamic acid. Boil a mixture of 23.5 g (0.125 mol) of 4-benzylidene-2-methylloxazol-5-one (the crude product is satisfactory), 90 ml of water and 225 ml of acetone in a 500-ml round-bottomed flask under reflux for 4 hours. Remove most of the acetone with a rotary evaporator, dilute the residual solution with 200 ml of water, heat to boiling for 5–10 minutes and filter through a hot-water funnel. Dissolve any crystals which separate from the filtrate by heating, add 5 g of decolourising carbon, boil for 5 minutes, filter with gentle suction through a warm Buchner funnel, and wash the residue with four 25 ml portions of boiling water. Place the combined filtrate and washings in a refrigerator overnight. Collect the colourless crystals by suction filtration, wash with about 100 ml of cold water and dry at 100 °C. The yield of 2-acetamidocinnamic acid, m.p. 191–192 °C, is 22 g (86%).

Cognate preparation. Benzoylglycine (hippuric acid). Dissolve 25 g (0.33 mol) of glycine (Expt 5.180) in 250 ml of 10 per cent sodium hydroxide solution contained in a conical flask. Add 54 g (45 ml, 0.385 mol) of benzoyl chloride in five portions to the solution. Stopper the vessel and shake vigorously after each addition until all the chloride has reacted. Transfer the solution to a beaker and rinse the conical flask with a little water. Place a few grams of crushed ice in the solution and add concentrated hydrochloric acid slowly and with stirring until the mixture is acid to Congo red paper. Collect the resulting crystalline precipitate of benzoylglycine, which is contaminated with a little benzoic acid, upon a Buchner funnel, wash with cold water and drain well. Place the solid in a beaker with 100 ml of carbon tetrachloride, cover the beaker with a watch glass and boil gently for 10 minutes (fume cupboard); this extracts any benzoic acid which may be present. Allow the mixture to cool slightly, filter under gentle suction and wash the product on the filter with 10–20 ml of carbon tetrachloride. Recrystallise the dried product from boiling water (about 500 ml) with the addition of a little decolourising charcoal if necessary, filter through a hot-water funnel and allow to crystallise. Collect the benzoylglycine in a Buchner funnel and dry it in an oven. The yield is 45 g (76%), m.p. 187 °C.

4-Benzylidene-2-phenyloxazol-5-one. Place a mixture of 27 g (26 ml, 0.25 mol) of redistilled benzaldehyde, 45 g (0.25 mol) of benzoylglycine, 77 g (71.5 ml, 0.75 mol) of acetic anhydride and 20.5 g (0.25 mol) of anhydrous sodium acetate in a 500-ml conical flask and heat on an electric hotplate with constant shaking. As soon as the mixture has liquefied completely, transfer the flask to a water bath and heat for 2 hours. Then add 100 ml of ethanol slowly to the contents of the flask and allow the mixture to stand overnight. Filter the crystalline product with suction, wash with two 25 ml portions of ice-cold alcohol and then wash with two 25 ml portions of boiling water: dry at 100 °C. The yield of almost pure oxazolone, m.p. 165–166 °C, is 40 g (64%). Recrystallisation from benzene raises the m.p. to 167–168 °C.

8.3.4 Indoles, Benzo furans and Benzothiophenes

The four target molecules are indole [(63), \(R^1 = R^2 = H\)], 5-chloro-2-phenylindole [(63), \(R^1 = \text{Ph}, R^2 = \text{Cl}\)], benzo furan (64) and 5-chloro-3-methylbenzothiophene (65). The retrosynthetic analyses shown below individually illustrate
In the synthesis of indole [(63), $R^1 = H$, $R^2 = H$], the cyclisation step is effected when $N$-formyl-$o$-toluidine [$N$-(2-methylphenyl)-formamide] is treated with strong base (e.g. potassium alkoxide or sodamide) at high temperatures. The reaction, the *Madelung indole synthesis*, may be regarded mechanistically as an intramolecular Claisen condensation. In the preparative example (Expt 8.22) a simplified procedure is described in which the somewhat hazardous preparation of a potassium alkoxide from potassium metal and the alcohol is avoided by using a mixture of sodium methoxide and anhydrous potassium acetate. The yields are however poor; there is extensive loss of carbon monoxide and about half the starting material is recovered as the parent amine. Furthermore, the reaction is limited in that the presence of halogen or alkoxy ring substituents causes the reaction to fail, and the use of amides having $N$-aryloyl or branched $N$-alkanoyl groups [e.g. (63), $R^1 = Ar$ or $Bu'$], leading to the corresponding 2-aryloxy or 2-alkyldinolones, gives poor yields. This drawback has been overcome by the use of 2 or 3 molar equivalents of butyllithium in tetrahydrofuran at $-20$ to $+25 \, ^\circ C$, followed by standing overnight at room temperature. The reaction sequence is formulated in Expt 8.23 which describes the preparation of 5-chloro-2-phenylindole.

The analysis depicted for (64) reveals that the synthesis of benzo [furan] involves the conversion of salicylaldehyde into the corresponding aryloxyacetic acid by reaction with sodium chloroacetate in the presence of alkali, followed by heating with a mixture of acetic anhydride, acetic acid and sodium acetate (Expt 8.24). The ensuing cyclisation may be regarded as an internal Perkin reaction (Section 6.12.3, p. 1036) accompanied by a decarboxylative dehydration step.

The analysis for (65) illustrates the value of disconnecting the bond which joins the aromatic ring to a side-chain or functional substituent. The synthesis therefore involves reaction of thiophenol with $\alpha$-chloroacetone under basic conditions and cyclisation of the resulting substituted ketone by heating with phosphorus pentoxide (Expt 8.25).

An important general method for the preparation of substituted indoles (low yields with indole itself), known as the *Fischer indole synthesis*, consists of heating the phenylhydrazone of an aldehyde, ketone, or keto acid in the presence of
an acid catalyst. Zinc chloride, hydrochloric acid or glacial acetic acid may be used, but polyphosphoric acid is often preferred. Thus acetophenone phenylhydrazone [(66), \( R^1 = H, R^2 = \text{Ph} \)] gives 2-phenylindole [(66), \( R^1 = H, R^2 = \text{Ph} \)] (Expt 8.26). The reaction sequence involves an intramolecular condensation with the elimination of ammonia and the mechanism of the reaction is outlined below (see also the synthesis of tryptophan, Expt 5.184).

![Diagram of the reaction sequence](image)

A further interesting application is the preparation of 1,2,3,4-tetrahydrocarbazole (69) (Expt 8.26, cognate preparation) which is formed when phenylhydrazone is added to a boiling solution of cyclohexanone in acetic acid; the phenylhydrazone (68), intermediately produced, undergoes ring closure directly.

![Diagram of the reaction sequence](image)

**Experiment 8.22 INDOLE**

\[
o\text{-Me} \cdot C_6H_4 \cdot NH_2 + H \cdot CO_2H \rightarrow o\text{-Me} \cdot C_6H_4 \cdot NH \cdot CHO + H_2O
\]

*N-Formyl-o-toluidine* [N-(2-methylphenyl)formamide]. Mix together 43 g (43 ml, 0.4 mol) of o-toluidine and 21 g (17.5 ml, 0.4 mol H\( \cdot CO\_2H \)) of 90 per cent w/w formic acid in a 100-ml round-bottomed flask fitted with a reflux condenser, and heat the mixture on a boiling water bath for 3 hours. Replace the reflux condenser by a Claisen still-head and an air condenser arranged for distillation under reduced pressure, and distil the product using a water pump, collecting the formyl-o-toluidine as a fraction of b.p. 173–175 °C/25 mmHg, which solidifies on cooling, m.p. 57–59 °C; the yield is 43 g (80%).
A pure specimen, m.p. 61 °C, may be obtained by crystallisation from a mixture of benzene and light petroleum (b.p. 40–60 °C).

**Indole.** Prepare a solution of sodium methoxide in 125 ml of anhydrous methanol using 5.75 g (0.25 mol) of sodium in a 250-ml flask fitted with a reflux condenser protected by a calcium chloride guard-tube, and add 34 g (0.25 mol) of \textit{N}-formyl-\textit{o}-toluidine. Then add rapidly 50 g (0.51 mol) of coarsely ground, freshly fused potassium acetate (1) and heat under reflux with shaking until all has dissolved. Remove the methanol under reduced pressure (rotary evaporator), transfer the flask to a fume cupboard and fit a still-head and condenser set for downward distillation. Surround the flask with a bath of molten Wood’s metal (Section 2.13) and raise the temperature steadily to about 300–350 °C. The subsequent reaction is accompanied by the distillation of \textit{o}-toluidine and the evolution of carbon monoxide; continue to heat until no further distillation occurs (about 30 minutes) and finally remove traces of \textit{o}-toluidine by carefully applying partial vacuum. Remove the heating bath, allow the flask to cool and decompose the residue by adding 100 ml of water and steam distilling. Colourless plates of indole separate from the cooled distillate; make the latter slightly acidic with hydrochloric acid, collect the crystals by suction filtration and wash them with a little cold water. The yield of indole, m.p. 48–49 °C, is 5 g (17%). A purer specimen, m.p. 52 °C, may be obtained by crystallisation from light petroleum, b.p. 40–60 °C.

**Note.** (1) Heat the potassium acetate in a porcelain dish until a tranquil melt is obtained, and allow to cool in a desiccator (cf. anhydrous sodium acetate, Section 4.2.69, p. 464).

**Experiment 8.23 5-CHLORO-2-PHENYLINDOLE\textsuperscript{20}**

\[ \text{Cl} \quad \text{Me} \quad \text{NH}_2 \quad \xrightarrow{\text{Ph-COCl}} \quad \text{Cl} \quad \text{Me} \quad \text{CO-Ph} \quad \xrightarrow{\text{BuLi}} \quad \text{Cl} \quad \text{Ph} \quad \text{HN} \]

\textit{N-(4-chloro-2-methylphenyl)benzamide.} A mixture of 4-chloro-2-methylaniline (14.2 g, 0.10 mol), benzoyle chloride (14.1 g, 0.10 mol) and triethylamine (10.1 g, 0.10 mol) in anhydrous toluene (150 ml) is stirred and refluxed for 3 hours and then allowed to stand for c. 16 hours at room temperature. The resulting solids (mixture of product and salts) are filtered off and stirred at room temperature for c. 1.5 hours with water (150 ml). The solid product is filtered off and recrystallised from dichloromethane–toluene (yield 87%, m.p. 170–171 °C).

5-Chloro-2-phenylindole. A stirred solution of the foregoing amide (12.5 g, 0.05 mol) in dry tetrahydrofuran (100 ml) (from storage over 3 A molecular sieves) is maintained under a nitrogen atmosphere at an internal temperature of −20 °C and treated dropwise with butyllithium in hexane (0.10 mol using either a 1.4 or a 1.6 M solution). The stirred solution is kept at ambient temperature for 15 hours, cooled in an ice bath and treated dropwise with 2 M hydrochloric acid (60 ml). The organic layer is separated and the aqueous layer washed with benzene. The combined organic layers are dried with anhydrous magnesium sulphate, filtered, and concentrated \textit{in vacuo}. The resi-
due is recrystallised from ether-benzene: the yield of 5-chloro-2-phenylindole is 94 per cent, m.p. 195–196 °C.

Experiment 8.24 BENZOFURAN

\[
\begin{align*}
&\text{CHO} + \text{ClCH}_2\cdot\text{CO}_2\text{H} \\
&\text{OH} &\xrightarrow{(i) \text{NaOH}} &\xrightarrow{(ii) \text{HCl}}
\end{align*}
\]

\[\text{CHO} \xrightarrow{(\text{Me-CO}_2\text{O})} \text{CO}_2\text{H} \xrightarrow{\text{Me-CO}_2\text{Na}^{\text{c}}\text{H}} \]

\[\xrightarrow{\text{CO}_2 + \text{H}_2\text{O}}\]

\text{o-Formylphenoxyacetic acid.} To a mixture of 35 ml (40 g, 0.33 mol) of salicylaldehyde, 31.5 g (0.33 mol) of chloroacetic acid and 250 ml of water contained in a 500-ml, two-necked round-bottomed flask fitted with a stirrer unit, add slowly with stirring a solution of 26.7 g (0.66 mol) of sodium hydroxide in 700 ml of water. Heat the mixture to boiling with stirring and reflux for 3 hours. The solution acquires a red-brown colour. Cool and acidify the solution with 60 ml of concentrated hydrochloric acid and steam distil to remove unreacted salicylaldehyde; 12 ml (14 g) are thus recovered. Cool the residual liquor which first deposits some dark red oil which then solidifies; on standing, almost colourless crystals appear in the supernatant solution. Decant the supernatant solution and crystals and filter off the crystals, and air dry; the yield of almost pure product, m.p. 132–133 °C, is 21 g. The solidified red oil may be extracted with small quantities of hot water, the extracts treated with decolourising charcoal and cooled, to yield a further 6 g of product; total yield 27 g (71% calculated on salicylaldehyde consumed in reaction).

Benzofuran. Heat under reflux for 8 hours a mixture of 20 g (0.11 mol) of o-formylphenoxyacetic acid, 40 g of anhydrous sodium acetate, 100 ml of acetic anhydride and 100 ml glacial acetic acid. Pour the light brown solution into 600 ml of iced water, and allow to stand for a few hours with occasional stirring to aid the hydrolysis of acetic anhydride. Extract the solution with three 150 ml portions of ether and wash the combined ether extracts with 5 per cent aqueous sodium hydroxide until the aqueous layer is basic; the final basic washing phase acquires a yellow colour. Wash the ether layer with water until the washings are neutral, dry the ethereal solution over anhydrous calcium chloride and remove the ether on a rotary evaporator. Distil the residue and collect the benzofuran as a fraction of b.p. 170–172 °C. The yield of colourless product is 9.5 g (91%).

Experiment 8.25 5-CHLORO-3-METHYLBENZOTHIOPHENE

\[
\begin{align*}
&\text{Cl} + \text{ClCH}_2\cdot\text{CO}\cdot\text{Me} \xrightarrow{\text{O\text{OH}}} \\
&\text{Cl} \xrightarrow{\text{PPA}} \text{Me}
\end{align*}
\]
CAUTION: This preparation should be carried out in an efficient fume cupboard.

(p-Chlorophenylthio)acetone. To a solution of 5.6 g (0.14 mol) of sodium hydroxide in 200 ml of water in a 500-ml conical flask equipped with a stirrer, add 20.2 g (0.14 mol) of p-chlorothioacetophenol followed by 13.0 g (0.14 mol) of chloroacetone (1). Stir the mixture at room temperature for about 45 minutes and then extract with ether. Wash the combined ether extracts with water, dry over magnesium sulphate and evaporate the ether on the rotary evaporator. Distil the residue under reduced pressure and collect (p-chlorophenylthio)-acetone as a fraction of b.p. 180–183 °C/16 mmHg; the yield is 23 g (82%).

5-Chloro-3-methylbenzothiophene. Heat 10 g (0.05 mol) of p-chlorophenylthio)acetone and 100 g of polyphosphoric acid (Section 4.2.58, p. 458) in a 250-ml flask on an oil bath maintained at 120–140 °C. When the contents of the flask initially reach the reaction temperature swirl vigorously to ensure thorough mixing of the reactants. After 2 hours allow the reaction mixture to cool and add 100 ml of water. Extract the organic product with ether, wash the combined extracts with water and dry over magnesium sulphate. Distil the residue under reduced pressure and collect 5-chloro-3-methylbenzothiophene as a fraction of b.p. 98–100 °C/0.1 mmHg. The yield is 4.7 g (52%).

Note. (1) See Expt 8.20, Note (1); the compound is lachrymatory.

Experiment 8.26 2-PHENYLINDOLE

\[
\begin{align*}
\text{Me} & \quad \text{Ph} \\
\text{NH} \cdot \text{NH}_2 & \quad \text{H} \\
\text{N} & \quad \text{N} \\
\end{align*}
\]

Prepare acetophenone phenylhydrazone by warming a mixture of 20 g (0.167 mol) of acetophenone and 18 g (0.167 mol) of phenylhydrazine (CAUTION, in handling) with 60 ml of ethanol and a few drops of glacial acetic acid. Filter the cold reaction mixture, wash the solid with dilute hydrochloric acid followed by about 12 ml of cold rectified spirit. Recrystallise a small portion from ethanol and thus obtain a sample of pure acetophenone phenylhydrazone as a white solid, m.p. 106 °C.

Place 28 g of the crude phenylhydrazone in a 250-ml beaker containing 180 g of polyphosphoric acid (Section 4.2.58, p. 458). Heat on a boiling water bath, stir with a thermometer and maintain at 100–120 °C for 10 minutes (the reaction is exothermic). Add 450 ml of cold water and stir well to complete solution of the polyphosphoric acid. Filter at the pump and wash well with water. Heat the crude solid under reflux with 300 ml of rectified spirit, add a little decolourising charcoal and filter through a preheated Buchner funnel; wash the residue with 40 ml of hot rectified spirit. Cool the combined filtrates to room temperature, filter off the 2-phenylindole and wash it three times with 10 ml portions of cold alcohol. Dry in a vacuum desiccator over anhydrous calcium chloride. The yield of pure 2-phenylindole, m.p. 188–189 °C, is 20 g (79%).

Cognate preparation. 1,2,3,4-Tetrahydrocarbazole. In a 500-ml three-necked
flask fitted with a dropping funnel, a sealed stirrer unit and reflux condenser, place a mixture of 49 g (0.5 mol) of cyclohexanone and 180 g of glacial acetic acid. Heat under reflux with stirring and add 54 g (49 ml, 0.5 mol) of redistilled phenylhydrazine (CAUTION) during 1 hour; continue the stirring for a further hour. Pour the reaction mixture into a 1-litre beaker and stir vigorously while it solidifies. Cool to 5°C and filter at the pump through a Buchner funnel; cool the filtrate in ice and refilter through the same Buchner funnel. Wash the solid on the filter with 50 ml of water, suck almost dry and then wash with 50 ml of 75 per cent ethanol. Spread the crude solid upon absorbent paper and dry in the air overnight. Recrystallise the slightly damp solid from 350 ml of methanol: add a little decolourising carbon and filter through a hot-water funnel. The yield of 1,2,3,4-tetrahydrocarbazole, m.p. 116–117°C, is 65 g (76%). A further 5 g of product may be obtained by concentrating the mother-liquor to one-quarter of the original volume.

### 8.3.5 BENZIMIDAZOLES AND BENZOTRIAZOLE FROM O-PHENYLENE DIAMINE

Disconnection of the two carbon–nitrogen bonds in benzimidazole (41) reveals the ortho-diamine and formic acid.

\[
\begin{align*}
\text{N} & \quad \text{H} \\
\text{N} & \quad \text{H} \\
\end{align*}
\]

\[\text{NH}_2 + \text{O} \quad \text{H} \quad \text{HO}\]

(41)

The synthesis is effected by simply heating the reagents together. 2-Methylbenzimidazole and 2-benzylbenzimidazole are similarly formed from o-phenylene diamine and acetic acid or phenylacetic acid respectively (Expt 8.27).

Disconnection of benzotriazole (42) is almost trivial; in fact conversion of the diamine into the mono-diazenium derivative is followed by spontaneous cyclisation (Expt 8.28).

\[
\begin{align*}
\text{N} & \quad \text{N} \\
\text{N} & \quad \text{H} \\
\text{H} & \quad \text{NH}_2 + \text{HNO}_2
\end{align*}
\]

(42)

### Experiment 8.27 BENZIMIDAZOLE

\[
\begin{align*}
\text{NH}_2 & \quad + \text{H} \cdot \text{CO}_2\text{H} \\
\text{NH}_2 & \quad \rightarrow \quad \text{N} \quad \text{H} \\
\end{align*}
\]

Place 27 g (0.25 mol) of o-phenylenediamine (Expt 6.49) in a 250-ml round-bottomed flask and add 17.5 g (16 ml, 0.34 mol) of 90 per cent formic acid. Heat the mixture on a water bath at 100°C for 2 hours. Cool, add 10 per cent sodium hydroxide solution slowly, with constant rotation of the flask, until the mixture is just alkaline to litmus. Filter off the crude benzimidazole at the
pump, wash with ice-cold water, drain well and wash again with 25 ml of cold water. Dissolve the crude product in 400 ml of boiling water, add 2 g of de-colourising carbon and digest for 15 minutes. Filter rapidly at the pump through a preheated Buchner funnel and flask. Cool the filtrate to about 10 °C, filter off the benzimidazole, wash with 25 ml of cold water and dry at 100 °C. The yield of pure benzimidazole, m.p. 171–172 °C, is 25 g (85%).

Cognate preparations. **2-Methylbenzimidazole.** Heat together a mixture of 5.43 g (0.03 mol) of o-phenylenediamine dihydrochloride (Expt 6.49, Note (3)), 20 ml of water and 5.4 g (0.09 mol) of acetic acid under reflux for 45 minutes. Make the cooled reaction mixture distinctly basic by the gradual addition of concentrated ammonia solution, collect the precipitated product and recrystallise it from 10 per cent aqueous ethanol. The yield is 2.2 g (56%), m.p. 176 °C.

**2-Benzylbenzimidazole.** Use 5.43 g (0.03 mol) of o-phenylenediamine dihydrochloride, 20 ml of water, 12.3 g (0.09 mol) of phenylacetic acid (Expt 5.128) and proceed as for 2-methylbenzimidazole. Recrystallise the crude product from 40 per cent aqueous ethanol. The yield is 3.4 g (55%), m.p. 191 °C.

**Experiment 8.28 BENZOTRIAZOLE**

![Benzotriazole](attachment:image.png)

Dissolve 10.8 g (0.1 mol) of o-phenylenediamine (1) in a mixture of 12 g (11.5 ml, 0.2 mol) of glacial acetic acid and 30 ml of water contained in a 250-ml beaker; slight warming may be necessary. Cool the clear solution to 15 °C, stir magnetically and then add a solution of 7.5 g (0.11 mol) of sodium nitrite in 15 ml of water in one portion. The reaction mixture becomes warm and within 2–3 minutes reaches a temperature of about 85 °C and then begins to cool while the colour changes from deep red to pale brown. Continue stirring for 15 minutes, by which time the temperature will have dropped to 35–40 °C, and then thoroughly chill in an ice-water bath for 30 minutes. Collect by vacuum filtration the pale brown solid which separates and wash with three 30 ml portions of ice-cold water. Dissolve the solid in about 130 ml of boiling water, add decolourising charcoal, filter and allow the filtrate to cool to about 50 °C before adding a few crystals of the crude benzotriazole which have been retained for seeding. Allow the mixture to attain room temperature slowly (to avoid separation of the material as an oil) and then thoroughly chill in ice and collect the benzotriazole which separates as pale straw-coloured needles, m.p. 99–100 °C. A second crop may be obtained by concentrating the filtrate. The yield is about 8 g (67%). The benzotriazole crystallises much more readily from benzene (c. 55 ml) but the material is still slightly coloured. A pure white product can be obtained by sublimation at 90–95 °C at 0.2 mmHg.

**Note.** (1) o-Phenylenediamine is generally contaminated by highly coloured impurities. A somewhat more pure benzotriazole may be obtained by using purified o-phenylenediamine (see Expt 6.49).
8.4 SIX-MEMBERED HETEROCYCLES

The six-membered nitrogen heteroaromatic compound is pyridine (70); the benzo analogues are quinoline (71) and isoquinoline (72).

The selected examples of six-membered heterocyclic rings containing two nitrogen atoms are based on the pyrimidine [(73), 1,3-diazabenzene], pyrazine [(74), 1,4-diazabenzene] and quinoxaline [(75), benzopyrazine] systems.

The pyrylium salts (76) are the six-membered oxygen heteroaromatic compounds. The 2- and 4-pyrones [(77) and (78) respectively] and the corresponding benzo analogues [coumarins (79) and chromones (80)] are represented by examples which further illustrate the usefulness of retrosynthetic analysis in the derivation of preparative methods.

The 2- or 4-hydroxypyridines [(81) and (82)] are tautomeric and in solution exist preferentially in the corresponding pyridone forms. Their synthesis from the corresponding pyrones by a heteroatom exchange reaction is possible.

Barbituric acid (83), which is formally 2,4,6-trihydroxyprimidine, is extensively tautomeric (p. 1175). The barbiturate drugs are derivatives of the triketo form. Piperazine-2,5-dione (84) is a diamide based upon the pyrazine ring system.
As in the five-membered heterocyclic section the discussion of the relevant ring-forming reaction is related, as appropriate, to an overall strategy of skeletal assembly, and to a more rigorous retrosynthetic analysis. The reactions are conveniently discussed in relation to the synthesis of compounds belonging to the following groups of heterocycles.

1. Pyridines and pyrylium salts.
2. Pyrones and pyridones.
3. Barbituric acid and barbiturates.
4. Quinolines, isoquinolines and quinoxalines.
5. Coumarins and chromones.

### 8.4.1 PYRIDINES AND PYRYLIUM SALTS

The two target molecules, which illustrate cyclisation reactions involving substituted 1,5-dicarbonyl compounds in the presence of appropriate reagents, are diethyl 2,6-dimethylpyridine-3,5-dicarboxylate (85) and 2,4,6-triphenylpyrylium fluoroborate (86). The latter is of specific interest since it provides a simple example to illustrate a general procedure for the conversion of pyrylium salts into pyridinium derivatives; these latter compounds are important reagents for a variety of functional group interconversions (see Sections 5.5.6, p. 574, and 5.15.3, p. 768).

In the case of (85) an initial reduction transform to the corresponding 1,4-dihydropyridine (87) facilitates recognition of the synthons arising from subsequent disconnections. This reduction step is legitimate since the reverse oxidation step in the synthesis is particularly facile owing to mesomeric stabilisation of the aromatic ring system. Disconnection of both carbon–nitrogen bonds in the 1,4-dihydropyridine, in a manner similar to that formulated for pyrrole derivatives, reveals the bis-keto ester (88) and ammonia. Further rational disconnection of the bis-keto ester then finally discloses two molecules of ethyl acetoacetate and one of formaldehyde as the other starting materials.
The preparation of (83) (Expt 8.29) is an example of the Hantzsch pyridine synthesis. This is a widely used general procedure since considerable structural variation in the aldehydic compound (aliphatic or aromatic) and in the 1,3-dicarbonyl component (β-keto ester or β-diketone) is possible, leading to the synthesis of a great range of pyridine derivatives. The precise mechanistic sequence of ring formation may depend on the reaction conditions employed. Thus if, as implied in the retrosynthetic analysis above, ethyl acetoacetate and the aldehyde are first allowed to react in the presence of a base catalyst (as in Expt 8.29), a bis-keto ester [e.g. (88)] is formed by successive Knoevenagel and Michael reactions (Section 5.11.6, p. 681). Cyclisation of this 1,5-dione with ammonia then gives the dihydropyridine derivative. Under different reaction conditions condensation between an aminocrotonic ester and an alkylidene acetoacetate may be involved.

Oxidation of the dihydropyridine derivative is most conveniently carried out with an aqueous nitric–sulphuric acid mixture. Removal of the ethoxycarbonyl groups may be achieved by a stepwise hydrolysis and decarboxylation sequence, but the one-step reaction described in Expt 8.29 using soda-lime is convenient.

The retrosynthetic analysis of 2,4,6-triphenylpyrylium tetrafluoroborate (86), involving an initial reduction followed by a disconnection of one carbon–oxygen bond (cf. disconnection of 2,5-dimethylfuran, Section 8.3.1, p. 1146), reveals the substituted 1,5-dicarbonyl compound (89). Further rational disconnection then reveals acetophenone and 1,3-diphenylprop-2-en-1-one (chalcone); clearly the latter may originate from acetophenone and benzaldehyde (cf. Section 6.12.2, p. 1032).
A convenient synthetic procedure\textsuperscript{21} (Expt 8.30) involves stirring and warming acetophenone and benzaldehyde with boron trifluoride-etherate; hydrogen is evolved during the final oxidation stage which leads to the pyrylium tetrafluoroborate derivative. An alternative method using chalcone, acetophenone and fluoroboric acid has been published.\textsuperscript{22} 2,4,6-Triphenylpyrylium perchlorate is formed when chalcone and acetophenone are heated in the presence of perchloric acid\textsuperscript{23}; the perchlorates tend to decompose with explosive violence if not handled with care.

Either the pyrylium tetrafluoroborate or the perchlorate salt may be converted into the corresponding halide by initial conversion into the pseudobase [(90), 1,3,5-triphenylpent-2-en-1,5-dione] with dilute alkali, followed by recyclication in the presence of the hydrogen halide.\textsuperscript{24}

All these various pyrylium salts are converted by ammonia, or alkyl, arylkyl or aryl primary amines into the corresponding pyridinium salts.\textsuperscript{25} The probable reaction sequence is given in the illustrative example 1-benzyl-2,4,6-triphenylpyridinium tetrafluoroborate\textsuperscript{26} (Expt 8.31).

The preparations of 2-alkyl- and 2-arylpypyridines from pyridine itself are of interest in that their syntheses illustrate the activating influence of the ring nitrogen on the 2- and 4-ring carbons and on the 2- and 4-alkyl substituents. A preparative example to exemplify the former is the synthesis of 2-phenylpyridine by the reaction of pyridine with phenyllithium (Expt 8.32). Addition of the organometallic derivative to the azomethine linkage in pyridine gives an intermediate derived from a 1,2-dihydropyridine system. This undergoes thermal elimination of lithium hydride to form 2-phenylpyridine. The formation of 2-alkylpyridines may be effected similarly using the appropriate alkyl lithium.

Activation of alkyl substituents is illustrated by the synthesis of the isomeric pentyldpyridines (Expt 8.33) and ethyl 2-pyridylacetate (Expt 8.32, cognate preparation). Thus removal of a proton from the 2-methyl group of 2-methylpyridine (2-picoline) with the aid of base (e.g. sodamide) gives a mesomerically
stabilised anion (91) which may then be alkylated with an alkyl halide. Alternatively, the anion may be reacted with carbon dioxide to give 2-pyridylacetic acid, which may be subsequently esterified by treatment with ethanolic hydrogen chloride.

4-Methylpyridine, and even the less reactive 3-methyl derivative, may also be alkylated in a similar manner.

**Experiment 8.29 DIETHYL 2,6-DIMETHYLpyRIDINE-3,5-DICARBOXYLATE AND 2,6-DIMETHYLpyRIDINE**

**Diethyl 1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate.** Cool 52 g (51 ml, 0.4 mol) of ethyl acetoacetate to 0°C and add 15 ml (0.2 mol) of 40 per cent aqueous formaldehyde solution, followed by a few drops of diethylamine as a catalyst. Keep the mixture at 0°C for 6 hours and then at room temperature for 40 hours. Separate the lower organic layer, extract the aqueous phase with ether and dry the combined organic fractions over anhydrous calcium chloride. Remove the ether under reduced pressure (rotary evaporator) and transfer the residue together with an equal volume of ethanol to a stout reagent bottle cooled in an ice bath. Pass a steady stream of ammonia gas (from a cylinder) into the solution held at 0°C for 1 hour, close the bottle with a bung securely attached with wire and set the bottle and contents aside at room temperature for 40 hours. Filter the resulting yellow solution to remove a small quantity of almost colourless material and heat the filtrate on a boiling water bath in an evaporating dish until most of the ethanol has been removed, and then cool and crystallise the residue from about 400 ml of rectified spirit. The yield of the pale yellow crystalline dihydropyridine derivative is 36 g (71%), m.p. 181–183°C.

**Diethyl 2,6-dimethylpyridine-3,5-dicarboxylate.** Place 35.5 (0.14 mol) of the above dihydropyridine derivative in a 1-litre round-bottomed flask and add carefully a cold mixture of 50 ml of water, 9 ml of concentrated nitric acid (d 1.42) and 7.5 ml of concentrated sulphuric acid. Swirl the mixture and heat
it cautiously on a boiling water bath until a vigorous reaction, accompanied by much foaming, sets in. When the reaction has moderated continue to heat cautiously for 15 minutes until oxidation is complete and a deep red solution is obtained. Cool the solution, add 100 ml of water and 100 g of crushed ice, and make it distinctly alkaline with concentrated aqueous ammonia solution (d 0.88). Filter off the solid product, wash it with a little cold water and recrystallise it from aqueous ethanol. The yield of colourless crystals of the pyridine derivative, m.p. 71–72 °C, is 22.5 g (64%).

2,6-Dimethylpyridine. Place an intimate mixture of 10 g (0.04 mol) of the above pyridine di-ester and 60 g of soda-lime (10–14 mesh) in a 100-ml round-bottomed flask fitted with a still-head and condenser arranged for distillation. Heat the flask gradually in an oil bath to about 250 °C, and maintain this temperature until no further material distils below 105 °C (about 2 hours may be required). Remove the oil bath, clean the outside of the flask and continue to heat more strongly with a Bunsen burner held in the hand, keeping the flame moving over the surface of the flask. Collect the product which now distils, and continue to heat strongly until the flask reaches dull red heat and no further distillate is obtained. Treat the distillate with potassium hydroxide pellets so that the pyridine separates, and isolate the latter by extraction with ether. Dry the ether extract over fresh potassium hydroxide pellets, and remove the ether and distil the residue at atmospheric pressure. Collect the dimethylpyridine as a fraction of b.p. 142–145 °C; the yield is 2.8 g (65%).

Experiment 8.30 2,4,6-TRIPHENYLPYRYLIUM TETRAFLUOROBORATE

\[
\begin{align*}
\text{Me} & \quad \text{Ph} \\
\text{Ph} & \quad \text{CO} \quad \text{CHO} \\
\text{Me} & \quad \text{CO} \quad \text{Ph}
\end{align*}
\]

\[\quad + \frac{4}{3} \text{BF}_3 \rightarrow \quad \frac{3}{3} \text{BF}_4^+ \quad + \text{H}_2 + \frac{1}{3} \text{B(OH)}_3 + \text{H}_2\text{O}\]

CAUTION: As hydrogen is evolved in this reaction the preparation should be conducted in a well-vented fume cupboard.

To a mixture of acetophenone (60 g, 0.5 mol) and benzaldehyde (26.5 g, 0.25 mol) is added, with stirring, boron trifluoride-etherate (84 g, 0.65 mol); the mixture becomes coloured and the temperature rises, often to about 70 °C. On maintaining the temperature at 100 °C for 2 hours ether distils from the reaction mixture. The product of the reaction is a viscous brown oil which must be dissolved in acetone (300 ml) and the tetrafluoroborate salt precipitated by the addition of ether (3 litres). 2,4,6-Triphenylpyrylium tetrafluoroborate (yield 40%) is obtained as a yellow crystalline solid by filtration and recrystallisation from acetone; m.p. 253–255 °C.
Experiment 8.31 1-BENZYL-2,4,6-TRIPHENYLPYRIDINIUM TETRAFLUOROBORATE

2,4,6-Triphenylpyrylium tetrafluoroborate (12 g, 0.03 mol) and benzylamine (2.8 g, 0.03 mol) are stirred in absolute ethanol (50 ml) with triethylamine (0.3 g, 0.003 mol) for 2 hours. The crude product is filtered off, washed with ether (25 ml) and recrystallised as white needles from absolute ethanol (15 ml). The product is obtained in 81 per cent yield; m.p. 193–195 °C.

Experiment 8.32 2-PHENYLPYRIDINE

The first stage is the preparation of a solution of phenyllithium in dry ether. Equip a 1-litre three-necked flask as shown in Fig. 2.60. Flush the apparatus with dry, oxygen-free nitrogen gas. Place 7.35 g (1.06 mol) of lithium shavings (1) in the flask, and introduce a solution of 78.5 g (52.5 ml, 0.5 mol) of dry, redistilled bromobenzene in 250 ml of anhydrous ether into the dropping funnel. Start the stirrer. Run in about 2 ml of the solution; when the reaction starts, as indicated by an initial cloudiness, add the remainder at such a rate that the solvent refluxes gently (about 45 minutes). Finally, add 50 ml of anhydrous ether through the dropping funnel. Continue the stirring until all or most of the lithium disappears (1–1.5 hours) (2).

Now introduce slowly, and with stirring, 79 g (1 mol) of pure anhydrous pyridine (Section 4.1.29, p. 410) (CAUTION) dissolved in 200 ml of anhydrous toluene: remove the ether by distillation, replace the dropping funnel by a thermometer and stir the residual suspension at 110 °C (internal temperature) for 8 hours. Then cool to about 40 °C, and add cautiously 75 ml of water through the condenser. Filter the liquids if necessary, separate the upper toluene layer, dry it by shaking for an hour with 20 g of potassium hydroxide pellets and distil slowly through a short fractionating column. When the temperature reaches 150 °C at ordinary pressure (thus indicating the removal of most of the toluene, etc.), distil the residue under reduced pressure and collect the liquid passing over at 138–142 °C/12 mmHg. Upon redistillation 38 g (49%) of pure 2-phenylpyridine, b.p. 140 °C/12 mmHg, is obtained.

Notes. (1) See p-toluic acid, Expt 6.158, Note (1).
(2) The yield of phenyllithium generally exceeds 95 per cent. One interesting and instructive method of determination is to allow the phenyllithium to react with excess benzophenone and to weigh the triphenylmethanol formed which is assumed to be
formed quantitatively. A better method is to hydrolyse a 2 ml aliquot portion of the filtered solution with distilled water and to titrate the hydrolysate with standard acid, using phenolphthalein as indicator. To obtain the filtered solution, the dropping funnel is replaced by a short L-shaped tube loosely plugged with glass wool, and the solution is decanted through this tube into a graduated flask that has been swept out with nitrogen.

**Cognate preparation. Ethyl 2-pyridylacetate.** Prepare a solution of phenyl-lithium in anhydrous ether as detailed above for 2-phenylpyridine, using 7.35 g (1.06 mol) of lithium. Introduce 46.5 g (49 ml, 0.5 mol) of dry, redistilled 2-methylpyridine, with continued stirring dropwise during about 10 minutes. Stir the dark red-brown solution of 2-pyridylmethyllithium for a further 30 minutes, and then pour it slowly (1) and with shaking on to about 400 g of solid carbon dioxide contained in a 1.5-litre round-bottomed flask. Break up the lumpy residue of lithium salts before adding 375 ml of absolute ethanol. Cool the solution in ice, saturate it with dry hydrogen chloride and then insert a calcium chloride drying tube into the neck of the flask. Allow the mixture to stand overnight, remove the ethanol under reduced pressure (rotary evaporator) on a water bath. Dissolve the syrupy residue in 375 ml of dichloromethane and transfer to a three-necked flask fitted with a mechanical stirrer and a reflux condenser. Prepare a paste from 112.5 g (0.815 mol) of potassium carbonate and 70 ml of water, and add it slowly through the third neck to the dichloromethane solution with constant stirring. Stir the almost boiling solution vigorously for 1 hour. Decant the dichloromethane solution from the inorganic salts, remove the solvent by distillation from a water bath (rotary evaporator) and distil the residue under diminished pressure from a flask with a short fractionating column. 2-methylpyridine (c. 20 g) passes over first, followed by ethyl 2-pyridylacetate as a pale yellow liquid at 135–137 °C/28 mmHg, or 110–112 °C/6 mmHg. The yield is 30 g (36%).

**Note.** (1) It is advisable to filter the 2-pyridylmethyllithium solution rapidly through a thin layer of glass wool (to remove any unreacted lithium) before it is added to the solid carbon dioxide.

**Experiment 8.33 2-PENTYLPYRIDINE**

![Chemical Structure](attachment:image.png)

Into a 500-ml three-necked flask fitted with a dropping funnel, a sealed stirrer unit and reflux condenser protected by a drying tube, place a fine suspension of 40 g (1 mol) of good quality sodamide (Section 4.2.67, p. 462) in about 150 ml of anhydrous xylene. Introduce 37.5 g (40 ml, 0.4 mol) of 2-methylpyridine through the dropping funnel and rinse the latter with a few ml of dry xylene. Set the stirrer in motion and add 44.5 g (50.5 ml, 0.48 mol) of butyl chloride (Expt 5.50) over a period of 1 hour; reflux the mixture with stirring for 2–3 hours. When cold, destroy the excess of sodamide by the cautious addition of 100 ml of water. Transfer the contents of the flask to a separatory funnel and discard the lower aqueous layer. Extract the xylene solution with four 50 ml portions of 1:1 hydrochloric acid. Steam distil the acid extracts to remove traces of xylene, cool the aqueous solution and render strongly alka-
line by the addition of solid sodium hydroxide: a brown oil appears. Steam distil again and collect about 700 ml of distillate. Separate the upper layer in the steam distillate, extract the aqueous layer with ether and dry the combined upper layer and ether extract with anhydrous potassium carbonate. After removing the ether, distil through a Fenske-type column (15 cm diameter and packed with glass helices for a length of 12-15 cm) at a pressure of 50 mmHg (manostat, see Section 2.30) and collect the 2-pentylpyridine (42 g, 70%) at 122.5-124.5 °C/50 mmHg. Upon redistillation, the product boils almost entirely at 105 °C/17 mmHg.

Cognate preparations. 4-Pentylpyridine. Charge a 1-litre three-necked flask (equipped with a sealed stirrer unit, a dropping funnel and a short air condenser) with 600 ml of liquid ammonia (Section 2.17.7, p. 116). Stir vigorously, add 0.5 g of powdered iron(III) nitrate followed, after 1 minute, by 11.9 g (0.52 mol) of clean sodium in small pieces through the short air condenser over a period of half an hour; continue the stirring until the initial blue colour is replaced by a colourless or pale grey suspension of sodamide (see p. 462). Introduce 42.0 g (44.0 ml, 0.45 mol) of pure 4-methylpyridine through the air condenser; a green colour develops immediately. Stir for 15-20 minutes and add 46.3 g (52.6 ml, 0.5 mol) of butyl chloride (or an equivalent amount of butyl bromide) from the dropping funnel at such a rate that the reaction does not become unduly vigorous (c. 10 minutes); upon completion of the addition the green colour will have been discharged. Stir for a further 10-15 minutes, pour the reaction mixture into a 2-litre beaker: allow the liquid ammonia to evaporate overnight. Rinse the reaction flask with 100 ml of water and add the rinsings to the residue in the beaker; two layers form. Separate them and keep the upper layer of 4-pentylpyridine: extract the lower layer with a little xylene and wash the xylene extract with 25 ml of 1:1 hydrochloric acid. Dissolve the 4-pentylpyridine in 1:1 hydrochloric acid, combine it with the acid washings of the xylene extract and steam distil to remove traces of xylene; cool, add solid sodium hydroxide until strongly alkaline and steam distil again. Isolate the 4-pentylpyridine as described above for the 2-pentyl compound. The yield of the pure base, b.p. 95 °C/6 mmHg, is 46 g (69%).

3-Pentylpyridine. Proceed exactly as described for 4-pentylpyridine using 11.9 g (0.52 mol) of sodium, 42 g (0.45 mol) of 3-methylpyridine and 46.3 g (0.5 mol) of butyl chloride. The yield of pure 3-pentylpyridine, b.p. 100.5 °C/9 mmHg, is 46 g (69%).

8.4.2 PYRONES AND PYRIDONES

In this section the synthesis of coumalic acid (92), representing the α(2)-pyrone system, is described. α-Pyrones readily undergo a simple lactone–amide transformation, and the conversion of coumalic acid into the tautomeric 6-hydroxy-nicotinic acid (93) provides a further illustration of the conversion of a six-membered oxygen heterocycle into the corresponding nitrogen system.
Application of the principles of disconnection in heterocyclic rings to coumalic acid (92) reveals two molecules of formylacetic acid.

In the synthesis (Expt 8.34), formylacetic acid is formed in situ by the action of a concentrated sulphuric acid–fuming sulphuric acid mixture on malic acid (HO₂C·CHOH·CH₂·CO₂H). This α-hydroxydicarboxylic acid undergoes decarbonylation and dehydration under these conditions before the acid-catalysed self-condensation of formylacetic acid. The cyclisation step is generally applicable to β-keto esters.

Conversion of the derived methyl coumalate into methyl 6-hydroxynicotinate (Expt 8.35) is effected by the action of concentrated aqueous ammonia; subsequent hydrolysis with aqueous alkali yields 6-hydroxynicotinic acid.

**Experiment 8.34 COUMALIC ACID**

\[
2 \text{CH(OH)·CO₂H} \xrightarrow{\text{H₂SO₄}} \text{HO₂C} + 2\text{CO} + 4\text{H₂O}
\]

Add 180 ml of sulphuric acid to 202 g (1.5 mol) of finely powdered malic acid contained in a 2-litre round-bottomed flask. At intervals of 45 minutes, add three 50 ml portions of fuming sulphuric acid (25% SO₃); a slight exothermic reaction sets in with the steady evolution of gas. Swirl the mixture frequently to obviate excessive foaming, and when the evolution of gas has slackened, heat the reaction mixture on a water bath for 2 hours. Cool the mixture and pour on to 800 g of ice with stirring. Set the mixture aside in a refrigerator for
24 hours and then filter the crude coumalic acid and wash with small portions of iced water. Recrystallise the crude product from methanol to give coumalic acid as light yellow crystals, m.p. 206–208 °C. The yield is 65 g (62%). Record the p.m.r. spectrum (Me$_2$SO-$d_6$) and assign the signals which appear at $\delta$ 6.40 (d of d, 1H), 7.81 (d of d, 1H), 8.49 (d of d, 1H) and 10.32 (broad, 1H).

Experiment 8.35 6-HYDROXYNICOTINIC ACID

Methyl coumalate. Place 100 ml of concentrated sulphuric acid in a 250-ml round-bottomed flask and add with swirling 35 g (0.224 mol) of finely powdered coumalic acid (Expt 8.34). The solution acquires a deep red-brown colour and the temperature tends to rise but should be kept below 30 °C by cooling in an ice-water bath. Add 50 ml of methanol with continued swirling in small portions so that the temperature of the reaction mixture does not rise above 35 °C. Heat the reaction mixture on a boiling water bath for 1.5 hours. Cool the mixture and pour slowly into 500 ml of an ice-water slurry with stirring. Add about 150 g of sodium carbonate as a slurry in water until the mixture is just neutral. If too much carbonate has been added the supernatant liquid will acquire a red colour; in these circumstances add a few drops of sulphuric acid. The final solution containing a suspension of methyl coumalate and inorganic salts should be an orange colour. Filter the solution, and slurry the residue with four 70 ml portions of cold water containing a drop of concentrated sulphuric acid. Filter off the methyl coumalate; the yield after air drying is 18 g (47%). Although the product may be used for the next stage, a sample may be purified by vacuum sublimation; pure methyl coumalate has m.p. 74 °C.

6-Hydroxynicotinic acid. Place a mixture of 20 ml of ammonia solution ($d$ 0.880) and 30 ml of water in a 250-ml beaker sited in an ice-water cooling bath on a magnetic stirrer unit. Insert a magnetic follower and add portion-wise 18 g (0.105 mol) of methyl coumalate over a period of about 5 minutes, ensuring that the temperature is kept below 20 °C. Stir the resulting dark red solution for a further 45 minutes at 20 °C and then add it to boiling aqueous sodium hydroxide prepared from 40 g of sodium hydroxide and 250 ml of water. Boil the reaction mixture for 5 minutes, cool to 10 °C in an ice-water cooling bath and add concentrated hydrochloric acid with stirring to precipitate the product; the temperature of the solution during neutralisation should not rise above 30 °C. Allow the acidified solution to stand in the ice-water bath for 1 hour and then collect the bright yellow crystalline solid by filtration. Wash the crystals with water and then air dry. The yield of 6-hydroxynicotinic acid, m.p. 299–300 °C (decomp.), is 8.5 g (58%).

8.4.3 BARBITURIC ACID AND BARBITURATES

The target molecules selected to illustrate some further cyclisation reactions are barbituric acid (83) and 5-ethyl-5-phenylbarbituric acid (94), the latter being an
example of the well-known barbiturate drugs. Piperazine-2,5-dione [diketopiperazine (84)] has also been included here because of the similar disconnection involved in retrosynthetic analysis.

![Chemical structures](image)

Barbituric acid (83) may be regarded as 2,4,6-trihydroxypyrimidine, but in the crystalline state it exists as the triketo-form (95). In aqueous solution the compound is remarkably acidic as the result of ionisation of the mono-enolic form (96) with the formation of a resonance stabilised anion (97).

![Chemical reactions](image)

Urea may be recognised as a structural feature in the triketo form; disconnection then reveals diethyl malonate as the other reagent. The synthesis of barbituric acid is therefore effected (Expt 8.36) by condensation of diethyl malonate with urea in the presence of sodium ethoxide. Barbituric acid undergoes nitration in the 5-position on treatment with fuming nitric acid, and reduction of the nitro derivative (98) yields 5-aminobarbituric acid (99) (uramil).

![Chemical reactions](image)

A similar retrosynthetic analysis for 5-ethyl-5-phenylbarbituric acid (94) discloses urea and diethyl ethylphenylmalonate.
The synthesis of the disubstituted malonic ester cannot be achieved by successive ethylation and phenylation procedures [cf. Section 5.11.6, p. 680] since for the latter reaction the aryl halide is not sufficiently reactive. The procedure described below (formulated in Expt 8.37) provides a suitable indirect alternative route. This involves a mixed Claisen ester condensation (cf. Section 5.14.3, p. 738) between ethyl phenylacetate and diethyl oxalate, followed by decarbonylation of the α-keto diester on heating to 175 °C.

Piperazine-2,5-dione (84) is a cyclic diamide based upon the alternative 1,4-diaza heterocyclic system and appropriate disconnection of the N—CO bond reveals two molecules of glycine.

\[
\text{O} \quad \text{N} \quad \text{N} \quad \text{O} \\
\text{N} \quad \text{O} \\
(84)
\]

The synthesis of (84) is effected by heating glycine in solvent such as ethylene glycol (Expt 8.38). Brief treatment with hot concentrated aqueous hydrochloric acid cleaves one of the amide linkages with the formation of the dipeptide, glycylglycine, which is isolated as the hydrochloride monohydrate and may be converted into the ester hydrochloride under Fischer–Speier conditions (Section 5.12.3, p. 696).

\[
\text{H}_3\text{N}^+ \quad \text{O} \quad \text{N} \quad \text{O} \\
\text{H} \quad \text{NH}_2 \quad \text{HO} \quad \text{O} \\
(84) \xrightarrow{\text{HCl}} \xrightarrow{\text{EtOH/HCl}} \text{Cl}[\text{H}_3\text{N}^+ \quad \text{O} \quad \text{N} \quad \text{O}] \quad \text{Et}
\]

**Experiment 8.36 BARBITURIC ACID**

In a 2-litre round-bottomed flask, fitted with a double surface reflux condenser, place 11.5 g (0.5 mol) of clean sodium. Add 250 ml of absolute ethanol in one portion: if the reaction is unduly vigorous, immerse the flask momentarily in ice. When all the sodium has reacted, add 80 g (76 ml, 0.5 mol) of diethyl malonate, followed by a solution of 30 g (0.5 mol) of dry urea in 250 ml of hot (c. 70 °C) absolute ethanol. Shake the mixture well, fit a calcium chloride guard-tube to the top of the condenser and reflux the mixture for 7 hours in an oil bath heated to 110 °C. A white solid separates. Treat the reaction mixture with 450 ml of hot (50 °C) water and then with concentrated hydrochloric acid, with stirring, until the solution is acid (about 45 ml). Filter the resulting almost clear solution and leave it in the refrigerator overnight. Filter the solid at the pump, wash it with 25 ml of cold water, drain well and then dry at 100 °C for 4 hours. The yield of barbituric acid is 50 g (78%). It melts with decomposition at 245 °C.
Conversion to aminobarbituric acid (uramil). *Nitrobarbituric acid.* Place 72 ml of fuming nitric acid, *d* 1.52, in a 1-litre flask equipped with a mechanical stirrer and surrounded by an ice bath. Add 50 g (0.39 mol) of barbituric acid with stirring, over a period of 2 hours; keep the temperature below 40 °C during the addition. Stir for a further 1 hour, and continue the stirring while 215 ml of water is added and the solution is cooled to 10 °C. Filter with suction through a sintered glass funnel, wash with cold water and dry on a clock glass at 60–80 °C. Dissolve the crude nitrobarbituric acid in 450 ml of boiling water, filter and allow to stand overnight. Collect the crystals by suction filtration, wash well with cold water, and dry at 90–95 °C for 2–3 hours. The product is the trihydrate, m.p. 181–183 °C (decomp., rapid heating), and weighs 70 g. Drying at 110–115 °C for 2–3 hours gives 47 g (70%) of anhydrous nitrobarbituric acid, m.p. 176 °C (decomp.).

*Uramil.* In a 3-litre flask place 38 g (0.22 mol) of anhydrous nitrobarbituric acid and 300 ml of concentrated hydrochloric acid; heat the mixture on a boiling water bath. Add 125 g of granulated tin and 200 ml of concentrated hydrochloric acid over a period of about 30 minutes: continue the heating until the yellow colour, due to the nitro compound, in the liquid is no longer visible. Introduce 1500 ml more of concentrated hydrochloric acid and heat until all the white solid dissolves; add a little decolourising charcoal, and filter the hot mixture through a sintered glass funnel. Keep the filtrate at 0 °C overnight, collect the uramil by filtration with suction, wash well with dilute hydrochloric acid and finally with water. Concentrate the filtrate under reduced pressure (rotary evaporator) to about 500 ml and cool overnight. Collect the second crop of uramil, wash it as before and combine it with the first product. Dry in a vacuum desiccator over concentrated sulphuric acid. The resulting uramil (23 g, 73%) is a fine white powder, it does not melt below 400 °C, and becomes pink to red on standing, particularly if ammonia is present in the air.

**Experiment 8.37 5-ETHYL-5-PHENYLBARBITURIC ACID (Phenobarbitone)**

\[
\begin{align*}
\text{Ph} \cdot \text{CH}_2 \cdot \text{CO}_2 \text{Et} & \quad + \quad \text{EtO}_2 \text{C} \cdot \text{CO}_2 \text{Et} \\
& \rightarrow \begin{align*}
(i) & \text{OEt} \quad \rightarrow \quad \text{Ph} \cdot \text{CH} \cdot \text{CO} \cdot \text{CO}_2 \text{Et} \\
(ii) & \text{H}_2 \text{O} \oplus \quad \rightarrow \quad \text{Ph} \cdot \text{CH} \cdot \text{CO}_2 \text{Et}
\end{align*}
\end{align*}
\]

![Diagram of reaction](image)

Diethyl phenylmalonate. In a thoroughly dried 1-litre flange flask, equipped with a dropping funnel, reflux condenser (both protected with calcium chloride guard-tubes) and a sealed stirrer unit, place 11.5 g (0.5 mol) of clean sodium pieces (see Section 4.2.68, p. 462); add 250 ml of super-dry ethanol
(Section 4.1.9, p. 400) and allow the vigorous reaction to proceed, cooling only if the reaction appears to be beyond control. When all the sodium has reacted, cool the solution to 60 °C, and add 73 g (67 ml, 0.5 mol) of pure, freshly distilled diethyl oxalate from the dropping funnel in a rapid stream with vigorous stirring. Wash this down with 5 ml of absolute ethanol and add immediately 87.5 g (85 ml, 0.535 mol) of pure ethyl phenylacetate (Expt 5.152). Discontinue stirring and raise the stirrer clear of the reaction mixture. Within 4–7 minutes after the ethyl phenylacetate has been added, crystallisation commences. Allow the nearly solid paste of the sodio derivative to cool to room temperature, remove the flange lid and stir manually with 400 ml of dry ether. Collect the solid by suction filtration and wash it repeatedly with dry ether. Transfer the solid to a beaker and liberate the ethyl phenylxaloacetate with ice-cold dilute sulphuric acid (14–15 ml of concentrated sulphuric acid in 250 ml of water). Separate the almost colourless oil and extract the aqueous layer with three 50 ml portions of ether; dry the combined oil and ethereal extracts with magnesium sulphate, remove the ether with a rotary evaporator. Equip the flask containing the residue for distillation under reduced pressure and heat the flask under a pressure of about 15 mm of mercury (water pump) in an oil bath. Raise the temperature of the bath gradually to 175 °C and maintain this temperature until the evolution of carbon monoxide is complete (fume cupboard); if the pressure rises unduly during the heating (owing to a rather rapid evolution of gas), discontinue the heating momentarily. When the reaction is complete (5–6 hours), return the oil which has passed over to the flask, and distil under reduced pressure. Collect the diethyl phenylmalonate at 159–161 °C/10 mmHg (or at 165–166 °C/15 mmHg). The yield is 95 g (80.5%).

Diethyl ethylphenylmalonate. In a dry 500-ml round-bottomed flask, fitted with a reflux condenser and guard-tube, prepare a solution of sodium ethoxide from 7.23 g (0.315 mol) of clean sodium and 150 ml of super-dry ethanol in the usual manner; add 1.5 ml of pure ethyl acetate (dried over anhydrous calcium sulphate) to the solution at 60 °C and maintain this temperature for 30 minutes. Meanwhile equip a 1-litre three-necked flask with a dropping funnel, a sealed mechanical stirrer and a double surface reflux condenser: the apparatus must be perfectly dry and guard-tubes should be inserted in the funnel and condenser respectively. Place a mixture of 74 g (0.315 mol) of diethyl phenylmalonate and 60 g (0.385 mol) of ethyl iodide in the flask. Heat the apparatus in a bath at 80 °C and add the sodium ethoxide solution, with stirring, at such a rate that a drop of the reaction mixture when mixed with a drop of phenolphthalein indicator is never more than faintly pink (1). The addition occupies 2–2.5 hours; continue the stirring for a further 1 hour at 80 °C. Allow the flask to cool, and remove the ethanol under reduced pressure using a rotary evaporator. Add 100 ml of water to the residue in the flask and extract the ester with three 100 ml portions of toluene. Dry the combined extracts with anhydrous sodium sulphate, distil off the toluene at atmospheric pressure and the residue under diminished pressure. Collect the diethyl ethylphenylmalonate at 159–160 °C/8 mmHg. The yield is 72 g (87%).

5-ethyl-5-phenylbarbituric acid. In a 250-ml round-bottomed flask, fitted with an efficient reflux condenser and guard-tube, prepare a solution of sodium methoxide from 4.6 g (0.2 mol) of clean sodium and 50 ml of anhydrous meth-
anol (Section 4.1.8, p. 400). Add 15 g (0.25 mol) of urea (previously dried at 60 °C for 4 hours), and then 26.4 g (0.1 mol) of diethyl ethylphenylmalonate dropwise down the condenser. Reflux the mixture for 6 hours and then remove the excess methanol under reduced pressure (rotary evaporator) from a water bath held below 60 °C. Transfer the residue to a small beaker cooled in a freezing mixture and add 100 ml of ice-water with mechanical stirring: the temperature of the reaction mixture must be kept below 5 °C since barbiturates are decomposed by concentrated alkali into the salt of the corresponding malonic acid, sodium carbonate and ammonia. Filter and extract the filtrate with two 50 ml portions of toluene in order to remove esters; acidify the aqueous solution cautiously to Congo red, allow to stand for a few hours and filter off the crude phenobarbitone, boil in a small beaker cooled in an ice-bath: the product is obtained if rectified spirit is employed for recrystallisation, but the recovery is considerably less.

Note. (1) The rate of addition should be controlled so that the reaction mixture does not become strongly basic.

Experiment 8.38 PIPERAZINE-2,5-DIONE (Diketopiperazine)

\[
\begin{align*}
\text{O} & \quad \text{H}_2\text{N} \\
\text{O} & \quad \text{HO}^\text{-}\text{CO} \\
\text{NH}_2 & \quad \text{O} \\
& \quad \text{H} \\
& \quad \text{N} \\
& \quad \text{H}
\end{align*}
\]

Place 100 g (1.33 mol) of glycine and 500 ml of ethylene glycol in a 1-litre three-necked flask fitted with an air-cooled reflux condenser and a sealed mechanical stirrer; fit a thermometer so that the bulb is in the liquid. Heat the mixture in the fume cupboard to 175 °C and maintain the temperature at this level with continuous stirring for 1 hour. Cool the dark brown reaction product to room temperature and leave overnight in the refrigerator. Centrifuge the resulting suspension (1) and decant the mother-liquor. Transfer the solid to a Buchner funnel with the aid of cold methanol and wash on the filter with gentle suction with more methanol, using about 200 ml in all. Crystallise the product from 300 ml of boiling water but do not attempt to filter the hot solution at this stage; collect the light brown crystals which separate on cooling in ice. Dissolve the crude material in 350 ml of hot water, add 4 g of decolourising carbon and boil for 3 minutes. Filter the hot suspension through a preheated Buchner funnel (2) and cool the filtrate in ice. Collect the colourless crystals of pure piperazine-2,5-dione, wash with a little ice-cold water and dry in the oven at 50 °C; the yield is 34 g (45%). The m.p. is rather indefinite and depends on the rate of heating: when introduced into a rapidly heated (10 °C/minute) melting point apparatus at 280 °C, piperazine-2,5-dione has m.p. 310–312 °C (decomp.).

Boil a few mg each of the product and of ninhydrin (Expt 5.99) in 0.5 ml of water; the absence of a blue-purple coloration shows that the product is free from contaminating peptide material.

Notes. (1) If a centrifuge of suitable capacity is not available, the product may be iso-
lated by decanting the suspension through a pad of glass wool in an ordinary filter funnel and allowing the crystals to drain as much as possible. In this case the methanol washing procedure is best omitted, and the product together with the glass wool subjected directly to the preliminary crystallisation from hot water described in the text.

(2) If the filtrate from this treatment with decolourising carbon is not colourless it should be boiled with more of the carbon and re-filtered.

**Conversion into glycyglycine ethyl ester hydrochloride.** Heat 150 ml of concentrated hydrochloric acid almost to boiling, add in one portion 28.5 g (0.25 mol) of piperazine-2,5-dione and boil for exactly 90 seconds. Cool the resulting solution immediately with swirling in an ice-salt bath, and scratch the sides of the vessel to induce crystallisation. Leave at 0 °C for 1 hour, filter off the resulting glycyglycine hydrochloride monohydrate with suction using an acid-resistant paper (e.g. Whatman No. 50–54) and wash it with three 15 ml portions of cold ethanol. Suspend the entire product in 600 ml of absolute ethanol in a 3-litre three-necked flask fitted with a sealed stirrer unit, a gas inlet tube and a reflux condenser leading to a gas absorption trap (Fig. 2.61(c). Surround the flask with an ice bath, start the stirrer and pass into the suspension a steady stream of dry hydrogen chloride (Section 4.2.38, p. 438) until about 60 g have been absorbed. Replace the cooling bath with a heating mantle and boil the mixture under reflux for 10 minutes. Cool the flask in an ice bath while still stirring and keep at 0 °C for 1 hour. Collect the crystals by filtration and wash them with 12 ml of cold ethanol. Recrystallise the product from about 290 ml of absolute ethanol, filter, wash the crystals with a little cold ethanol and dry in the air. The yield of glycyglycine ethyl ester hydrochloride, m.p. 183 °C, is 30 g (61%).

### 8.4.4 QUINOLINES, ISOQUINOLINES AND QUINOXALINES

The examples selected to illustrate some of the important cyclisation reactions leading to substituted quinolines and isoquinolines are quinoline [(100), \(X = H\)], 8-nitroquinoline [(100), \(X = NO_2\)], 8-hydroxyquinoline [(100), \(X = OH\)], 2-methylquinoline (101), 2,4,6-trimethylquinoline (102), 2-phenylquinoline-4-carboxylic acid (103) and 6-methylisoquinoline (104).
The quinoline derivatives (100) to (103) exemplify two important overall strategies by which the heterocyclic ring may be constructed, indicated by (105) and (106). The isoquinoline derivative (104) has been selected to illustrate the overall strategy shown in (107). It should be pointed out however that a range of other strategies have been employed for the synthesis of quinolines and isoquinolines and the reader's attention is directed to specialist texts.27

![Chemical structures](image)

With quinoline [(100), X = H] the first retrosynthetic transform is reduction to 1,2-dihydroquinoline (cf. pyridines above) to facilitate recognition of the derived synthons obtained in the subsequent disconnection.

![Reaction scheme](image)

The Skraup synthesis, the above analysis reveals, is an important method for quinoline and many of its derivatives (e.g. 8-nitro- and 8-hydroxyquinoline). The reaction involves heating a mixture of an aromatic amine, glycerol, concentrated sulphuric acid and a suitable oxidising reagent. The original Skraup procedure employed nitrobenzene as the oxidant, in which case the reaction is frequently very vigorous and requires moderation by the addition of iron(II) sulphate. Other oxidising agents which may be used include, for example, iodine and arsenic pentoxide. The overall sequence for [(100), X = H] involves first the conversion of glycerol into acrolein by the action of sulphuric acid, then the conjugate 1,4-addition of aniline to acrolein to yield 3-phenylaminopropanal [(108), X = H], followed by an acid-catalysed cyclisation and dehydration to form the 1,2-dihydroquinoline, which is finally oxidised to quinoline.

The preparation of quinoline itself (Expt 8.39) proceeds smoothly without becoming excessively violent when iodine is employed as the oxidising agent. In the preparation of 8-nitroquinoline (from o-nitroaniline, Expt 8.39, cognate preparation), the oxidant is arsenic pentoxide. In the case of 8-hydroxyquinoline (oxine; Expt 8.39, cognate preparation), a pre-mix of o-aminophenol, glycerol and sulphuric acid held at 80 °C is added portionwise to a mixture of o-nitrophenol and iron(II) sulphate maintained at 100–120 °C; this procedure serves to control the vigour of the reaction. Oxine is a useful reagent in qualitative and quantitative analysis since it forms water-insoluble complexes with such metals as aluminium, magnesium, bismuth, zinc, etc.

A final point to note with the Skraup reaction is that although ortho- and para-substituted amines lead to 8-substituted or 6-substituted quinolines respectively, meta-substituted amines give a mixture of regioisomers, namely the 5- and 7-substituted quinolines.
In a reaction which is mechanistically related to the Skraup reaction an \( \alpha,\beta \)-unsaturated carbonyl compound, generated by way of an acid-catalysed aldol condensation, reacts with a primary aromatic amine in the presence of acid to yield a quinoline derivative (Doebner–Miller reaction). For example, when aniline is heated with paraldehyde (which depolymerises to acetaldehyde during the reaction) in the presence of hydrochloric acid the final product is 2-methylquinoline (101) (quinaldine, Expt 8.40). Retrosynthetic analysis for the 1,2-dihydroquinoline reveals crotonaldehyde as the unsaturated carbonyl component which is in turn formed from acetaldehyde (see Section 5.18.2, p. 799).

\[
\begin{align*}
\text{Me} \quad \text{Me} & \quad \longrightarrow & \quad \text{PhNH}_2 + 2\text{Me} \cdot \text{CHO} \\
\text{H} & & \\
\end{align*}
\]

In this case the final dehydrogenation of 1,2-dihydroquinaldine to quinaldine is effected by anils formed by the condensation of aniline with either acetaldehyde or crotonaldehyde during the course of the reaction. This yields secondary amines as by-products; these together with excess aniline are separated from the quinaldine by acetylation of the reaction mixture. The acetylated primary and secondary amines thus formed are less steam volatile than quinaldine which forms the basis of the isolation of the latter.

The starting materials for the synthesis of 2-phenylquinoline-4-carboxylic acid (Expt 8.41) may be discovered by a similar retrosynthetic analysis for the 1,2-dihydro derivative.

\[
\begin{align*}
\text{CO}_2\text{H} \quad \text{CO}_2\text{H} & \quad \longrightarrow & \quad \text{PhNH}_2 \quad \text{O} = \text{CH} \cdot \text{Ph} \\
\text{Ph} & & \\
\text{Ph} & & \\
\end{align*}
\]

This is an example of the Doebner synthesis of quinoline-4-carboxylic acids (cinchoninic acids), which consists of the condensation of a primary aromatic amine with pyruvic acid and an aldehyde. The mechanism is probably similar to the synthesis of quinolines discussed above and involves the intermediate formation of a dihydroquinoline derivative, which is subsequently dehydrogenated by the anils derived from the aromatic amine and the aldehyde.

A retrosynthetic analysis for 2,4,6-trimethylquinoline (102) reveals \( p \)-toluidine and pentane-2,4-dione. This is an example of the Combes reaction.

\[
\begin{align*}
\text{Me} & \quad \text{Me} & \quad \longrightarrow & \quad \text{Me} \quad \text{NH}_2 \quad \text{O} = \text{Me} \\
\text{Me} & & \\
\text{Me} & & \\
\end{align*}
\]
The reaction proceeds by way of the imine (109) which is converted into the enamine (110) by prototropic rearrangement before being cyclised with concentrated sulphuric acid.

Formation and isolation of the enamine are achieved by heating the amine and the diketone in xylene under reflux using a Dean and Stark apparatus until the theoretical amount of water has separated, or alternatively at 100 °C in the presence of anhydrous calcium sulphate. The latter is the most convenient and is the procedure used in Expt 8.42.

Retrosynthetic analysis for 6-methylisoquinoline (104) reveals \( p \)-tolualdehyde and \( \alpha \)-aminoacetaldehyde.

The synthesis of isoquinolines by this overall strategy represents the Pomeranz-Fritsch reaction. In fact the dimethyl (or diethyl) acetal of the aminoaldehyde is used to effect the formation of the aldimine (111) before the cyclisation step. In the classical procedure rather vigorous conditions for cyclisation are required. The milder, one-pot reaction sequence which is described below, and illustrated in Expt 8.43, has considerable advantages.²⁸ The aldimine (111) is first treated with ethyl chloroformate which activates the imine, and then with trimethyl phosphate to form the carbamate phosphonate (112) by a type of Arbusov reaction; subsequent treatment with titanium(IV) chloride in dichloromethane effects cyclisation with loss of the carbamate and phosphonate groups and the formation of the isoquinoline ring. Although several solvents are used during the course of the reaction sequence, the original publication indicates that chloroform may be used throughout without loss of yield.
Quinoxalines (113) transform into \( o \)-phenylenediamine and 1,2-dicarbonyl compounds.

\[
\begin{align*}
\text{R}^1 & \quad \text{R}^2 \\
& \quad 
\end{align*}
\]

(113)

For quinoaxaline itself (Expt 8.44) glyoxal is the dicarbonyl component. The interest in this synthesis is that 2,3-dihydroxy-1,4-dioxane is employed as a stable reagent equivalent for anhydrous glyoxal. It is prepared by the azeotropic removal of water from a benzene solution of aqueous glyoxal and ethylene glycol.\(^{29}\)

\[
\begin{align*}
\text{OH} & \quad \text{O} \quad \text{H} \\
\text{OH} & \quad \text{O} \quad \text{H} \\
& \quad \text{O} \quad \text{OH} \\
& \quad \text{O} \quad \text{OH}
\end{align*}
\]

Also included in Expt 8.44, is the preparation of 2,3-diphenylquinoxaline (114) and 3-benzyl-2-oxo-1,2-dihydroquinoxaline (115) from \( o \)-phenylenediamine and benzil or phenylpyruvic acid respectively.

(115)
Experiment 8.39 QUINOLINE

\[
\begin{align*}
\text{H}_2\text{C} & \rightarrow \text{H} \\
\text{H}_2\text{C} & \rightarrow \text{N} \\
\text{H}_2\text{C} & \rightarrow \text{N} \\
\end{align*}
\]

CAUTION: This preparation should be carried out in a fume cupboard.

Equip a 250-ml three-necked flask with a double surface condenser, a sealed stirrer and a screw-capped adapter carrying a thermometer positioned so that subsequently the temperature of the reaction mixture may be noted. Place 10.0 g (9.8 ml, 0.107 mol) of pure aniline, 15.0 g (0.163 mol) of glycerol (1) and 0.5 g of iodine in the flask. Stir the reaction mixture and add down the condenser from a dropping funnel 30 g (16.4 ml, 0.306 mol) of concentrated sulphuric acid. Reaction soon commences, the temperature rises to 100–105 °C. Heat the flask gradually, with stirring, in an air bath or oil bath to 140 °C; the reaction proceeds with the evolution of sulphur dioxide and a little iodine vapour and the liquid reflexes. Continue heating at 170 °C for 1 hour, allow to cool and then add cautiously with stirring sufficient 5 M sodium hydroxide solution (about 85 ml) to render the mixture alkaline. Re-arrange the apparatus for steam distillation (Fig. 2.102) and steam distil until no more oily drops pass over. The distillate contains quinoline and a little aniline. Extract the distillate with three 25 ml portions of ether, combine the ethereal extracts and remove the ether on a rotary evaporator.

To remove the aniline present in the residual crude quinoline, advantage is taken of the fact that bis-quinolinium tetrachlorozincate(II) [(C₆H₅N)₂(ZnCl₄)²⁺] is almost insoluble in water and crystallises out, while under the same experimental conditions, bis-anilinium tetrachlorozincate(II) [(C₆H₅·NH₃)₂(ZnCl₄)²⁺] remains in solution (2). Dissolve the crude quinoline in 100 ml of dilute hydrochloric acid (1:4 by volume), warm the solution to 60 °C and add, with stirring, a solution of 13 g (0.095 mol) of zinc chloride in a 22 ml portion of the diluted hydrochloric acid. Cool the well-stirred mixture thoroughly in ice-water and, when crystallisation is complete, filter the bis-quinolinium tetrachlorozincate(II) with suction, wash with two 10 ml portions of dilute hydrochloric acid and drain well. Transfer the solid to a 250-ml beaker, add a little water and then 10 per cent sodium hydroxide solution until the initial precipitate of zinc hydroxide dissolves completely. Extract the quinoline with three 25 ml portions of ether in a separatory funnel and dry the combined ethereal extracts with anhydrous calcium sulphate. Remove the ether by flash distillation using a 10-ml flask and finally distil the residue from an air bath using an air condenser. Collect the quinoline at 236–238 °C as a colourless liquid; the yield is 6.9 g (50%). If distilled under reduced pressure quinoline has b.p. 118–120 °C/20 mmHg.

Notes. (1) Laboratory grade glycerol may be used since anhydrous glycerol is not necessary when iodine is used as the oxidising agent. Anhydrous glycerol may be pre-
pared by heating commercial glycerol in a porcelain evaporating dish carefully over a wire gauze (preferably in a fume cupboard), stirring it steadily with a thermometer until the temperature rises to 180°C, allowing it to cool to about 100°C, pouring it into a Pyrex beaker and transferring the beaker to a large desiccator containing concentrated sulphuric acid. It must be remembered that glycerol is a very hygroscopic substance.

(2) An alternative method of removing the aniline is to add 8 ml of concentrated sulphuric acid carefully to the steam distillate, cool the solution to 0–5°C and add a concentrated solution of sodium nitrite until a drop of the reaction mixture colours potassium iodide-starch paper a deep blue instantly. As the diazotisation approaches completion, the reaction becomes slow; it will therefore be necessary to test for excess of nitrous acid after an interval of 5 minutes, stirring all the while. About 3 g of sodium nitrite are usually required. The diazotised solution is then heated on a boiling water bath for an hour (or until active evolution of nitrogen ceases), treated with a solution of 15 g of sodium hydroxide in 50 ml of water, the mixture steam-distilled and the quinoline isolated from the distillate by extraction with ether as above.

**Cognate preparations. 8-Nitroquinoline.** Place a mixture of 69 g (0.5 mol) of o-nitroaniline, 86 g (0.375 mol) of arsenic pentoxide (CAUTION) and 184 g (2 mol) of anhydrous glycerol in a 500-ml three-necked flask, fitted with a sealed stirrer unit, a thermometer and a reflux condenser. Set the stirrer in motion, heat to 100°C (oil bath) and add 220 g (120 ml, 2.24 mol) of concentrated sulphuric acid gradually down the condenser at such a rate that the temperature does not rise above 120°C (about 20 minutes). Insert a calcium chloride guard-tube into the top of the condenser, gradually raise the temperature to 130–135°C and maintain this temperature for 7–8 hours. Watch the reaction during the first hour of heating: should the reaction become very vigorous, lower the oil bath momentarily. Allow the contents of the flask to cool and pour into 1500 ml of water contained in a 2-litre beaker. Add 15 g of decolourising carbon, stir mechanically, heat at 90°C for 1 hour and filter. Neutralise the cold filtrate slowly with aqueous ammonia solution (1 vol concentrated ammonia, d 0.88 + 1 vol water), filter off the crude nitro compound at the pump and wash with a little water. Recrystallise from hot water or from methanol. The yield of 8-nitroquinoline, m.p. 92°C, is 45 g (52%).

**8-Hydroxyquinoline (‘oxine’).** Place 170 ml (3.18 mol) of concentrated sulphuric acid in a 1-litre three-necked flask provided with a stirrer, and add 112.5 g (1.03 mol) of o-aminophenol, followed by 287 g (3.12 mol) of anhydrous glycerol: maintain the temperature below 80°C by cooling, if necessary. Keep the mixture in a fluid state by placing the flask on a steam bath.

In a 3-litre three-necked flask, fitted with a thermometer, stirrer and reflux condenser, place 72.5 g (0.52 mol) of o-nitrophenol and 10 g of crystallised iron(II) sulphate, and heat to 100–120°C. Add the liquid amine–glycerol–sulphuric acid pre-mix in about ten portions over 2 hours: allow the reaction to proceed at 135–150°C before adding the subsequent portions. Reflux the mixture for a further 4 hours, during which time the temperature drops to about 130°C. Neutralise the cooled reaction mixture with sodium hydroxide solution (250 g in 250 ml of water) with rapid stirring and addition of ice so that the temperature does not rise above 40°C. The pH of the resulting solution is about 7, and the 8-hydroxyquinoline together with tarry by-products precipitates. Filter the precipitate at the pump, dry at 50–60°C and then distil under reduced pressure from a flask through a fractionating side-arm. A little
water passes over first and this is followed by 8-hydroxyquinolone at 100–110 °C/5 mmHg. It crystallises on cooling to a white solid, m.p. 74–75 °C. The yield of ‘oxine’ is 140 g (94%).

Experiment 8.40 2-METHYLQUINOLINE (Quinaldine)

\[
\begin{align*}
\text{Me} & \quad \text{H} \\
\text{O} & \quad \text{Me} \\
\text{NH}_2 & \quad \text{H} \quad \text{Me}
\end{align*}
\]

Place 62 g (61 ml, 0.67 mol) of aniline in a 1-litre round-bottomed flask fitted with a reflux condenser the top of which is connected to a gas absorption trap (Fig. 2.61(a)). Cool the flask in an ice bath, add 120 ml of concentrated hydrochloric acid slowly, followed by 90 g (2.04 mol) of paraldehyde: swirl the contents of the flask to ensure thorough mixing. Remove the flask from the ice bath and shake it frequently at room temperature during 1–2 hours. Heat cautiously to the boiling point: keep an ice-water bath at hand in case the reaction should become unduly vigorous and require moderating. Reflux the mixture for 3 hours and allow to cool. Render alkaline with about 100 ml of 12 M sodium hydroxide solution and steam distil the mixture: collect about 2.4 litres of distillate. Separate the upper oily layer, extract the aqueous phase with a little chloroform (or with ether) and combine the extract with the crude oil. Dry the combined oil and extract with magnesium sulphate, remove the solvent and heat the residue under reflux for 20 minutes with 20 ml of acetic anhydride. After cooling, render alkaline with sodium carbonate solution and steam distil; collect about 2.4 litres of distillate. Extract the latter with two 50 ml portions of toluene. Distil the toluene from the combined toluene extracts and distil the residue with the aid of an air bath. Collect the pure quinaldine at 245–248 °C: the yield is 40 g (42%). Alternatively, distil the quinaldine under reduced pressure; b.p. 116–118 °C/12 mmHg. Keep the colourless liquid in a well-stoppered bottle since it darkens on exposure to air.

Experiment 8.41 2-PHENYLQUINOLINE-4-CARBOXYLIC ACID (Atophan)

\[
\text{Ph} \quad \text{CHO} + \text{Me-COCO}_2\text{H} \rightarrow \text{CO}_2\text{H}
\]

In a 1-litre round-bottomed flask, equipped with a reflux condenser, place 25 g (24 ml, 0.236 mol) of purified benzaldehyde (Expt 6.133, Note (1)), 22 g (0.25 mol) of freshly distilled pyruvic acid (Expt 5.173) and 200 ml of absolute ethanol. Heat the mixture to the boiling point on a water bath and add
slowly, with frequent shaking, a solution of 23 g (22.5 ml, 0.248 mol) of pure aniline in 100 ml of absolute ethanol. The addition usually occupies about 1 hour. Reflux the mixture on a water bath for 3 hours, and allow to stand over-night. Filter off the crude atophan (1) at the pump and wash the crystals with a little ether. Recrystallise from ethanol (about 20 ml per gram). The yield of pure 2-phenylquinoline-4-carboxylic acid, m.p. 210 °C, is 30 g (51%).

Note. (1) If the atophan does not crystallise – this is rarely the case unless pyruvic acid which has been standing for some time is employed – pour the reaction mixture into a solution of 25 g of potassium hydroxide in 1 litre of water, and extract the resulting solution two or three times with ether. Treat the aqueous layer with 70 ml of glacial acetic acid with vigorous stirring. Allow to stand for several hours and collect the crude atophan by filtration with suction.

Experiment 8.42 2,4,6-TRIMETHYLQUINOLINE

4-(p-Tolylamino)pent-3-en-2-one. Add 10 g of granular anhydrous calcium sulphate to a mixture of 5.32 g (0.05 mol) of p-toluidine and 5.1 g (0.05 mol) of pentane-2,4-dione (Expt 5.102) contained in a 100-ml round-bottomed flask. Attach an air condenser fitted with a calcium chloride guard-tube to the flask and heat the mixture on a steam bath for 1 hour (1), with occasional shaking. Cool, add 40 ml of ether to the reaction mixture and filter. Wash the calcium sulphate in the filter funnel with 40 ml of ether and evaporate the combined ether filtrates. Crystallise the solid so obtained from about 25 ml of hexane. The enamine is obtained as deep straw-coloured plates, m.p. 67–69 °C. The yield is 7.2 g (76%).

2,4,6-Trimethylquinoline. Add 6 g (0.032 mol) of the above enamine, in portions, to 25 ml of concentrated sulphuric acid (d 1.84) contained in a 250-ml conical flask. Swirl the mixture occasionally to ensure thorough mixing. The first portions of the enamine dissolve rather slowly but solution occurs more rapidly with the later portions as the temperature of the mixture increases to 60–70 °C. Heat the reaction mixture on the steam bath for 30 minutes, and then cool the brown solution to room temperature and add it slowly to 250 ml of ice-water in a 1-litre beaker. Add solid sodium carbonate to the solution until it is alkaline. During this addition the quinoline salt tends to separate and the whole mixture may solidify; if this happens the mass should be broken up and stirred with a stout glass rod or spatula while the sodium carbonate is added. The quinoline eventually separates as an oil from the alkaline solution. Cool the mixture in an ice-water bath until the quinoline solidifies; avoid over-cooling as this will result in the separation of a large
amount of solid hydrated sodium sulphate. Collect the quinoline by filtration and wash with a little cold water. Dissolve the product in about 20 ml of hot ethanol, add decolourising carbon, filter and add warm water (c. 20 ml) to the solution until it becomes slightly cloudy. Add a few drops of ethanol to remove the cloudiness and allow the solution to cool slowly to room temperature and finally chill in the refrigerator. 2,4,6-Trimethylquinoline dihydrate separates as long glistening white needles, m.p. 63–65 °C. The yield is 5.2 g (79%). Record the p.m.r. spectrum (D₂O + H₂SO₄) and assign the signals δ 2.55 (s, 3H), 2.70 (s, 3H), 2.90 (s, 3H), 7.64 and 7.70 (m, 4H).

**Note.** (1) The progress of the reaction may be followed by removing samples of the reaction mixture and noting the disappearance of either the pentanediene or p-toluidine on g.l.c. Using a 1.5-m column of 10 per cent Silicone oil on Chromosorb W at 100 °C, with a nitrogen flow rate of 40 ml/minute, the retention times are 1.3 minutes and 6.5 minutes respectively. On the same column, at 170 °C, the enamine has a retention time of 10.5 minutes.

**Experiment 8.43 6-METHYLSISOQUINOLINE**[^28]

![Chemical structure of 6-Methylisoquinoline](image)

A benzene solution (50 ml, CAUTION) of equimolar amounts of p-toluinaldehyde (8.4 g, 0.07 mol) and aminoacetaldehyde dimethyl acetal (7.35 g, 0.07 mol) is refluxed overnight into a Dean and Stark trap. The solution is evaporated in vacuo and then twice evaporated again with added benzene and the viscous oil dissolved in dry tetrahydrofuran. This solution is cooled to −10 °C and 1 equivalent of ethyl chloroformate (7.1 ml, 0.07 mol) is added with rapid stirring and the mixture stirred for a further 5 minutes. The cooling bath is removed and 1.2 equivalents of trimethyl phosphite (10.5 ml, 0.09 mol) is added with stirring. The solution is stirred at room temperature for 15 hours and then evaporated to an oil. The oil is then re-evaporated twice with added toluene to remove traces of trimethyl phosphite. The oil is dissolved in dry dichloromethane, 6 equivalents of titanium(iv) chloride (50 ml, 0.45 mol) is added and the solution refluxed for 36 hours under a drying tube. The cooled solution is shaken with 1 equivalent of aqueous sodium hydroxide solution to neutrality, whereupon titanium(iv) oxide precipitates as a white solid. The filtered organic layer is extracted with 3 m hydrochloric acid, and the extract is washed with dichloromethane, basified strongly with aqueous alkali, and extracted with dichloromethane. This organic extract is dried over anhydrous sodium sulphate and evaporated to afford 6-methylisoquinoline (yield 71%, m.p. 88 °C).

**Experiment 8.44 QUINOXALINE**[^29]

![Chemical structure of Quinoxaline](image)

[^28]: Quinoxaline
[^29]: Quinoxaline
2,3-Dihydroxy-1,4-dioxane. A solution of 40 per cent aqueous glyoxal (528 g, 3.62 mol) and ethane-1,2-diol (230 g, 3.70 mol) in benzene (2 litres) (CAUTION) is heated under reflux with efficient stirring and with azeotropic removal of water via a Dean and Stark trap. After 10 hours, removal of water is complete, and the reaction mixture is allowed to cool when it separates into two layers. The supernatant layer is decanted away, the residual amber syrup is thoroughly triturated with cold acetone (500 ml), and then refrigerated. The solid material is collected by filtration, washed with cold acetone (500 ml) and dried in vacuo over phosphorus pentoxide for 72 hours to give a lumpy solid, which is converted to a fine white powder by spinning in a rotary evaporator: yield 197 g (47%), m.p. 100–104 °C; i.r. (KBr disc) 3350 cm⁻¹; p.m.r. (Me₂SO-d₆, TMS) δ 3.20–4.05 (m, 4H), 4.32 (d, J = 5 Hz, 2H) and 6.45 (d, J = 5 Hz, 2H).

Quinoxaline. To a solution of 2,3-dihydroxy-1,4-dioxane (15.6 g, 130 mmol) in ethanol (250 ml) is added p-phenylenediamine (10.8 g, 100 mmol). The brown solution is stirred for 30 minutes at room temperature, at which time t.l.c. analysis (silica gel GF plates, dichloromethane–ethyl acetate 3:1 as solvent, ammonium molybdate char development) shows complete conversion to the product. The reaction mixture is evaporated, and the residue distilled to give quinoxaline, 12.4 g (95%), b.p. 220–223 °C/760 torr; the product solidifies on cooling, m.p. 29–31 °C; p.m.r. (CDCl₃, TMS) δ 7.70–8.05 (m, 2H), 8.10–8.35 (m, 2H) and 8.95 (s, 2H).

Cognate preparations. 2,3-Diphenylquinoxaline. To a warm solution of 2.1 g (0.01 mol) of benzil in 8 ml of rectified spirit add a solution of 1.1 g (0.01 mol) of o-phenylenediamine in 8 ml of rectified spirit. Warm in a water bath for 30 minutes, add water until a slight cloudiness persists and allow to cool. Filter and recrystallise from aqueous ethanol to give 1.43 g (51%) of 2,3-diphenylquinoxaline, m.p. 125–126 °C.

3-Benzyl-2-oxo-1,2-dihydroquinoxaline. Dissolve 2.7 g (0.025 mol) of o-phenylenediamine in 40 ml of hot rectified spirit, boil the solution with 0.5 g of decolourising carbon, filter and cool to room temperature. Add a solution of 4.1 g (0.025 mol) of phenylpyruvic acid (Expt 5.175) in 20 ml of rectified spirit, swirl to mix and set aside for 2 hours. Filter, wash the crystalline product with a little cold rectified spirit and recrystallise from about 100 ml of rectified spirit to obtain the oxodihydroquinoxaline as long silky colourless needles, m.p. 203 °C. The yield is 3.2 g (54%).

8.4.5 COUMARINS (BENZO-2-PYRONES) AND CHROMONES (BENZO-4-PYRONES)

Three target molecules, namely coumarin (116), 4-methylcoumarin (117) and flavone [2-phenylbenzo-4-pyrone, (118)], are used to illustrate typical cyclisation reactions.
Overall strategies for cyclisation are of the type illustrated (119), (120) and (121).

A retrosynthetic analysis for coumarin reveals salicylaldehyde and acetic anhydride (under basic conditions) as suitable reagent equivalents of the derived synthons.

The reaction involves a spontaneous cyclisation of o-hydroxycinnamic acid obtained by a Perkin reaction using triethylamine as the base catalyst (Expt 6.138).

A more general synthesis of coumarins involves the interaction of a phenol with a β-ketoester in the presence of an acid condensing agent (the Pechmann reaction). In the case of 4-methylcoumarin (117) appropriate disconnection reveals ethyl acetoacetate and phenol.

Concentrated sulphuric acid is generally used as the condensing agent for simple monohydric phenols and β-ketoesters, although phenol itself reacts better in the presence of aluminium chloride (Expt 8.45). The mechanism of the reaction is thought to involve the initial formation of a β-hydroxy ester, which then cyclises and dehydrates to yield the coumarin.

Polyhydric phenols, particularly when the two hydroxyl groups are meta oriented, react with great ease. If sulphuric acid is used as the condensing agent, careful temperature control is needed to ensure a good yield (e.g. 4-methyl-7-hydroxycoumarin, cognate preparation in Expt 8.45). In these cases the use of polyphosphoric acid is recommended and this alternative process is illustrated. Good yields are also obtained from polyhydric phenols by condensation in the presence of trifluoroacetic acid.\(^\text{30}\)
A retrosynthetic analysis for flavone (118) reveals o-benzoyloxyacetophenone (122), readily formed by the benzylation of o-hydroxyacetophenone.

In practice the cyclisation of (122) takes place in two stages. Initially a base-catalysed rearrangement converts (122) into o-hydroxydibenzoylmethane (123) which may be isolated, and then cyclised in the presence of acid to flavone (118) (Expt 8.46).

Experiment 8.45 4-METHYLCOUUMARIN

Place 94 g (1 mol) of phenol and 134 g (130.5 ml, 1.03 mol) of ethyl acetoacetate in 150 ml of redistilled nitrobenzene in a 3-litre three-necked flask, fitted with a dropping funnel, a sealed stirrer unit and an air condenser, the open end of which is connected to a gas absorption trap (Fig. 2.61). Heat the mixture to 100°C in an oil bath, stir and add a solution of 266 g (2 mol) of anhydrous aluminium chloride in 1 litre of nitrobenzene (1) from the dropping funnel over a period of 45 minutes. Replace the dropping funnel by a thermometer, raise the temperature of the solution to 130°C and maintain this temperature, with stirring, for 3 hours, by which time evolution of hydrogen chloride will have almost ceased. Cool the reaction mixture to room temperature and add 250 ml of 1:1 hydrochloric acid with stirring in order to decompose the excess of aluminium chloride. Equip the flask for steam distillation, warm it and pass steam into the reaction mixture: this will remove any unchanged keto ester and some of the nitrobenzene: collect about 100 ml of distillate. Transfer the residue in the flask while hot to a large separatory
funnel; separate and discard the aqueous layer. Filter the organic layer (with
the addition of a filter-aid, if necessary) through a Buchner or slit-sieve
funnel to remove tarry matter and distil under reduced pressure. The
nitrobenzene passes over first, followed by crude 4-methylcoumarin at 180–195°C/
15 mmHg (75 g) as a red-yellow oil which solidifies on cooling. Dissolve the
crude product in ether, shake the ether solution with small volumes of 5 per
cent sodium hydroxide solution until the aqueous layer is colourless. Dry,
evaporate the ether and recrystallise the residue from a 4:1 mixture of light
petroleum (b.p. 60–80°C) and benzene. The resulting 4-methylcoumarin
(62 g, 39%) is almost colourless and melts at 83–84°C.

Note. (1) Add the aluminium chloride in 25 g portions to the 1 litre of dry nitro-
benzene contained in a 2.5-litre round-bottomed flask; stir after each addition. The
temperature may rise to about 80°C during the addition: cool the flask occasionally
under running water. When all the aluminium chloride has been added, cool the solu-
tion to room temperature: a little solid may settle to the bottom.

Cognate preparation. 4-Methyl-7-hydroxycoumarin. Place 1 litre of concen-
trated sulphuric acid in a 3-litre three-necked flask fitted with a thermometer,
mechanical stirrer and a dropping funnel. Immerse the flask in an ice bath. When
the temperature falls below 10°C, add a solution of 100 g (0.91 mol) of
resorcinol in 134 g (130.5 ml, 1.03 mol) of redistilled ethyl acetoacetate drop-
wise and with stirring. Maintain the temperature below 10°C by means of an
ice-salt bath during the addition (c. 2 hours). Keep the reaction mixture at
room temperature for about 18 hours, then pour it with vigorous stirring into
a mixture of 2 kg of crushed ice and 3 litres of water. Collect the precipitate by
suction filtration and wash it with three 25 ml portions of cold water. Dis-
solve the solid in 1500 ml of 5 per cent sodium hydroxide solution, filter and
add dilute 2M sulphuric acid (about 550 ml) with vigorous stirring until the
solution is acid to litmus. Collect the crude 4-methyl-7-hydroxycoumarin by
filtration at the pump, wash it with four 25 ml portions of cold water and dry
at 100°C: the yield is 155 g (97%). Recrystallise from 95 per cent ethanol: the
pure compound separates in colourless needles, m.p. 185°C.

Polyphosphoric acid procedure. Add 160 g of polyphosphoric acid (Section
4.2.58, p. 458) to a solution of 11 g (0.1 mol) of resorcinol in 13 g (0.1 mol) of
ethyl acetoacetate. Stir the mixture and heat at 75–80°C for 20 minutes, and
then pour into ice-water. Collect the mixture and wash with a little cold water and dry at 60°C. The yield of crude 4-methyl-7-
hydroxycoumarin, m.p. 178–181°C, is 17 g (97%). Recrystallisation from
dilute ethanol yields the pure, colourless compound, m.p. 185°C.

Experiment 8.46 FLAVONE (2-Phenylbenzo-4-pyrone)
**o-Benzoyloxyacetophenone.** Place 34 g (0.25 mol) of *o*-hydroxyacetophenone in a flask and add 49 g (40 ml, 0.35 mol) of benzoyl chloride and 50 ml of dry, redistilled pyridine. Shake to mix the contents, which become warm. After 20 minutes, pour the reaction mixture with stirring into 1200 ml of 1 M hydrochloric acid containing 500 g of crushed ice. Filter off the product with suction and wash it with 50 ml of ice-cold methanol and then with 50 ml of water. Recrystallise from methanol (60 ml), cooling thoroughly in ice before collecting the purified product by filtration. The yield is 48 g (80%), m.p. 87–88°C.

**o-Hydroxydibenzoylmethane.** Dissolve 48 g (0.2 mol) of benzoyloxyacetophenone in 180 ml of dry pyridine in a 1-litre bolt-necked flask and heat the solution to 50°C. Add with mechanical stirring 17 g (0.3 mol) of potassium hydroxide which has been powdered rapidly in a mortar preheated in an oven at 100°C. Continue to stir for 15 minutes; if the separation of the yellow potassium salt of the product makes mechanical stirring impossible, stir by hand. Cool the reaction mixture to room temperature and acidify it by adding with stirring 250 ml of 10 per cent aqueous acetic acid. Collect the pale yellow precipitate by suction filtration and dry it in an oven at 50°C. The yield of *o*-hydroxydibenzoylmethane, m.p. 117–120°C, which is sufficiently pure for use in the next stage, is 38.5 g (80%). The pure product has m.p. 121°C after crystallisation from methanol.

**Flavone.** Dissolve 36 g (0.15 mol) of *o*-hydroxydibenzoylmethane in 200 ml of glacial acetic acid in a 500-ml flask and add with shaking 8 ml of concentrated sulphuric acid. Attach a reflux condenser and heat the mixture on a boiling water bath with intermittent shaking for 1 hour. Pour the reaction mixture with stirring on to about 1 kg of crushed ice, and allow the ice to melt. Filter off the flavone which has separated, wash it with water until the washings are no longer acidic (about 2 litres are required) and dry in an oven at 50°C. The yield of material having m.p. 95–97°C is 31.5 (95%). Recrystallisation of a portion from a large volume of light petroleum (b.p. 60–80°C) gives pure flavone, m.p. 98°C, as tufts of white needles.

**REFERENCES**

The organic chemist is frequently faced with the problem of characterising and ultimately elucidating the structure of unknown organic compounds. The worker in the field of natural products, for example, has the prospect of isolating such compounds from their sources in a pure state and then of determining their structures. On the other hand the synthetic organic chemist encounters new, or unexpected, compounds in the course of investigations into the applicability of new reagents or techniques or as by-products of established reactions. Not infrequently a literature report of a long-forgotten investigation comes to light, and the structure of the compounds is submitted to new scrutiny based upon the current understanding of reaction mechanisms.

In each of these and similar related instances, the elucidation of the structure requires the identification of the molecular framework, the nature of the functional groups which are present and their location within the skeletal structure, and finally the establishment of any stereochemical relationships which might exist. This challenging exercise is in a sense complementary to the question posed in Chapter 1, where the key objective was 'how may this compound be efficiently synthesised, given that its structure is X?' The key objective in this chapter is 'what is the structure of this substance (solid, liquid, oil, syrup or gum)?' Just as the former objective is, for the organic chemist, rooted in developing experience and understanding of methodology, strategy, and not infrequently impressive flights of intuition, so in the elucidation of structure the experienced organic chemist can often take 'short cuts' and does not usually need to proceed by a set pattern of procedures. The experience of the chemist (based both on intuitive deduction and on hard-won 'know-how') of the interrelated aspects of the typical behaviour of organic compounds and their spectroscopic properties is often overlooked when the success of the final structural achievement is reported.

Broadly speaking such a worker is frequently selecting from the topics and areas surveyed in this chapter the most appropriate aspects ('tools') to apply to the problem in hand. The undergraduate student needs therefore to consider carefully the relative ease with which some preliminary information of structure may be achieved at the bench, and its interrelationship with that obtained from various spectroscopic data, so that in due time a comprehensive appreciation of all aspects of the physical and chemical properties of particular compounds may be gained.

It is undeniable that for the student the problem of the elucidation of structure has been revolutionised by the progressive adoption, over the last thirty years or so, of the wide range of spectroscopic techniques which are now avail-
able; these are discussed in Chapter 3 and have been applied extensively in the preparative sections to confirm the structure of the expected products. Nevertheless, a valuable background to this area is provided by the performance of appropriate investigative exercises, involving the study of selected, relatively simple 'unknown' compounds to accomplish their classification and characterisation, and most systematic courses in chemistry include practical exercises of this type. Although structural elucidation projects in the interpretation of spectra may be conducted as a tutorial exercise, most benefit will be gained when the principal spectroscopic features are considered in conjunction with the practical results obtained at the bench.

With this in mind, it is suggested that the preliminary investigations outlined in the following Sections 9.1 to 9.3 should be carefully carried out, particularly the study of solubility. Accurate classification of a compound as acidic, basic, or neutral greatly assists the subsequent search to identify the characteristic functional group or groups present. This involves a careful consideration of the results of selected classifying chemical tests in conjunction with the recognition of adsorptions of diagnostic value in the appropriate spectra. Such cross-correlation of information may obviate a diversion into a blind 'cul-de-sac' owing to inexperience in spectroscopic interpretation, resulting in an invalid conclusion.

Having established the functionality, the spectroscopic information may reveal information of skeletal features, and the compound may then be converted into an appropriate solid derivative, which if known, may confirm the identity of the compound, or provide further compounds on which reactivity and spectroscopic studies could be relevant.

Derivative preparation involves the application of a concisely described general procedure to a specific compound (possibly at this stage of uncertain identity), and its success may well depend upon the use of intuition and initiative in the preparative and purification stages. As such it must be regarded as making an important contribution to the training of the organic chemist.

### 9.1 Physical Constants

The most widely used physical constants in the characterisation of organic compounds are melting points and boiling points. The technique of the determination of melting point is discussed in detail in Section 2.33. In general, a sharp melting point (say, within 0.5 °C) is a characteristic property of a pure organic compound. The purity should not, however, be assumed but must be established by observation of any changes in the melting point (or in the melting range) when the compound is subjected to purification by recrystallisation (the technique of recrystallisation is discussed fully in Section 2.20). If the melting point is unaffected by at least one recrystallisation, then the purity of the substance may be regarded as established. In some cases purification may be effected by sublimation at atmospheric pressure or under reduced pressure (see Section 2.21). Confirmation of purity may be obtained by t.l.c. analysis (see Section 2.31).

The various methods for the experimental determination of boiling point of a liquid by distillation are discussed in Section 2.24 for sample sizes ranging down to about 0.5 ml. If the liquid is shown by distillation to have a wide boiling range (10–30 °C), it will be necessary to subject it to fractional distillation, or to one of
the preparative chromatographic procedures, in order to obtain a reasonably
pure sample of the compound; suitable procedures are to be found in Section
2.26 and 2.31. If at all possible it is desirable to submit a sample of the liquid to
g.l.c. analysis to establish homogeneity. The boiling point of very small samples
may be determined by Siwoloboff's method (Section 2.34).

The determination of refractive index is useful in assisting the characterisation
of a pure liquid, particularly in the case of compounds which do not possess
functional groups suitable for conversion into solid derivatives. The refractive
index is conveniently determined with an Abbé refractometer (Section 2.37). An
additional characteristic is provided by the density of the liquid, which is deter-
mined with the aid of a pycnometer.

9.2 THE STUDY OF SOLUBILITY BEHAVIOUR

GENERAL DISCUSSION

When a mixture of a specified amount of a given solute and a specified amount
of a given solvent forms a homogeneous liquid, the former is said to be soluble in
the latter. The arbitrary standard employed in this book is 0.10 g of solid or
0.20 ml of liquid to 3.00 ml of solvent. The study of the solubility behaviour of an
unknown substance in various liquids, viz. water, ether, 5 per cent sodium
hydroxide solution, 5 per cent sodium hydrogen carbonate solution, 5 per cent
hydrochloric acid and cold concentrated sulphuric acid, may provide useful pre-
liminary information about the nature of the compound.

The substance should be tested for solubility in the various solvents in the
order cited above since, for example, when solubility in dilute acid or base is
being considered, it is important to note whether the unknown is more soluble in
aqueous acid or base than it is in water: this increased solubility is the positive
test for a basic or acidic functional group. Acidic compounds are detected by
their solubility in 5 per cent sodium hydroxide solution. Strong and weak acids
are differentiated by the solubility of the former, but not the latter, in the weakly
basic 5 per cent sodium hydrogen carbonate solution. Nitrogenous bases are fre-
cently detected by their solubility in 5 per cent hydrochloric acid. Many com-
ounds that are neutral even in concentrated aqueous acidic solutions behave as
bases in strongly acidic solvents, such as concentrated sulphuric acid; these in-
clude compounds that are neutral in water and contain oxygen in any form. The
presence of acidic or basic functional groups in water-soluble compounds is
detected by testing their aqueous solutions with litmus or other indicator paper.

The subsequent systematic search for functional groups is based primarily on
the knowledge as to whether the compound is neutral, acidic or basic in char-
acter as determined by the application of these preliminary solubility tests.

Solubility in water. Since water is a polar compound, it is a poor solvent for
hydrocarbons of all types. Salts are usually extremely polar, and are generally
water-soluble. Other compounds fall between these two extremes; these include
alcohols, esters, aldehydes, ketones, acids, ethers, amides, nitriles and amines.
Acids and amines are generally more soluble than neutral compounds.

For homologous series of mono-functional alcohols, esters, aldehydes,
ketones, acids, ethers, amides, nitriles and amines, the upper limit of water solu-
ability is found at about the member containing four carbon atoms. The solubil-
Solubility in water is due largely to the polar group, and as the homologous series is ascended the hydrocarbon (non-polar) part of the molecule increases while the polar function remains substantially unchanged; this accounts for the decrease in solubility in polar solvents such as water. This behaviour is an illustration of a general rule that increased structural similarity between the solute and the solvent results in increased solubility in that solvent.

It must be emphasised that the particular region (that of the member containing four carbon atoms) of water solubility for many homologous series is determined by the arbitrary proportions of solute and solvent defined in the previous general discussion. The limit would be elsewhere for a different ratio of solute to solvent.

**Solubility in ether.** Non-polar and slightly polar compounds will, in general, dissolve in ether because they are largely unassociated. Ionic compounds, such as salts, are not soluble in ether. The solubility of a polar compound in ether will depend upon the influence of the polar group or groups relative to that of the non-polar part of the molecule. Usually, compounds that have but one polar group per molecule will dissolve in ether unless they are highly associated or of extreme polarity (e.g. the sulphonic acids).

Many organic compounds that are insoluble in water dissolve in ether. If a compound is soluble in both ether and water, it probably (i) is non-ionic, (ii) contains five or less carbon atoms, (iii) has a functional group that is polar and capable of forming hydrogen bonds and (iv) does not contain more than one strongly polar group. If a compound dissolves in water but not in ether, it may (i) be ionic (a salt) or (ii) contain two or more polar groups but not more than four carbon atoms per polar group. There are, of course, exceptions to these statements.

**Solubility in dilute hydrochloric acid.** Most compounds that are soluble in dilute hydrochloric acid contain a basic nitrogen atom (incorporating an unshared electron pair) in the molecule. Thus most aliphatic amines (primary, secondary and tertiary) form salts (polar, water-soluble compounds) with hydrochloric acid. Aryl groups reduce the basicity of the nitrogen atom. Primary aromatic amines (e.g. aniline), although more weakly basic than primary aliphatic amines, are soluble, but in secondary and tertiary purely aromatic amines (e.g. diphenylamine, carbazole and triphenylamine) the basic character of the nitrogen atom has been diminished to such an extent that they do not form salts with dilute hydrochloric acid and consequently do not dissolve. Alkylarylamines (containing not more than one aryl group) and alicyclic amines, however, do dissolve. A few types of oxygen-containing compounds (such as the pyrones and the anthocyanidin pigments of certain flowers), which form oxonium salts, dissolve in dilute hydrochloric acid. Amides which are insoluble in water are generally unaffected by 5 per cent hydrochloric acid but may dissolve in higher concentrations (10–20%) of acid: this emphasises the importance of employing the correct strength of acid in the solubility tests. Many disubstituted amides which are of sufficiently high molecular weight to be water-insoluble dissolve in 5 per cent hydrochloric acid.

It may be noted that some aromatic amines react with 5 per cent hydrochloric acid to form insoluble hydrochlorides: the latter sometimes dissolve upon warming slightly and diluting with water. The appearance of the solid will usually show whether the arylamine has undergone a change: the solid should be
separated and its melting point compared with that of the original compound. A test with ethanolic silver nitrate solution would indicate the formation of a hydrochloride.

**Solubility in dilute sodium hydroxide solution and in dilute sodium hydrogen carbonate solution.** Carboxylic acids, sulphonic acids, sulphinic acids, phenols, thiophenols, thiols, amides, aryilsulphonamides, arylsulphonphenyl derivatives of primary amines, oximes, primary and secondary nitro compounds and some enols (e.g. of 1,3-diketones or β-keto esters) dissolve in dilute sodium hydroxide solution, i.e. they contain an acidic group of sufficient strength to react with the alkali. Carboxylic acids, sulphinic acids and sulphonyl acids are soluble in dilute solutions of sodium hydrogen carbonate with the evolution of carbon dioxide; some phenols substituted with electron-withdrawing groups (for example, picric acid, 2,4,6-tribromophenol and 2,4-dinitrophenol) are strongly acidic and also dissolve in sodium hydrogen carbonate solution with the evolution of carbon dioxide. Primary and secondary nitro compounds, imides, aryilsulphonamides and oximes are insoluble in sodium hydrogen carbonate solution. Some of the sodium salts of highly substituted phenols are insoluble in sodium hydroxide solution but may dissolve upon dilution and warming with water.

Certain substituents (e.g. the amino group) may markedly affect the solubility and other properties of a sulphonyl acid or a carboxylic acid. Thus such sulphonic acids as the aminobenzenesulphonic acids and the pyridine- and quinoline-sulphonic acids exist in the form of inner salts or dipolar ions that result from the interaction of the basic amino group and the acidic sulphonyl acid group. Sulphanilic acid, for example, is more accurately represented by formula (1) than by formula (2):

\[
p-H_3^+\cdot C_6H_4\cdot SO_3^- \quad p-H_2N\cdot C_6H_4\cdot SO_3H
\]

These aminosulphonic acids possess the high melting points usually associated with salts, but are sparingly soluble or insoluble in water. They all dissolve readily in dilute alkali but not in dilute acid, i.e. they appear to exhibit the reactions of the sulphonlic acid group but not of the amino group. The aliphatic aminocarboxylic acids (3), because of the presence of the strongly basic amino group, exist as dipolar ions (4):

\[
H_2N\cdot CHR\cdot CO_2H \quad H_3^+\cdot CHR\cdot CO_2^-
\]

they are soluble in water but not in ether, and dissolve in both dilute acid and dilute alkali but react slowly or not at all with dilute sodium hydrogen carbonate solution. The carboxyl derivatives of the arylamines (e.g. p-aminobenzoic acid) are also amphoteric, but the diminution of the basic character of the amino group because of its attachment to the aryl group prevents the formation of inner salts to any degree; they react normally with sodium hydrogen carbonate.

**Solubility in concentrated sulphuric acid.** Solubility in cold concentrated sulphuric acid is used to characterise further those compounds which by virtue of the results of the previous solubility tests are considered to be neutral.

The most important group of compounds to exhibit solubility in this reagent are those containing oxygen. The initial solubility of these compounds is due to
the basic character of one or more of the oxygen atoms that are present in the molecules, and results from oxonium ion formation; dilution of the sulphuric acid solution often results in recovery of the compound in an unchanged form. More fundamental changes resulting from subsequent transformations of the oxonium ion may, however, occur.

Unsaturated hydrocarbons dissolve through formation of soluble alkyl hydrogen sulphates, e.g.

$$R^1 \cdot CH=CH \cdot R^2 + H^+ \rightarrow [R^1 \cdot CH_2 \cdot CH_2 \cdot R^2]^+$$

Polyalkylated aromatic hydrocarbons and alkyl phenyl ethers undergo sulphonation, e.g.

$$ArH + 2H_2SO_4 \rightarrow Ar\cdot SO_3H + HSO_4^+ + H_3O^+$$

Compounds which dissolve in concentrated sulphuric acid may be further classified as those which are soluble in syrupy phosphoric acid and those which are insoluble in this solvent: in general dissolution takes place without the production of appreciable heat or colour. Those compounds soluble in phosphoric acid include alcohols, esters, aldehydes, methyl ketones and cyclic ketones provided that they contain less than nine carbon atoms. The solubility limit is somewhat lower than this for ethers; thus dipropyl ether dissolves in 85 per cent phosphoric acid but dibutyl ether and anisole do not. Ethyl benzoate and diethyl malonate are insoluble.

SUMMARY OF SOLUBILITY BEHAVIOUR

It is convenient to summarise the solubility characteristics of the commoner classes of organic compounds into seven groups as specified in Table 9.1. The compounds are grouped according to: (a) their solubility towards the reagents specified above, and (b) the elements, other than carbon and hydrogen, that they contain (see Section 9.3).

1. **Compounds soluble in both water and ether.** This includes the lower members of the various homologous series (4–5 atoms in a normal chain) that contain oxygen and/or nitrogen in their structures: they are soluble in water because of their low carbon content. If the compound is soluble in both water and in ether, it would also be soluble in other solvents so that further solubility tests are generally unnecessary: the aqueous solution should be tested with indicator paper. The test with sodium hydrogen carbonate solution should also be performed.

2. **Compounds soluble in water but insoluble in ether.** These compounds with the exception of Salts, are usually also soluble in dilute alkali and acid. The behaviour of salts to alkaline or acidic solvents may be informative. Thus, with a salt of a water-soluble base, the characteristic odour of an amine is usually apparent when it is treated with dilute alkali: likewise, the salt of a water-soluble, weak acid is decomposed by dilute hydrochloric acid or by concentrated sulphuric acid. The water-soluble salt of a water-insoluble acid or base will give a precipitate of either the free acid or the base when treated with dilute acid or dilute alkali. The salts of sulphonic acids and of quaternary bases are unaffected by dilute sodium hydroxide or hydrochloric acid.

3. **Compounds insoluble in water, but soluble in dilute sodium hydroxide.** It should be recalled that some of the compounds belonging to this group are

</table>
sufficiently strong acids to release carbon dioxide from sodium hydrogen carbonate (e.g. carboxylic acids, sulphonic and sulphinic acids, and certain substituted phenols, see above).

4. Compounds insoluble in water, but soluble in dilute hydrochloric acid. It should be remembered that the hydrochlorides of some bases are sparingly soluble in cold water and one should therefore not be misled by an apparent insolubility of a compound (containing nitrogen) in dilute hydrochloric acid. The suspension in dilute hydrochloric acid should always be filtered and the filtrate made alkaline. A precipitate will indicate that the compound is indeed a base and should be included in this group.

5. Water-insoluble hydrocarbons and oxygen compounds that do not contain N or S and are soluble in cold concentrated sulphuric acid. Any changes – colour, excessive charring, evolution of gases or heat, polymerisation and precipitation of an insoluble compound – attending the dissolution of the substance should be carefully noted.

Alcohols, esters (but not ethyl benzoate, diethyl malonate or diethyl oxalate), aldehydes, methyl ketones and cyclic ketones containing less than nine carbon atoms as well as ethers containing less than seven carbon atoms are also soluble in 85 per cent phosphoric acid.

6. Compounds, not containing N or S, insoluble in concentrated sulphuric acid. This test provides for a differentiation inter alia between alkanes and cycloalkanes and also simple aromatic hydrocarbons which are insoluble, and unsaturated hydrocarbons which are soluble in the reagent.

7. Compounds that contain N or S which are not in groups 1–4; many of the compounds in this group are soluble in concentrated sulphuric acid.

It will be observed that halogen compounds are not listed separately, but appear in each of the seven categories in accordance with their solubility behaviour.

PROCEDURE FOR SOLUBILITY TESTS
All solubility determinations are carried out at the laboratory temperature in small test tubes (e.g. 100 × 12 mm) but of sufficient size to permit vigorous shaking of the solvent and the solute.

Amount of material required. It is convenient to employ an arbitrary ratio of 0.10 g of solid or 0.20 ml of liquid for 3.0 ml of solvent. Weigh out 0.10 g of the finely powdered solid to the nearest 0.01 g; after some experience, subsequent tests with the same compound may be estimated by eye. Measure out 0.20 ml of the liquid either with a calibrated dropper or a small graduated pipette. Use either a calibrated dropper of a graduated pipette to deliver 3.0 ml of solvent.

Much time will be saved if each of the solvents (water, ether, 5% sodium hydroxide, 5% sodium hydrogen carbonate and 5% hydrochloric acid) be contained in a 30- or 60-ml reagent bottle fitted with a ground-in calibrated dropper.

Solubility in water. Treat a 0.10 g portion of the solid with successive 1.0 ml portions of water, shaking vigorously after each addition, until 3.0 ml have been added. If the compound does not dissolve completely in 3.0 ml of water, it may be regarded as insoluble in water. When dealing with a liquid, add 0.20 ml of the compound to 3.0 ml of water and shake. In either case, test the contents of the small test-tube with Universal indicator paper: it is best to remove a little of the
solution or supernatant liquid with a dropper. It is usually convenient at this stage to test for the presence of water-soluble enolic compounds by observing any coloration resulting from the addition of neutral aqueous iron(III) chloride solution.

**Solubility in ether.** Use 0.10 g of solid or 0.20 ml of a liquid in a dry test tube and proceed exactly as in testing the solubility in water, but do not employ more than 3.0 ml of solvent.

**Solubility in 5 per cent sodium hydroxide solution.** Note whether there is any rise in temperature. If the compound appears insoluble, remove some of the supernatant liquid by means of a dropper to a semimicro test tube (75 x 10 mm), add 5 per cent hydrochloric acid dropwise until acid and note whether any precipitate (or turbidity) is formed. The production of the latter will confirm the presence of an acidic compound.

**Solubility in 5 per cent sodium hydrogen carbonate solution.** If the compound is soluble in 5 per cent sodium hydroxide solution, test its solubility in a 5 per cent solution of sodium hydrogen carbonate. Observe whether it dissolves and particularly whether carbon dioxide is evolved either immediately (carboxylic acids, sulphonyl acids, negatively substituted phenols) or after a short time (some amino acids).

**Solubility in 5 per cent hydrochloric acid.** Add the acid to 0.10 g of the solid or 0.20 ml of the liquid in quantities of 1.0 ml until 3.0 ml have been introduced. Some organic bases form hydrochlorides that are soluble in water but are precipitated by an excess of acid: if solution occurs at any time, the unknown is classified as a basic compound. If the compound appears insoluble, remove some of the supernatant liquid by means of a dropper to a semimicro test tube (75 x 10 mm), and add 5 per cent sodium hydroxide solution until basic and observe whether any precipitate is produced: the formation of a precipitate will confirm that the compound is a base.

**Solubility in concentrated sulphuric acid.** Place 3.0 ml of pure concentrated sulphuric acid in a dry test tube and add 0.10 g of a solid or 0.20 ml of a liquid. If the compound does not dissolve immediately, agitate for some time but do not heat. Observe any change in colour, charring, evolution of gaseous products, polymerisation accompanied by precipitation, etc.

**Solubility in syrupy phosphoric acid.** This test should only be applied if the compound is soluble in concentrated sulphuric acid. Place 3.0 ml of 85 per cent orthophosphoric acid in a dry test tube and add 0.10 g of a solid or 0.20 ml of a liquid. If the compound does not dissolve immediately, agitate for some time but do not boil.

### 9.3 Detection of Elements Present

The most commonly occurring elements in organic compounds are carbon, hydrogen, oxygen, nitrogen, sulphur and the halogen elements; less common elements are phosphorus, arsenic, antimony, mercury or other metals which may be present as salts of organic acids. There is no direct method for the detection of oxygen.
There are three straightforward tests which will provide useful information as to the general properties of the compound, and the presence of the more important of the elements noted above other than carbon, hydrogen and oxygen; these tests are: the ignition test; heating with soda-lime; and the sodium fusion test (Lassaigne's test).

IGNITION TEST

Procedure. Place about 0.1 g of the compound on a metal spatula. Heat it gently at first and finally to dull redness. Observe:
(a) whether the substance melts, is explosive or is flammable and note the nature of the flame;
(b) whether gases or vapour are evolved, and their odour (CAUTION);
(c) whether the residue fuses.

Evidence of the organic nature of the compound, i.e. the presence of carbon and hydrogen (1), and the absence of metals, is indicated by burning with a more or less smoky flame, and a black residue consisting largely of carbon, which 'burns off' on prolonged heating, leaving no residue. In general, aromatic compounds characteristically burn with a very smoky flame.

If an appreciable amount of residue remains, note its colour. Add a few drops of water and test the solution (or suspension) with Universal indicator paper. Then add a little dilute hydrochloric acid and observe whether effervescence occurs and the residue dissolves. Apply a flame test with a platinum wire, which may determine the metal present.

Note. (1) If it is desired to test directly for carbon and hydrogen in a compound, mix 0.1 g of the substance with 1−2 g of freshly ignited, fine copper (ii) oxide powder in a dry test tube, and fit the latter with a bung carrying a tube bent at an angle so that escaping gases can be bubbled below the surface of lime water contained in a second test tube. Clamp the test tube near the top and heat the mixture gradually. If carbon is present, carbon dioxide will be evolved which will produce a turbidity in the lime water. If hydrogen is present, small drops of water will collect in the cooler part of the tube.

HEATING WITH SODA-LIME

This is often a useful preliminary test. Mix thoroughly about 0.2 g of the substance with about 1 g of powdered soda-lime. Place the mixture in a Pyrex test tube; close the tube by a bung and delivery tube. Incline the test tube so that any liquid formed in the reaction cannot run back on the hot part of the tube. Heat the test tube gently at first and then more strongly. Collect any condensate produced in a test tube containing 2−3 ml of water: Nitrogenous compounds will usually evolve ammonia or vapours alkaline to indicator paper and possessing characteristic odours; hydroxybenzoic acids yield phenols; formates and acetates yield hydrogen; simple carboxylic acids yield hydrocarbons (methane from acetic acid, benzene from benzoic or phthalic acid, etc.); amine salts and aromatic amino carboxylic acids yield aromatic amines, etc.

SODIUM FUSION TEST

In order to detect nitrogen, sulphur and halogen in organic compounds, it is necessary to convert them into ionisable inorganic substances so that ionic tests of inorganic analysis may be applied. This may be accomplished by several methods, but the best procedure is to fuse the organic compound with metallic sodium (Lassaigne's test). In this way sodium cyanide, sodium sulphide and
Sodium halides, which are readily identified, are formed respectively if the above elements are present. It is essential to use an excess of sodium, otherwise if sulphur and nitrogen are both present sodium thiocyanate, NaCN, may be produced; this may give a red coloration with iron(III) ions but will not of course respond to tests for cyanide or sulphide ions. With excess of sodium the thiocyanate, if formed, will be decomposed thus:

\[ \text{NaCNS} + 2\text{Na} \rightarrow \text{NaCN} + \text{Na}_2\text{S} \]

Cyanide ion, and hence nitrogen in the sample, may be detected by the Prussian Blue test. The filtered alkaline solution, resulting from the action of water upon the sodium fusion, is treated with iron(II) sulphate and thus forms sodium hexacyanoferrate(II). Upon boiling the alkaline iron(II) salt solution, some iron(III) ions are inevitably produced by the action of air; upon addition of dilute sulphuric acid, thus dissolving the iron(II) and (III) hydroxides, the hexacyanoferrate(II) reacts with the iron(III) salt producing iron(III) hexacyanoferrate(II), Prussian blue:

\[ \text{FeSO}_4 + 6\text{NaCN} \rightarrow \text{Na}_4[\text{Fe(CN)}_6] + \text{Na}_2\text{SO}_4 \]

\[ 3\text{Na}_4[\text{Fe(CN)}_6] + 2\text{Fe}_2(\text{SO}_4)_3 \rightarrow \text{Fe}_4[\text{Fe(CN)}_6]_{13} + 6\text{Na}_2\text{SO}_4 \]

Hydrochloric acid should not be used for acidifying the alkaline solution since the yellow colour, due to the iron(III) chloride formed, causes the Prussian blue to appear greenish. For the same reason, iron(III) chloride should not be added – as is frequently recommended: a sufficient concentration of iron(III) ions is produced by atmospheric oxidation of the hot alkaline solution. An alternative, sensitive test for cyanide ion is the formation of a deep purple coloration when the fusion solution is treated with an alkaline p-nitrobenzaldehyde-o-dinitrobenzene reagent.

Sulphur, as sulphide ion, may be detected by precipitation as black lead sulphide with lead acetate solution and acetic acid or by the purple colour produced on addition of disodium pentacyanodisulphoiron(III). Halogens are detected as the characteristic silver halides by the addition of dilute nitric acid and silver nitrate solution. Cyanide and sulphide ions both interfere with this test for halide by forming silver cyanide and silver sulphide precipitates. If nitrogen or sulphur has been detected, therefore, the interfering ions must be removed by boiling the acidified fusion solution as detailed later, before the silver nitrate solution is added to detect the halogen.

**Procedure for Lassaigne's test.** Support a Pyrex test tube (150 x 12 mm) vertically in a clamp lined with sheet cork. Place a cube \((c. 4 \text{ mm} = 0.04 \text{ g})\) of freshly cut sodium in the tube (for precautions in the use of sodium see Section 4.2.68, p. 462). Have in readiness about 0.05 g of the compound (if a solid) on a microspatula or tip of a knife blade, or about 3 drops of the compound (if a liquid) in a dropping pipette. Heat the tube steadily until sodium vapour, which is dark grey in colour, rises 2–3 cm in the test tube and drop the sample, preferably portionwise, directly on to the molten sodium (CAUTION: there may be a slight explosion). Do not allow the sample to fall on to the side of the tube above the vapour layer. Heat the tube to redness for about 2 minutes, and then allow it to cool. Add about 3 ml of methanol to decompose any unreacted sodium and then half-fill the tube with distilled water. Boil gently for a few minutes to remove the methanol and extract inorganic salts from the fusion residue; gently crush the...
residue with a glass rod to assist the extraction process. Filter and use the clear, colourless filtrate for the various tests detailed below. If the filtrate is dark coloured, decomposition was probably incomplete; repeat the entire fusion procedure. Keep the test tube for further sodium fusions; it will become discoloured and should be cleaned from time to time with a little scouring powder.

**Test for nitrogen.** Either of the following methods may be used.

1. Pour 2–3 ml of the filtered fusion solution into a test tube containing 0.1–0.2 g of powdered iron(II) sulphate crystals. Heat the mixture gently with shaking until it boils, then, without cooling, add just sufficient dilute sulphuric acid to dissolve the iron hydroxides and give the solution an acid reaction. {The addition of 1 ml of 5% potassium fluoride solution is beneficial (possibly owing to the formation of potassium hexafluoroferrate(III), K₃[FeF₆]) and usually leads to a purer Prussian blue.} A Prussian blue precipitate or coloration indicates that nitrogen is present. If no blue precipitate appears at once, allow to stand for 15 minutes, filter through a small filter and wash the paper with water to remove all traces of coloured solution: any Prussian blue present will then become perceptible in the cone of the filter paper. If in doubt, repeat the sodium fusion, preferably using a mixture of the compound with pure sucrose or naphthalene. In the absence of nitrogen, the solution should have a pale yellow colour due to iron salts.

If sulphur is present, a black precipitate of iron(II) sulphide is obtained when the iron(II) sulphate crystals dissolve. Boil the mixture for about 30 seconds, and acidify with dilute sulphuric acid; the iron(II) sulphide dissolves and a precipitate of Prussian blue remains if nitrogen is present.

2. Mix together 5 drops of a 1.5 per cent solution of p-nitrobenzaldehyde in 2-methoxyethanol, 5 drops of a 1.7 per cent solution of o-dinitrobenzene in 2-methoxyethanol and 2 drops of a 2.0 per cent aqueous solution of sodium hydroxide. To this mixture add 1 drop of fusion solution. A deep purple coloration is positive for cyanide ions, a yellow or tan colour is negative. Neither halide ions nor sulphide ions interfere.

**Test for sulphur.** This element may be tested for by either of the following two methods.

1. Acidify 2 ml of the fusion solution with dilute acetic acid, and add a few drops of lead acetate solution. A black precipitate of lead sulphide indicates the presence of sulphur.

2. To 2 ml of the fusion add 2–3 drops of a freshly prepared dilute solution (c 0.1%) of di-sodium pentacyanonitrosyl ferrate Na₂[Fe(CN)₅NO]. (The latter may be prepared by adding a minute crystal of the solid to about 2 ml of water.) A purple coloration indicates sulphur; the coloration slowly fades on standing.

**Test for halogens.** *Nitrogen and sulphur absent.* 1. Acidify a portion of the fusion solution with dilute nitric acid and add an excess of silver nitrate solution. A precipitate indicates the presence of a halogen. Decant the mother-liquor and treat the precipitate with dilute aqueous ammonia solution. If the precipitate is white and readily soluble in the ammonia solution, chlorine is present; if it is pale yellow and difficultly soluble, bromine is present; if it is yellow and insoluble, then iodine is indicated. Iodine and bromine may be confirmed by
tests (2) or (3); these tests may also be used if it is suspected (e.g. from behaviour in the silver nitrate test) that more than one halogen is present.

2. Acidify 1–2 ml of the fusion solution with a moderate excess of glacial acetic acid and add 1 ml of dichloromethane. Then introduce 20 per cent sodium nitrite solution drop by drop with constant shaking. A purple or violet colour in the organic layer indicates the presence of iodine. The reaction is:

\[ 2\text{NaI} + 2\text{NaNO}_2 + 4\text{Me} \cdot \text{CO}_2\text{H} \rightarrow \text{I}_2 + 2\text{NO} + 4\text{Me} \cdot \text{CO}_2\text{Na} + 2\text{H}_2\text{O} \]

This solution may also be employed in the test for bromine. If iodine has been found, add further additional quantities of sodium nitrite solution, warm and by means of a dropper pipette remove and replace the organic phase with fresh portions of dichloromethane; repeat until the organic phase is colourless. Boil the acid solution until no more nitrous fumes are evolved and cool. Add a small amount of lead dioxide, place a strip of fluorescein paper (1) across the mouth of the tube and warm. If bromine is present, it will colour the test paper rose-pink (eosin is formed). If iodine has been found to be absent use 1 ml of the fusion solution, acidify strongly with glacial acetic acid, add lead dioxide and proceed as above.

In this test for bromine, lead dioxide in acetic acid solution gives lead tetra-acetate which oxidises hydrogen bromide (and also hydrogen iodide), but has practically no effect under the above experimental conditions upon hydrogen chloride:

\[ 2\text{NaBr} + \text{PbO}_2 + 4\text{Me} \cdot \text{CO}_2\text{H} \rightarrow \text{Br}_2 + (\text{Me} \cdot \text{CO}_2)_2\text{Pb} + 2\text{Me} \cdot \text{CO}_2\text{Na} + 2\text{H}_2\text{O} \]

To test for chlorine in the presence of iodine and/or bromine, acidify 1–2 ml of the fusion solution with glacial acid, add a slight excess of lead dioxide (say, 0.5 g) and boil gently until all the iodine and bromine is liberated. Dilute, filter off excess lead dioxide and test for chloride ions with dilute nitric acid and silver nitrate solution.

3. Acidify 1–2 ml of the fusion solution with dilute sulphuric acid, cool and add 1 ml of dichloromethane. Prepare the equivalent of ‘chlorine water’ by acidifying 10 per cent sodium hypochlorite solution with one-fifth of its volume of dilute hydrochloric acid. Add this solution dropwise with vigorous shaking to the mixture. If iodine is present the organic phase first becomes purple in colour. As the addition of chlorine water is continued, the purple colour disappears (owing to oxidation of iodine to iodate) and, if bromine is present, is replaced by a brown or reddish colour. If bromine is absent, the organic layer will be colourless. It is, of course, evident that if the dichloromethane layer remains uncoloured and the results of test (1) were positive, the halogen present is chlorine.

**Nitrogen and/or sulphur present.** To remove cyanide and sulphide ions, make 2–3 ml of the fusion solution just acidic with dilute nitric acid, and evaporate to half of the original volume in order to expel hydrogen cyanide and/or hydrogen sulphide which may be present (CAUTION). Dilute with an equal volume of water and proceed as in test (1), (2) and (3) above.

Alternatively, add 1–2 drops of 5 per cent nickel(II) nitrate solution to 2–3 ml of the fusion solution, filter off the nickel(II) cyanide and/or nickel sulphide, acidify the filtrate with 2 M nitric acid and test for halides as above.
The presence of halogens may be further confirmed by the Beilstein test. This test serves to detect the presence of halogen in many organic compounds. In consists in heating the substance in contact with pure copper oxide in the Bunsen flame: the corresponding copper halide is formed, which, being volatile, imparts an intense green or bluish-green colour to the mantle of the flame.

Push one end of a 20-cm length of stout copper wire into a cork (this will serve as a holder); coil the other end by making two or three turns about a thin glass rod. Heat the coil in the outer mantle of a Bunsen flame until it ceases to impart any colour to the flame. Allow the wire to cool somewhat and, while still warm, dip the coil into a small portion of the substance to be tested and heat again in the non-luminous flame. If the compound contains a halogen element, a green or bluish-green flame will be observed (usually after the initial smoky flame has disappeared). Before using the wire for another compound, heat it until the material from the previous test has been destroyed and the flame is not coloured.

It has been stated that many halogen-free compounds, e.g. certain derivatives of pyridine and quinoline, purines, acid amides and cyano compounds, when ignited on copper oxide impart a green colour to the flame, presumably owing to the formation of volatile copper cyanide. The test is therefore not always trustworthy. The test is not given by fluorides since copper fluoride is not volatile.

The detection of the following elements, which occur in organic less frequently compounds, is included here for the sake of completeness.

**Test for fluorine.** Use either of the following tests.

1. Strongly acidify about 2 ml of the fusion filtrate with glacial acetic acid, and boil until the volume is reduced to about one-half. Cool. Place one drop of the solution upon zirconium-alizarin red S test paper (2). A yellow colour on the red paper indicates the presence of fluoride. Large amounts of sulphates and phosphates may interfere with this test.

2. If nitrogen and/or sulphur is present, acidify 3–4 ml of the fusion solution with dilute nitric acid and evaporate to half the original volume in order to expel any HCN and/or H₂S which may be present. If nitrogen and sulphur are absent, proceed directly with 2 ml of the sodium fusion filtrate. Render the solution just neutral to litmus by the addition of dilute (5 m) aqueous ammonia solution, then add 5 drops of 5 m acetic acid and 20 mg of lanthanum chloranilate (2,5-dichloro-3,6-dihydroxy-p-benzoquinone, lanthanum salt) and shake intermittently for 10–15 minutes. Filter. A pink-violet coloration of the filtrate is a positive test for fluorine.

**Test for phosphorus.** The presence of phosphorus may be indicated by a smell of phosphine during the sodium fusion and the immediate production of a jet-black colour when a piece of filter paper moistened with silver nitrate solution is placed over the mouth of the ignition tube after the sample has been dropped on the hot sodium. Treat 1.0 ml of the fusion solution with 3 ml of concentrated nitric acid and boil for 1 minute. Cool and add an equal volume of ammonium molybdate reagent (3). Warm the mixture to 40–50 °C, and allow to stand. If phosphorus is present, a yellow crystalline precipitate of ammonium 12-molybdophosphate, \((\text{NH}_4)_3[\text{PMO}_{12}\text{O}_{40}]\), will separate.

It is usually preferable to oxidise the compound directly as follows. Intimately mix 0.02–0.05 g of the compound with 3 g of sodium peroxide and 2 g of
9.4 PRACTICAL ORGANIC CHEMISTRY

anhydrous sodium carbonate in a nickel crucible. Heat the crucible and its contents with a small flame, gently at first, afterwards more strongly until the contents are fused, and continue heating for a further 10 minutes. Allow to stand, extract the contents of the crucible with water and filter. Add excess of concentrated nitric acid to the filtrate and test with ammonium molybdate reagents as above. A yellow precipitate indicates the presence of phosphorus. It must be borne in mind that the above treatment will convert any arsenic present into arsenate.

Notes. (1) Fluorescein test paper is prepared by dipping filter papers into a dilute solution of fluorescein in ethanol; it dries rapidly and is then ready for use. The test paper has a lemon yellow colour.
(2) Prepare the zirconium–alizarin red S paper as follows. Soak dry filter paper in a 5 per cent solution of zirconium nitrate in 5 per cent hydrochloric acid and, after draining, place it in a 2 per cent aqueous solution of sodium alizarin sulphonate (BDH 'Alizarin Red S'). The paper is coloured red-violet by the zirconium lake. Wash the paper until the wash water is nearly colourless and then dry in the air.
(3) Ammonium molybdate reagent may be prepared by dissolving 45 g of pure ammonium molybdate in a mixture of 40 ml of aqueous ammonia (d 0.88) and 60 ml of water and then adding 120 g of ammonium nitrate and diluting the solution to 1 litre with water.

9.4 SPECTROSCOPIC INFORMATION

The techniques for the determination of the spectroscopic features of organic compounds, and of their relationship to the presence of skeletal and functional group structures are considered in Chapter 3. Chapters 5 and 6 provide spectroscopic summaries of classes of compounds, and more detailed spectroscopic information on specific known compounds as examples in which the interpretation of spectra may be further explored.

When considering the use of spectra for the classification of an unknown compound with the aim of elucidating its structure, some careful judgement on the relative merits of each spectroscopic tool is required.

In general, the main value of i.r. spectroscopic features is for the detection of functional groups, although the information on skeletal structure is clearly of importance. To use a very simple illustration, the technique would clearly distinguish between functional isomers (e.g. alcohols and ethers), or aromatic and aliphatic compounds, but would be inadequate, for example, to distinguish between adjacent straight-chain members of a homologous series of four carbons upwards of a particular functional type.

With n.m.r. spectroscopy (13C and 1H), the main value lies in the provision of information on skeletal structure (e.g. aliphatic straight or branched chain, aromatic, heterocyclic, etc.); confirmatory evidence on the nature of the functional group is deduced from a consideration of the chemical shift values, and from the definitive information in the case of groups having replaceable hydrogens, or groups with highly deshielded protons.

The m.s. data, particularly now that recent techniques give a 'best-fit' elemental composition of molecular ions and fragment ions which facilitates speculation of fission processes, provides in association with the above techniques, further information of structural value. Polyhalogenated compounds are particularly easily handled by this technique.
The principal merit of u.v.-visible spectroscopy is in the assessment of the degree of conjugation (not readily deduced from the previous methods) in polyenes, polyenynes, and polyenones, and in the recognition of the presence of aromatic structures.

Chapter 3 includes a recommended sequence for the systematic examination of i.r. spectra (p. 271), p.m.r. spectra (p. 359) and m.s. (p. 373).

9.5 FUNCTIONAL GROUP IDENTIFICATION

The solubility behaviour of an unknown compound will serve to classify it into one of the three main divisions, namely, acidic, basic or neutral. This information, supplemented by elemental analysis if deemed necessary, and as noted above cross-correlated with spectroscopic inferences, forms the basis for the subsequent systematic search to identify definitively the functional group or groups present. It cannot be too clearly emphasised that inexperience in spectroscopic interpretation can lead to erroneous conclusions of structure. The value of chemical tests is that they reduce the chance of this happening, furthermore they are frequently easily and quickly performed and provide experience in accurate and reliable observation and reporting.

When an organic compound contains more than one functional group, the classification is generally based upon the one which is most easily detected and manipulated. Thus benzoic acid, p-chlorobenzoic acid, p-methoxybenzoic acid (anisic acid) and p-nitrobenzoic acid will be classified as acids both by the solubility tests and the class reactions, and the identification of, say, the nitrogen-containing acid may be completed by the preparation of derivatives of the carboxyl group without the absolute necessity of applying the class reactions that would discover the nitro group; however, if possible, it is always desirable to establish the nature of the subsidiary functional group or groups (including the presence of unsaturation), the presence of which may become apparent when the preliminary identification of the compound has been completed.

9.5.1 ACIDIC COMPOUNDS

The principle classes of acidic compounds are listed in Table 9.1 (Column 3). The distinction between true acids and the weakly acidic pseudo acids (e.g. phenols, enols, nitroalkanes) should be made by observing the nature of the reaction with sodium hydrogen carbonate. To ensure that evolution of carbon dioxide does not go unnoticed in those cases where reaction appears sluggish, add a solution of the compound in methanol carefully to a saturated solution of sodium hydrogen carbonate solution, when a vigorous effervescence at the interface will be observed.

CARBOXYLIC ACIDS

The presence of a carboxylic acid group is indicated by strong infrared absorption in the region of 1720 cm\(^{-1}\) (C=O str.) and broad absorption between 3400 cm\(^{-1}\) and 2500 cm\(^{-1}\) (OH str.); in the nuclear magnetic resonance spectrum the acidic hydrogen (replaceable by D\(_2\)O) will appear at very low field (\(\delta\) 10-13).
Confirmatory test for carboxylic acids. **Ester formation.** Warm a small amount of the acid with 2 parts of absolute ethanol and 1 part of concentrated sulphuric acid for 2 minutes. Cool, and pour cautiously into aqueous sodium carbonate solution contained in an evaporating dish, and smell immediately. An acid usually yields a sweet, fruity smell of an ester. (Acids of high molecular weight often give almost odourless esters, however.)

For derivative preparations for carboxylic acids see Section 9.6.15, p. 1261.

**CARBOXYLIC ACID HALIDES**
With these compounds the presence of the halogen will have been detected in the tests for elements. Most acid halides undergo ready hydrolysis with water to give an acidic solution and the halide ion produced may be detected and confirmed with silver nitrate solution. The characteristic carbonyl adsorption at about 1800 cm\(^{-1}\) in the infrared spectrum will be apparent. Acid chlorides may be converted into esters as a confirmatory test: to 1 ml of absolute ethanol in a dry test tube add 1 ml of the acid chloride dropwise (use a dropper pipette; keep the mixture cool and note whether any hydrogen chloride gas is evolved). Pour into 2 ml of saturated salt solution and observe the formation of an upper layer of ester; note the odour of the ester. Acid chlorides are normally characterised by direct conversion into carboxylic acid derivatives (e.g. substituted amides) or into the carboxylic acid if the latter is a solid (see Section 9.6.16, p. 1265).

**CARBOXYLIC ACID ANHYDRIDES**
The simpler examples are readily hydrolysed in aqueous solution, and therefore react with sodium hydrogen carbonate and also give the ester test; they may be confirmed by applying the hydroxamic ester test (Section 9.5.3, p. 1222). Carbonyl adsorption is apparent in the infrared spectrum at about 1820 cm\(^{-1}\) and at about 1760 cm\(^{-1}\). It should be noted that aromatic anhydrides and higher aliphatic anhydrides are not readily hydrolysed with water and are therefore effectively neutral (Section 9.5.3, p. 1218). The final characterisation of the acid anhydride is achieved by conversion into a crystalline carboxylic acid derivative as for acid halides.

**SULPHONIC AND SULPHINIC ACIDS**
These compounds are suggested if sulphur is present. If nitrogen is also present the compound may be an aminosulphonic acid. The infrared spectrum will show absorption at 3400–3200 cm\(^{-1}\) (OH str.) and 1150 and 1050 cm\(^{-1}\) (S—O str. in a sulphonic acid) or at 1090 cm\(^{-1}\) (S—O str. in a sulphonic acid). For derivative preparations for sulphonic acids see Section 9.6.26, p. 1284. The presence of an aromatic sulphonic acid may be further confirmed by dissolving in cold concentrated sulphuric acid and adding one drop of phenetole or anisole when a blue colour is produced (Smiles’s test), due to formation of a para-substituted aromatic sulphoxide. The reaction is:

\[
\text{Ar·SO}_2\text{H} + \text{PhOR} \rightarrow \text{Ar·SO·C}_6\text{H}_4\text{OR} + \text{H}_2\text{O}
\]

Aromatic sulphinic acids are oxidised by potassium permanganate to sulphonic acids and are reduced by zinc and hydrochloric acid to thiophenols.

**PHENOLS**
These do not usually liberate carbon dioxide from 5 per cent sodium hydrogen
carbonate solution; most are crystalline solids although notable exceptions are m-cresol and o-bromophenol. The monohydric phenols generally have characteristic odours. The solubility in water increases with the number of hydroxyl groups in the molecule. The infrared spectrum shows broad strong absorption at 3400–3200 cm\(^{-1}\) (OH str.).

**Confirmatory tests for phenols. Iron(III) chloride solution.** Dissolve about 0.05 g of the compound in 5 ml of water; if the compound is sparingly soluble, prepare a hot saturated aqueous solution, filter and use 1 ml of the cold filtrate. Place the solution in a test tube and add 1 drop of neutral 1 per cent iron(III) chloride solution and observe the colour; add another drop after 2–3 seconds. If a transient or permanent coloration (usually purple, blue or green) other than yellow or orange is observed, the substance is probably a phenol (or an enol). If no coloration is obtained, repeat the test as above but substitute absolute ethanol or methanol for water as solvent.

Prepare the *neutral ferric chloride* solution (i.e. free from hydrochloric acid) by adding dilute sodium hydroxide solution to the bench reagent until a slight precipitate of iron(III) hydroxide is formed. Filter off the precipitate and use the clear filtrate for the test.

**Bromine water.** Many phenols (with the exception of those with strong reducing properties) yield crystalline bromo compounds on the addition of bromine water. Dissolve or suspend 0.25 g of the compound in 10 ml of dilute hydrochloric acid or of water, and add bromine water dropwise until decolourisation is slow: a white precipitate of the bromophenol may form.

**Phthalein test.** Many phenols yield phthaleins, which give characteristic colorations in alkaline solution, when fused with phthalic anhydride and a little concentrated sulphuric acid. Place in a dry test tube 0.5 g of the compound and an equal bulk of pure phthalic anhydride, mix well together and add 1 drop of concentrated sulphuric acid. Stand the tube for 3–4 minutes in a small beaker of Silicone oil (or paraffin oil) previously heated to 160°C. Remove from the bath, allow to cool, add 4 ml of 5 per cent sodium hydroxide solution and stir until the fused mass has dissolved. Dilute with an equal volume of water, filter and examine the colour of the filtrate against a white background: if the solution exhibits a fluorescence, observe the colour against a black background.

It must be borne in mind that there are many nitrogen-containing phenols and acids; of these the nitro and amino derivatives are the most common. The influence of the nitro and other groups in the *ortho*- and *para*-positions upon the acidity of a phenol has already been noted: such groups tend to produce a marked deepening in the colour of alkaline solutions of the phenol. Amino substituents in water-insoluble phenols and acids cause these compounds to be soluble in both dilute acid and dilute alkali, i.e. to be amphoteric. Frequently it is helpful to destroy the basic character of the nitrogen by conversion of the amino group into a neutral amide group by acetylation or benzylation in aqueous alkaline solution: the resulting compound is not amphoteric.

For derivative preparations for phenols see Section 9.6.6, p. 1248.

**ENOLS**

These compounds (e.g. β-keto esters and 1,3-diketones) usually respond to the following tests.
Iron(III) chloride. Add a few drops of neutral iron(III) chloride solution to a solution of 0.1 g of the compound in water or in methanol. Most enols give a red coloration.

Copper derivative. Shake 0.2 g of the substance vigorously with a little cold, saturated, aqueous copper(II) acetate solution. Many enols give a solid, green or blue, copper derivative, which can be crystallised from ethanol and often has a definite m.p. (e.g. from ethyl acetoacetate, m.p. 192°C; from diethyl acetonedi-carboxylate, m.p. 142°C.

For derivative preparations for enols see Section 9.6.7.

THIOLS
These are generally liquids with an unmistakable penetrating, disagreeable and characteristic odour, which persists even at extremely low concentrations in air. Alkanethiols are partly soluble in concentrated solutions of sodium hydroxide but their salts are hydrolysed to the free thiols on dilution with water. Thiophenols are soluble in sodium hydroxide solution but like the alkanethiols do not evolve carbon dioxide from sodium hydrogen carbonate solution. Treatment of a dry thiophenol with sodium results in the evolution of hydrogen (cf. Alcohols, Section 9.5.3, p. 1223).

For derivative preparations for thiols see Section 9.6.25, p. 1283.

NITROGEN-CONTAINING COMPOUNDS
Those which are soluble in sodium hydroxide include aliphatic primary and secondary nitro compounds, oximes, imides and primary sulphonamides. Aliphatic primary and secondary nitro compounds dissolve in sodium hydroxide solution to give, in general, a yellow solution; on acidification with hydrochloric acid the nitro compound is regenerated. The nitro compounds show pronounced absorption due to the nitro group in the infrared at about 1530 and 1370 cm⁻¹ (NO₂, asymmetric and symmetric str.). The presence of the nitro group is confirmed by reduction to the corresponding hydroxylamine (see nitro compounds, Section 9.5.3, p. 1227), which can be detected by its action upon Tollens's reagent. To distinguish between primary, secondary and tertiary aliphatic nitro compounds (the latter are neutral) the following test should be performed. Dissolve a few drops of the nitro compound in concentrated sodium hydroxide solution, and add excess of sodium nitrite solution. Upon cautiously acidifying with dilute sulphuric acid, added a drop at a time, the following effects may be observed.

(a) Primary nitro compound: intense red colour, disappearing upon acidification. The coloration is that of the alkali salt of the nitrolic acid.

\[
\begin{align*}
R\cdot CH=NO^+ & \quad \rightarrow \quad R\cdot CH\cdot NO_2 \quad \rightleftharpoons \quad R\cdot C\cdot NO_2 \\
O & \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \ quad
For further characterisation of oximes, imides and primary sulphonamides see p. 1226 under the miscellaneous neutral and acidic compounds containing nitrogen.

### 9.5.2 BASIC COMPOUNDS

Organic compounds that dissolve in dilute hydrochloric acid usually contain nitrogen: the rarely encountered pyrones and anthocyanidin pigments are exceptions. The most important basic nitrogen compounds are the primary, secondary and tertiary amines.* The only hydrazines commonly encountered in the group are the monoaryl hydrazines, which are recognised by their ability to reduce Fehling’s solution with the evolution of hydrogen. They are also conveniently detected by their condensation with benzoaldehyde or some other suitable carbonyl compound as a reagent. The lower aliphatic amines and diamines are soluble in water and possess characteristic ammoniacal odours which distinguish them from water-insoluble amines. The reactions to be described below apply to both water-soluble and water-insoluble amines.

### PRIMARY, SECONDARY AND TERTIARY AMINES

Primary amines may be readily distinguished from secondary and tertiary analogues by the presence of two absorption bands in the infrared spectrum between 3320 and 3500 cm\(^{-1}\) (symmetric and antisymmetric NH str.). Secondary amines exhibit a single absorption band at about 3350 cm\(^{-1}\) (NH str.). In both cases deformation modes for the NH bond appear at about 1600 cm\(^{-1}\). There is no satisfactory absorption to allow a definitive characterisation in the case of tertiary amines. In the nuclear magnetic resonance spectrum of primary and secondary amines, the nitrogen-bound hydrogens are recognisable by their replaceability on the addition of deuterium oxide.

**Chemical classification of the amine function.** The classification of primary, secondary or tertiary amines should be carried out by means of the reaction with nitrous acid.

**Nitrous acid test.** Dissolve 0.2 g of the substance in 5 ml of 2 M hydrochloric acid: cool in ice and add 2 ml of ice-cold 10 per cent aqueous sodium nitrite solution slowly by means of a dropper and with stirring until, after standing for 3–4 minutes, an immediate positive test for nitrous acid is obtained with starch–iodide paper (see Section 6.7). If a clear solution is obtained with a continuous evolution of nitrogen gas the substance is a primary aliphatic or aralkyl amine. If there is apparently no evolution of nitrogen from the clear solution, add one-half of the solution to a cold solution of 0.4 g of 2-naphthol in 4 ml of 5 per cent sodium hydroxide solution. The formation of a coloured (e.g. orange-red) azo-dye indicates the presence of a primary aromatic amine; in which case warm the other half of the diazotised solution and note the evolution of nitrogen and the strong phenolic aroma which is produced. If a colourless solution is obtained which gives an immediate and sustained positive test with starch–iodide paper when only a little sodium nitrite solution has been added, the compound is a tertiary aliphatic amine.

---

* Many amines are regarded as being potentially carcinogenic: those which are on the restricted list have been specified in the Tables of Physical Constants.
The formation of \( N \)-nitrosamines* which usually separate as orange-yellow oils or low melting solids indicates the presence of a secondary amine. Confirm the formation of the nitrosamine by the Liebermann nitroso reaction. This consists in warming the nitrosamine with phenol and concentrated sulphuric acid. The sulphuric acid liberates nitrous acid from the nitrosamine, and the nitrous acid reacts with the phenol to form \( p \)-nitrosophenol, which then combines with another molecule of phenol to give red indophenol. In alkaline solution the red indophenol yields a blue indophenol anion.

\[
R_2N\cdot NO \xrightarrow{H_2SO_4} R_2NH + HONO \xrightarrow{PhOH} \text{HO} \xrightarrow{\text{PhOH}} \text{HO-} \xrightarrow{\text{O}^+} \text{O}^+ \xrightarrow{\text{PhOH}} \text{red} \xrightarrow{\text{blue}}
\]

Extract the oil obtained in the nitrous acid test with about 5 ml of ether and wash the extract successively with water, dilute sodium hydroxide and water, and evaporate off the ether. Apply Liebermann’s nitroso reaction to the residual oil or solid. Place 1 drop of 0.01–0.02 g of the nitroso compound in a dry test tube, add 0.05 g of phenol and warm together for 20 seconds; cool, and add 1 ml of concentrated sulphuric acid. An intense green (or greenish-blue) coloration will be developed, which changes to pale red upon pouring into 30–50 ml of cold water; the colour becomes deep blue or green upon adding excess of sodium hydroxide solution.

If the unknown base is a tertiary aromatic amine the treatment with nitrous acid will yield a dark orange-red solution or an orange crystalline precipitate resulting from the formation of the hydrochloride of the \( C \)-nitrosamine. Basification of the solution or of the isolated orange precipitate with either sodium hydroxide or carbonate solution yields the bright green nitrosamine base. In favourable cases this may be isolated by extraction with ether, recrystallised and used for characterisation purposes (see p. 1278).

**Confirmatory tests for primary amines. Carbylamine test.** To 1 ml of 0.5 M-alcoholic potassium hydroxide solution (or to a solution prepared by dissolving a fragment of potassium hydroxide half the size of a pea in 1 ml of ethanol) add 0.05–0.1 g of the amine and 3 drops of chloroform, and heat to boiling. A carbylamine (isocyanide) is formed and will be readily identified by its extremely nauseating odour (CAUTION):

\[
R\text{NH}_2 + \text{CHCl}_3 + 3\text{KOH} \rightarrow R\text{NC} + 3\text{KCl} + 3\text{H}_2\text{O}
\]

When the reaction is over, add concentrated hydrochloric acid to decompose the isocyanide and pour it away after the odour is no longer discernible. The test is extremely delicate and will often detect traces of primary amines in secondary and tertiary amines; it must therefore be used with due regard to this and other factors.

**5-Nitrosalicylaldehyde reagent test.** This test is based upon the fact that 5-nitrosalicylaldehyde and nickel ions when added to a primary amine produce an immediate precipitate of the nickel derivative of the Schiff’s base.

* Potentially carcinogenic, see Section 2.3.4, p. 49.
To 5 ml of water add 1–2 drops of the amine; if the amine does not dissolve, add a drop or two of concentrated hydrochloric acid. Add 0.5–1 ml of this amine solution to 2–3 ml of the reagent; an almost immediate precipitate indicates the presence of a primary amine. A slight turbidity indicates the presence of a primary amine as an impurity. (Primary aromatic amines generally require 2–3 minutes for the test. Urea and other amides, as well as amino acids, do not react.)

The 5-nitrosalicylaldehyde reagent is prepared as follows. Add 0.5 g of 5-nitrosalicylaldehyde (m.p. 124–125 °C) to 15 ml of pure triethanolamine and 25 ml of water; shake until dissolved. Then introduce 0.5 g of crystallised nickel(II) chloride dissolved in a few ml of water, and dilute to 100 ml with water. If the triethanolamine contains some ethanolamine (thus causing a precipitate), it may be necessary to add a further 0.5 g of the aldehyde and to filter off the resulting precipitate. The reagent is stable for long periods.

Rimini's test (for primary aliphatic amines). To a suspension or solution of 1 drop of the compound or to an equivalent quantity of its solution in 3 ml of water, add 1 ml of pure acetone and 1 drop of a freshly prepared 1 per cent aqueous solution of disodium pentacyanonitrosoferrate(III) (nitroprusside). A violet-red colour will develop within 1 minute.

Confirmatory tests for secondary aliphatic amines. Simon's test. To a solution or suspension of 1 drop of the compound or to an equivalent quantity of its solution in 3 ml of water, add 2 drops of freshly prepared acetaldehyde solution, followed by 1 drop of a 1 per cent aqueous solution of disodium pentacyanonitrosoferrate(III). A blue coloration is produced within 5 minutes, after which the colour gradually changes through greenish-blue to yellow.

Carbon disulphide reagent test. This test is based upon the formation from a secondary amine and carbon disulphide of a dialkyldithiocarbamate; the latter readily forms a nickel derivative with a solution of a nickel salt:

\[
\begin{align*}
R_2NH + CS_2 & \xrightarrow{NH_3} R_2N\cdot C=S \xrightarrow{NiCl_2} \left( R_2N\cdot C=S \right)_2Ni
\end{align*}
\]

To 5 ml of water add 1–2 drops of the secondary amine; if it does not dissolve, add a drop or two of concentrated hydrochloric acid. Place 1 ml of the reagent in a test tube, add 0.5–1 ml of concentrated ammonia solution, followed by 0.5–

1 ml of the above amine solution. A precipitate indicates a secondary amine. A slight turbidity points to the presence of a secondary amine as an impurity. The test is very sensitive; it is not given by primary amines.

The carbon disulphide reagent is prepared by adding to a solution of 0.5 g crystallised nickel(II) chloride in 100 ml of water enough carbon disulphide so that after shaking a globule of carbon disulphide is left at the bottom of the bottle. The reagent is stable for long periods in a well-stoppered bottle. If all the carbon disulphide evaporates, more must be added (CAUTION).

It should be noted that aliphatic and aromatic primary and secondary amines may be distinguished from tertiary amines by their reaction with acetyl chloride, benzoyl chloride and benzenesulphonyl chloride. In the latter case a primary amine yields an alkali-soluble derivative which distinguishes it from a secondary amine when the derivative is neutral and insoluble in acid and alkali.
The separation of primary, secondary and tertiary amines using toluene-\(p\)-
sulphonyl chloride (Hinsberg’s method) is described in Section 9.7.

For the preparation of derivatives of primary, secondary and tertiary amines
see Sections 9.6.21, and 9.6.22.

9.5.3 NEUTRAL COMPOUNDS

COMPOUNDS CONTAINING CARBON, HYDROGEN AND POSSIBLY OXYGEN

It is convenient to consider the indifferent or neutral oxygen derivatives of the
hydrocarbons – (a) aldehydes and ketones, (b) esters and anhydrides, (c) alcohols
and ethers – together. All of these, with the exception of the water-soluble
members of low molecular weight, are soluble only in concentrated sulphuric
acid, as are alkenes and readily sulphonated arenes. The above classes of com-
 pounds must be tested for in the order in which they are listed, otherwise
 erroneous conclusions may be drawn from the reactions for the functional group
 about to be described.

ALDEHYDES AND KETONES

These compounds contain the carbonyl group, hence a general test for carbonyl
compounds will immediately identify both classes of compounds. The preferred
reagent is 2,4-dinitrophenylhydrazine, which gives sparingly soluble dinitrophen-
ethylhydrazones with carbonyl compounds (including many quinones). Add 2
drops or 0.05–0.1 g of the substance to be tested to 3 ml of 2,4-dinitrophenylhyd-
razine reagent, and shake. If no precipitate forms immediately allow to stand for
5–10 minutes. A crystalline precipitate indicates the presence of a carbonyl com-
pound. Occasionally the precipitate is oily at first, but this becomes crystalline
upon standing.

2,4-Dinitrophenylhydrazine reagent may be prepared by either of the follow-
ing methods.

1. Suspend 2.0 g. of 2,4-dinitrophenylhydrazine in 100 ml of methanol; add cau-
tiously and slowly 4.0 ml of concentrated sulphuric acid. The mixture
becomes warm and the solid usually dissolves completely. Filter, if necessary.

2. Dissolve 0.25 g of 2,4-dinitrophenylhydrazine in a mixture of 42 ml of concen-
trated hydrochloric acid and 50 ml of water by warming on a water bath:
dilute the cold solution to 250 ml with distilled water. This reagent is more
suitable for water-soluble aldehydes and ketones since alcohol is absent.

The above reagent is very dilute and is intended for qualitative reactions. It is
hardly suitable for the preparation of crystalline derivatives except in very small
quantities (compare Section 9.6.13, p. 1257).

The acetals \(R^1\cdot CH(OR^2)_2\) are so readily hydrolysed by acids that they may
give a positive result in the above test:

\[
R^1\cdot CH(OR^2)_2 + H_2O \xrightarrow{H^+} R^1\cdot CHO + 2R^2\cdot OH
\]

(For a more detailed discussion on Acetals, see Section 9.6.12, p. 1257).

If the unknown compound gives a positive test with 2,4-dinitrophenylhydra-
zine it then becomes necessary to decide whether it is an aldehyde or a ketone.
The infrared spectrum of the compound should be very informative; both alde-
hydes and ketones show strong absorption at 1740–1700 cm\(^{-1}\) (C\(=\)O str.), but
only aldehydes exhibit two absorption bands at about 2720 and 2820 cm\(^{-1}\)
(C—H str.). In the nuclear magnetic resonance spectrum of an aldehyde a low-field signal for the aldehydic hydrogen (δ 9–10) is characteristic.

**Chemical differentiation between aldehydes and ketones. Schiff’s reagent.** Aldehydes produces a pink colour, while ketones are without effect. Use 2 drops (or 0.05 g) of the compound and 2 ml of Schiff’s reagent and shake the mixture in the cold. Some aromatic aldehydes (e.g. vanillin) give a negative result.

The reagent may be prepared by either of the following methods.

1. Dissolve 0.2 g of pure p-rosaniline hydrochloride in 20 ml of a cold, freshly prepared, saturated aqueous solution of sulphur dioxide; allow the solution to stand for a few hours until it becomes colourless or pale yellow. Dilute the solution of 200 ml and keep it in a tightly stoppered bottle. If the bottle is not adequately stoppered, the reagent will gradually lose sulphur dioxide and the colour will return. The solution keeps well if not unnecessarily exposed to light and air.

2. Add 2 g of sodium metabisulphite to a solution of 0.2 g of p-rosaniline hydrochloride and 2 ml of concentrated hydrochloric acid in 200 ml of water.

By way of caution it should be noted that free alkali or the alkali salts of weak acids will redden the reagent like an aldehyde. It is also, of course, reddened by heat or when exposed in small quantities to the air for some time. Mineral acids greatly reduce the sensitivity of the test.

**Ammoniacal silver nitrate solution (Tollen’s solution).** Aldehydes alone reduce Tollen’s reagent and produce a silver mirror on the inside of the test tube. Add 2–3 drops (or 0.05 g) of the compound to 2–3 ml of Tollen’s solution contained in a clean test tube (the latter is preferably cleaned with hot nitric acid). If no reaction appears to take place in the cold, warm in a beaker of hot water. (CAUTION: After the test, pour the contents of the test tube into the sink and wash the test tube with dilute nitric acid. Any silver fulminate present, which is highly explosive when dry, will thus be destroyed.)

Tollen’s reagent is prepared as follows: Dissolve 3 g of silver nitrate in 30 ml of water (solution A) and 3 g of sodium hydroxide in 30 ml of water (solution B). When the reagent is required, mix equal volumes (say, 1 ml) of solutions A and B in a clean test tube, and add dilute ammonia solution drop by drop until the silver oxide is just dissolved. Great care must be taken in the preparation and use of this reagent, which must not be heated. Only a small volume should be prepared just before use, any residue washed down the sink with a large quantity of water, and the test tubes rinsed with dilute nitric acid.

**Fehling’s solution.** Aldehydes alone reduce Fehling’s solution to yellow or red copper(II) oxide. Use 2 drops (or 0.05 g) of the compound and 2–3 ml of Fehling’s solution; heat on a boiling water bath for 3–4 minutes. This test is positive for aliphatic aldehydes, but is often indecisive for aromatic aldehydes.

Preparation of Fehling’s solution. Solution No. 1. Dissolve 34.64 g of copper(II) sulphate crystals in water containing a few drops of dilute sulphuric acid, and dilute the solution to 500 ml.

Solution No. 2. Dissolve 60 g of pure sodium hydroxide and 173 g of pure Rochelle salt (sodium potassium tartrate) in water, filter if necessary through a sintered glass funnel and make up the filtrate and washings to 500 ml.

Keep the two solutions separately in tightly stoppered bottles and mix exactly equal volumes immediately before use.
Further classification tests for aldehydes and ketones. Sodium metabisulphite test. Aldehydes and simple ketones react with a saturated solution of sodium metabisulphite to yield crystalline bisulphite-addition compounds:

\[ R^1R^2\text{CO} + \text{NaHSO}_3 \rightleftharpoons R^1R^2\text{C(OH)SO}_3\text{Na} \]

A condition of equilibrium is reached (70-90 per cent of bisulphite compound with equivalent quantities of the reagents in 1 hour), but by using a large excess of bisulphite almost complete conversion into the addition compound results. Since the reaction is reversible, the carbonyl compound can be recovered by adding to an aqueous solution of the bisulphite compound sufficient sodium carbonate solution or hydrochloric acid to react with the free sodium metabisulphite present in the equilibrium mixture. Bisulphite compounds may therefore be employed for the purification of carbonyl compounds or for their separation from other organic substances.

The most satisfactory reagent is a saturated solution of sodium metabisulphite containing ethanol; it must be prepared as required since it oxides and decomposes on keeping. Frequently, a saturated aqueous solution is used without the addition of ethanol.

Prepare 10 ml of saturated sodium metabisulphite solution and add 4 ml of the carbonyl compound; shake thoroughly and observe the rise in temperature. Filter the crystalline precipitate at the pump, wash it with a little alcohol, followed by ether and allow it to dry. The sodium metabisulphite reagent is prepared by treating a saturated aqueous solution of sodium metabisulphite with 70 per cent of its volume of industrial spirit, and then adding just sufficient water to produce a clear solution.

Iodoform test. Methyl ketones and acetaldehyde, i.e. compounds containing the Me-\text{CO—} grouping, give a positive iodoform reaction. Alcohols having the structure Me-\text{CH(OH)}-R, which undergo oxidation to the corresponding methyl ketone, also slowly give a positive test. Dissolve 0.1 g or 4–5 drops of the compound in 2 ml of water; if it is insoluble in water, add sufficient dioxane to produce a homogeneous solution. Add 2 ml of 5 per cent sodium hydroxide solution and then introduce a potassium iodide–iodine reagent dropwise with shaking until a definite dark colour of iodine persists. Allow to stand for 2–3 minutes; if no iodoform separates at room temperature, warm the test tube in a beaker of water at 60 °C. Add more drops of the iodine reagent if the faint iodine colour disappears: continue the addition of the reagent until the dark colour is not discharged after 2 minutes heating at 60 °C. Remove the excess of iodine by the addition of a few drops of dilute sodium hydroxide solution with shaking, dilute with an equal volume of water and allow to stand for 10–15 minutes. The test is positive if a yellow precipitate of iodoform is deposited. Filter off the yellow precipitate, dry upon pads of filter paper and determine the m.p.: iodoform melts at 120 °C.

The potassium iodide–iodine reagent is prepared by dissolving 20 g of potassium iodide and 10 g of iodine in 100 ml of water.

For the preparation of derivatives of aldehydes and ketones see Section 9.6.13, p. 1257.

**QUINONES**

The following tests will be found useful for the detection of simple quinones.
Quinones are coloured (generally yellow) crystalline solids; they are usually insoluble in water, soluble in ether and sublime on heating. Frequently the vapour has a penetrating odour and attacks the eyes. The carbonyl groups of quinones often do not react in a normal way with carbonyl group reagents, because of their oxidising properties: thus quinones are reduced by sodium metabisulphite. Crystalline products are usually formed with one molecule of phenylhydrazine or with one molecule of 2,4-dinitrophenylhydrazine, but these are not always of normal structure. Thus p-benzoquinone reacts with 2,4-dinitrophenylhydrazine hydrochloride in hot alcoholic solution to give 2',4'-dinitrophenyl-4-azophenol, m.p. 185–186 °C.

\[
(\text{NO}_2)_2\text{C}_6\text{H}_3\cdot\text{NH}\cdot\text{NH}_2 + \text{O} = \text{O} \xrightarrow{\text{H}_2\text{O}} (\text{NO}_2)_2\text{C}_6\text{H}_4\cdot\text{N} = \text{N} \cdot\text{C}_6\text{H}_4\text{OH}
\]

Tests for quinones **Hydriodic acid.** Compounds of the p-benzoquinone type liberate iodine from hydriodic acid. Dissolve 0.1 g. of the quinone in a little rectified spirit. Add 10 ml of 10 per cent aqueous potassium iodide solution to a mixture of 5 ml of ethanol and 5 ml of concentrated hydrochloric acid, and then introduce the quinone solution. Iodine is liberated immediately. This test is also given by other oxidising agents.

**Reduction with zinc powder and acid.** Simple p-quinones are reduced to hydroquinones in the following manner. Dissolve or suspend 0.5 g of the quinone in dilute hydrochloric acid (1:5) and add a little zinc powder. When the solution is colourless, filter, neutralise with sodium hydrogen carbonate, extract the dihydric phenol with ether, remove the solvent and identify (Section 9.6.6, p. 1248).

**Reduction with zinc powder and sodium hydroxide.** Compounds of the anthraquinone type are reduced to oxanthrols. Treat 0.1 g of the quinone with dilute sodium hydroxide and zinc powder. Upon boiling the mixture a red colour is produced; this disappears when the solution is shaken owing to aerial oxidation to the original quinone.

**Distillation with zinc powder.** Quinones derived from polycyclic hydrocarbons may be reduced to the parent hydrocarbon as follows. Grind 0.5 g of the compound with 3–4 g of zinc powder, pour the mixture into a Pyrex test tube and cover it with an equal volume of zinc powder. Clamp the tube horizontally at the open end. Heat the zinc powder first, then the mixture of zinc powder and the compound to a dull red heat: the hydrocarbon sublimes into the cooler part of the tube. Remove the sublimate; determine the m.p. and characterise it by the preparation of the picrate (Section 9.6.3, p. 1238).

**Reaction with semicarbazide hydrochloride.** Many simple quinones yield crystalline mono-semicarbazones by the following procedure. Dissolve 0.2 g of semicarbazide hydrochloride in a little water, add 0.2 g of the quinone and warm. The mono-semicarbazone is immediately formed as a yellow precipitate. Filter and recrystallise from hot water; any bis-semicarbazone will remain undissolved.

**Reaction with o-phenylenediamine.** o-Quinones (and also aromatic α-diketones, e.g. benzil) react with o-phenylenediamine to yield quinoxalines. Dissolve the substance in ethanol or glacial acetic acid, add an equivalent amount of o-
phenylenediamine in ethanolic solution and warm for 15 minutes on a water bath. Cool, dilute with water, filter and recrystallise from dilute ethanol.

For the preparation of derivatives of quinones see Section 9.6.14, p. 1261.

ESTERS AND ACID ANHYDRIDES
When a compound fails to respond to the 2,4-dinitrophenylhydrazine test for aldehydes and ketones, yet exhibits carbonyl absorption in the infrared region, it may be either an ester, an acid anhydride or, possibly, a lactone. The infrared absorption for esters is in the region of 1750–1730 cm⁻¹ (C=O str.) and in the region 1000–1300 cm⁻¹ (C—O str.). Anhydrides exhibit two absorption bands at about 1820 and 1750 cm⁻¹ (C=O str.) together with absorption in the range of 1100–1200 (C—O str.). Lactones absorb at about 1750 cm⁻¹ (C=O str., the frequency depends upon the ring size), and in the range 1000–1300 cm⁻¹ (C—O str.).

The presence of any of these functional types may be established chemically by applying the hydroxamic acid test. These compounds react with hydroxylamine in the presence of sodium hydroxide to form the sodium salt of the corresponding hydroxamic acid. On acidification and addition of iron(III) chloride solution the magenta coloured iron(III) complex of the hydroxamic acid is formed.

$$R^1\cdot CO_2R^2 + H_2NOH \underset{\Theta \text{OH}}{\rightarrow} R^1\cdot CO\cdot NHOH + R^2OH$$

$$R^1\cdot CO\cdot O\cdot CO\cdot R^1 + H_2NOH \underset{\Theta \text{OH}}{\rightarrow} R^1\cdot CO\cdot NHOH + R^1\cdot CO_2H$$

The hydroxamic acid test is also given by acid chlorides and some primary aliphatic amides which are readily converted by hydroxylamine hydrochloride into hydroxamic acids. Some esters, mainly of carbonic, carbamic, sulphuric and other inorganic acids, give only a yellow colour.

It is always advisable to ensure that the sample does not give a colour with iron(III) chloride before carrying out the hydroxamic acid test.

Hydroxamic acid test. A. Dissolve a drop or a few small crystals of the compound in 1 ml of rectified spirit (95% ethanol) and add 1 ml of m hydrochloric acid. Note the colour produced when 1 drop of 5 per cent iron(III) chloride solution is added to the solution. If a pronounced violet, blue, red or orange colour is produced, the hydroxamic acid test described below is not applicable and should not be used.

B. Mix 1 drop or several small crystals (c. 0.05 g) of the compound with 1 ml of 0.5 m hydroxylamine hydrochloride in 95 per cent ethanol and add 0.2 ml of 6 m aqueous sodium hydroxide. Heat the mixture to boiling and, after the solution has cooled slightly, add 2 ml of m hydrochloric acid. If the solution is cloudy, add 2 ml of 95 per cent ethanol. Observe the colour produced when 1 drop of 5 per cent iron(III) chloride solution is added. If the resulting colour does not persist, continue to add the reagent dropwise until the observed colour pervades the entire solution. Usually only 1 drop of the iron(III) chloride solu-
tion is necessary. Compare the colour with that produced in test A. A positive test will be a distinct burgundy or magenta colour as compared with the yellow colour observed when the original compound is tested with iron(III) chloride solution in the presence of acid. It is often advisable to conduct in parallel the test with, say, ethyl acetate, to ensure that the conditions for this test are correct.

**Differentiation between esters and anhydrides.** The following simple test relies on the fact that hydrolysis of acid anhydrides is more rapid than that of esters under basic conditions. Add 1 ml of the compound to 2 ml of water to which has been added 1 drop of 1 M sodium hydroxide solution and a trace of phenolphthalein indicator. Warm the solution gently on a water bath; with anhydrides the pink colour is discharged within about 1 minute and the further dropwise addition of alkali enables the rate of hydrolysis to be monitored. With most esters hydrolysis is very slow under these conditions. For the preparation of derivatives of esters and anhydrides see Sections 9.6.17, p. 1266 and 9.6.16, p. 1265 respectively.

**ALCOHOLS AND ETHERS**

If the unknown, neutral, oxygen-containing compound does not give the class reactions for aldehydes, ketones, esters and anhydrides, it is probably either an alcohol or an ether. Alcohols are readily identified by the intense characteristic hydroxyl adsorption which occurs as a broad band in the infrared spectrum at 3600–3300 cm⁻¹ (O-H str.). In the nuclear magnetic resonance spectrum, the adsorption by the proton in the hydroxyl group gives rise to a broad peak the chemical shift of which is rather variable; the peak disappears on deuteration.

Chemically, alcohols and ethers may be simply distinguished by the use of two reagents – metallic sodium and acetyl chloride.

**Reaction with sodium.** Metallic sodium reacts with alcohols with the evolution of hydrogen.

\[ 2\text{ROH} + 2\text{Na} \rightarrow 2\text{RO}^-\text{Na}^+ + \text{H}_2 \]

The most common interfering substance, especially with alcohols of low molecular weight, is water; this may result in an inaccurate interpretation of the test if applied alone. Most of the water may usually be removed by shaking with a little anhydrous calcium sulphate. Dry ethers (and also the saturated aliphatic and the simple aromatic hydrocarbons) do not react with sodium. Treat 1.0 ml of the dried compound with a small thin slice of freshly cut sodium (handle with the tongs or with a penknife) in a small dry test tube. Observe whether hydrogen is evolved and the sodium reacts.

**The acetyl chloride test.** Acetyl chloride reacts vigorously with primary and secondary alcohols with the evolution of hydrogen chloride. Ethers are unaffected by acetyl chloride. In a small dry test tube place 0.5 ml of the dried compound with 0.3–0.4 ml of redistilled acetyl chloride and note whether reaction occurs. Add 3 ml of water and neutralise the aqueous layer with solid sodium hydrogen carbonate and note whether the smell of the products is different from that of the original alcohol. The product in the case of a tertiary alcohol is mainly the alkyl chloride.

**Differentiation between primary, secondary and tertiary alcohols.** The three classes of alcohols differ in their behaviour on oxidation with hot acidic dichromate solution. Primary alcohols yield aldehydes and secondary alcohols...
yield ketones; these products are readily distinguishable. Tertiary alcohols yield no carbonyl product under the conditions of the reaction; experimental details are given in Section 9.6.4, p. 1241.

For the preparation of derivatives of alcohols and ethers see Section 9.6.4, p. 1241 and Sections 9.6.10, p. 1254, and 9.6.11, p. 1255 respectively.

**POLYHYDRIC ALCOHOLS AND CARBOHYDRATES**

If the neutral substance containing carbon, hydrogen and possibly oxygen is insoluble in ether but freely soluble in water, a polyhydric alcohol or a simple mono- or di-saccharide (or related compound) is indicated. Treatment with concentrated sulphuric acid usually produces excessive charring.

*Polyhydric alcohols* are colourless viscous liquids, or crystalline solids. Upon heating with a little potassium hydrogen sulphate, they may yield aldehydes (e.g. ethylene glycol yields acetaldehyde; glycerol gives the irritating odour of acrolein which can additionally be detected with Schiff’s reagent). Two confirmatory tests for polyhydric alcohols are as follows.

**Boric acid test.** Add a few drops of phenolphthalein to a 1 per cent solution of borax; a pink coloration is produced. The addition of the polyhydric alcohol causes the pink colour to disappear, but it reappears on warming and vanishes again on cooling. This reaction is due to the combination of two *cis*-hydroxyl groups of the compound with boric acid to form reversibly a much stronger monobasic acid.

\[
\begin{align*}
\text{C} & \text{OH} \quad \text{HO} \quad \text{HO} \quad \text{B} \quad \text{OH} \\
\text{C} & \text{OH} \\
\end{align*}
\]  

\[
\begin{align*}
\text{HO}-\text{C} & \quad \xrightarrow{\text{H}_2\text{O}} \quad \left[ \begin{array}{c}
\text{C} \quad \text{O} \\
\text{C} \quad \text{O} \\
\end{array} \right] \\
\text{HO} & \text{C} \\
\end{align*}
\]

**Periodic acid test.** (For 1,2-glycols and *α*-hydroxylaldehydes and ketones, Section 4.2.55, p. 454). Add 1 drop (0.05 ml) of concentrated nitric acid to 2.0 ml of a 0.5 per cent aqueous solution of paraperiodic acid (H$_2$IO$_6$) contained in a small test tube and shake well. Then introduce 1 drop or a small crystal of the compound. Shake the mixture for 15 seconds and add 1–2 drops of 5 per cent aqueous silver nitrate. The immediate production of a *white* precipitate (silver iodate) constitutes a positive test and indicates that the organic compound has been oxidised by the periodic acid. The test is based upon the fact that silver iodate is sparingly soluble in dilute nitric acid whereas silver periodate is very soluble: if too much nitric acid is present the silver iodate will not precipitate.

An alternative procedure for the above test is as follows. Mix 2–3 ml of 2 per cent aqueous paraperiodic acid solution with 1 drop of dilute sulphuric acid (c. 1.25 m) and add 20–30 mg of the compound. Shake the mixture for 5 minutes, and then pass sulphur dioxide through the solution until it acquires a pale yellow colour (to remove the excess of periodic acid and also iodic acid formed in the reaction). Add 1–2 ml of Schiff’s reagent: the production of a violet colour constitutes a positive test.

For the preparation of derivatives of polyhydric alcohols see under *Alcohols and polyhydric alcohols*, Section 9.6.4, p. 1241.

*Mono- and di-saccharides* are colourless solids or syrupy liquids, which are freely soluble in water, practically insoluble in ether and other organic solvents, and neutral in reaction. Polysaccharides possess similar properties, but are
generally insoluble in water because of their high molecular weights. Both poly-
and di-saccharides are converted into monosaccharides upon hydrolysis. The
following are confirmatory tests for carbohydrates.

**Molisch's test.** This is a general test for carbohydrates. Place 5 mg of the
substance in a test tube containing 0.5 ml of water and mix it with 2 drops of a 10 per
cent solution of 2-naphthol in ethanol or in chloroform. Allow 1 ml of concen-
trated sulphuric acid to flow down the side of the inclined tube (it is best to use a
dropper pipette) so that the acid forms a layer beneath the aqueous solution
without mixing with it. If a carbohydrate is present, a red ring appears at the
common surface of the liquids; the colour quickly changes on standing or
shaking, a dark purple solution being formed. Shake and allow the mixture to
stand for 2 minutes, then dilute with 5 ml of water. In the presence of a carbo-
hydrate, a dull-violet precipitate will appear immediately.

**Barfoed’s reagent.** This reagent may be used as a general test for monosacchar-
ides. Heat a test tube containing 1 ml of the reagent and 1 ml of a dilute solution
of the carbohydrate in a beaker of boiling water. If red copper(I) oxide is formed
within 2 minutes, a monosaccharide is present. Disaccharides on prolonged
heating (about 10 minutes) may also cause reduction, owing to partial hydroly-
sis to monosaccharides.

The reagent is prepared by dissolving 13.3 g of crystallised neutral copper(II)
acetate in 200 ml of 1 per cent acetic acid solution. The reagent does not keep
well.

**Fehling's solution** (test for reducing sugars). Place 5 ml of Fehling’s solution
(prepared by mixing equal volumes of Fehling’s solution No. 1 and solution No.
2) in a test tube and heat to gentle boiling. Add a solution of 0.1 g of the carbo-
hydrate in 2 ml of water and continue to boil gently for a minute or two, and
observe the result. A yellow or red precipitate of copper(I) oxide indicates the
presence of a reducing sugar. An alternative method of carrying out the test is to
add the hot Fehling’s solution dropwise to the boiling solution of the carbo-
hydrate; in the presence of a reducing sugar the blue colour will disappear and a
yellow precipitate, changing to red, is thrown down.

**Benedict’s solution.** This is a modification of Fehling’s solution and consists of a
single test solution which does not deteriorate appreciably on standing. To 5 ml
of Benedict’s solution add 0.4 ml of a 2 per cent solution of the carbohydrate,
boil for 2 minutes and allow to cool spontaneously. If no reducing sugar is
present, the solution remains clear; in the presence of a reducing sugar, the solu-
tion will contain copper(I) oxide. The test may also be carried out according to
the experimental details given under *Fehling’s solution*.

The reagent is prepared as follows. Dissolve 86.5 g of crystallised sodium
citrate (2Na₃C₆H₅O₇·11H₂O) and 50 g of anhydrous sodium carbonate in
about 350 ml of water. Filter, if necessary. Add a solution of 8.65 g of crystallised
copper(II) sulphate in 50 ml of water with constant stirring. Dilute to 500 ml. The
resulting solution should be perfectly clear; if it is not, pour it through a fluted
filter paper.

Non-reducing sugars may be hydrolysed by boiling with dilute hydrochloric acid; if the solution is then neutralised with aqueous sodium hydroxide the
reduction of Fehling’s solution or Benedict’s solution occurs readily.
For the preparation of derivatives of mono- and di-saccharides see Section 9.6.5, p. 1245.

HYDROCARBONS

Hydrocarbons may be differentiated by their solubility in sulphuric acid since unsaturated hydrocarbons are soluble in concentrated sulphuric acid as are those arenes which are readily sulphonated, whereas the saturated alkanes and lesser reactive arenes are insoluble in this reagent. The presence of an alkene, alkyne or arene is usually readily apparent from an inspection of the infrared and nuclear magnetic resonance spectra, the characteristic features of which are fully discussed in Sections 5.2., 5.3 and 6.1 respectively and in Chapter 3.

The two tests employed for the detection of unsaturation are decolourisation of a dilute solution of bromine in dichloromethane, and reaction with dilute aqueous potassium permanganate. It is essential to apply both tests since some symmetrically substituted alkenes (e.g. stilbene, \( \text{C}_6\text{H}_5\text{CH}═\text{CH}\cdot\text{C}_6\text{H}_5 \)) react only slowly under the conditions of the bromine test. With dilute potassium permanganate solution the double bond is readily attacked, probably through the intermediate formation of a cis-diol.

\[
\text{Ph}•\text{CH}═\text{CH}•\text{Ph} \xrightarrow{[\text{O}]_{\text{H}_2\text{O}}} \text{Ph}•\text{CH(OH)}•\text{CH(OH)}•\text{Ph} \rightarrow 2\text{Ph}•\text{CO}_2\text{H}
\]

**Bromine test.** Dissolve 0.2 g or 0.2 ml of the compound in 2 ml of dichloromethane, and add a 2 per cent solution of bromine in dichloromethane dropwise until the bromine colour persists for one minute. Blow across the mouth of the tube to detect any hydrogen bromide which may be evolved.

**Potassium permanganate test.** Dissolve 0.2 g or 0.2 ml of the substance in 2 ml of water or in 2 ml of acetone (which gives a negative test with the reagent), and add 2 per cent potassium permanganate solution dropwise. The test is negative if no more than 3 drops of the reagent are decolourised.

**Differentiation between alkanes and aromatic hydrocarbons.** The most satisfactory reagent is fuming sulphuric acid. Place 2 ml of 20 per cent fuming sulphuric acid in a dry test tube, add 0.5 ml of the hydrocarbon and shake vigorously. Only the aromatic hydrocarbon dissolves completely, heat is evolved, but excessive charring should be absent. Warm the solution gently, cool and pour cautiously on to crushed ice; the aromatic hydrocarbon which undergoes sulphonation gives a homogeneous aqueous solution.

For the preparation of derivatives and for further characterisation of alkanes, alkenes, alkynes and arenes see Sections 9.6.1, p. 1235, 9.6.2, p. 1235, and 9.6.3, p. 1238 respectively.

**COMPOUNDS CONTAINING NITROGEN**

The neutral nitrogen compounds include: tertiary aliphatic nitro compounds and aromatic nitro compounds; amides (simple and substituted); nitrogen derivatives of aldehydes and ketones (hydrazones, semicarbazones, etc.); nitriles; nitroso, azo, hydrazo and other intermediate reduction products of aromatic nitro compounds. The imides, primary and secondary nitro compounds, oximes and primary sulphonamides are weakly acidic nitrogen compounds. All the above nitrogen compounds and also the secondary sulphonamides, with few
exceptions, respond to the same classification reactions (reduction and hydrolysis) and hence will be considered together (experimental procedures below).

α-Amino acids are appreciably water-soluble giving solutions which are essentially neutral towards indicator paper. Water-insoluble α-amino acids are readily soluble in both dilute alkali and dilute acid as the result of their amphoteric character.

In most instances, confirmation of the presence of any of the above functional groups may be obtained from a consideration of the spectroscopic properties of the compound.

Nitro compounds and their reduction products. Tertiary aliphatic nitro compounds and aromatic nitro compounds are reduced by zinc and ammonium chloride solution to the corresponding hydroxylamines, which may be detected by their reducing action upon an ammoniacal solution of silver nitrate or Tollen's reagent:

\[ R \cdot NO_2 + 4[H] \xrightarrow{Zn, NH_4Cl aq.} R \cdot NHOH + H_2O \]

It must be remembered, however, that nitroso, azoxy and azo compounds (which are usually more highly coloured than nitro compounds) may be reduced by zinc powder to the corresponding hydroxylamine, hydrazo and hydrazine compounds respectively, all of which reduce Tollen's reagent in the cold.

Nitro compounds are reduced in acid solution (for example, by tin and hydrochloric acid) to the corresponding primary amines.

\[ R \cdot NO_2 + 6[H] \rightarrow R\cdot NH_2 + 2H_2O \]

Nitrosamines are similarly reduced to secondary amines:

\[ R_2N \cdot NO + 6[H] \rightarrow R_2NH + NH_3 + H_2O \]

The N-nitrosamines (and some C-nitroso compounds that yield nitrous acid when treated with concentrated sulphuric acid) may be detected by Liebermann's reaction (p. 1216).

Azo compounds may be identified by examination of the amine(s) formed on reduction in acid solution.

\[ R^1 \cdot N\equiv-N \cdot R^2 + 4[H] \rightarrow R^1 \cdot NH_2 + H_2NR^2 \]

They are always coloured but give colourless products upon reduction. Hydrazo and azoxy compounds are reduced in acid solution to the parent amine.

Amides. Simple (primary) amides when warmed with dilute sodium hydroxide solution give ammonia readily, together with the salt of the corresponding acid:

\[ R \cdot CONH_2 + H_2O \rightarrow R \cdot CO_2H + NH_3 \]

Complete hydrolysis may be effected by boiling either with 10 per cent sodium hydroxide solution or with 10 per cent sulphuric acid for 1–3 hours. It is preferable to employ the non-volatile sulphuric acid for acid hydrolysis; this acid should also be used for acidification of the solution resulting from alkaline hydrolysis so that any volatile organic acid (formic acid, acetic acid, etc.) may be distilled off.

Substitute amides undergo hydrolysis with greater difficulty. The choice of an acid or an alkaline medium will depend upon the solubility of the compound in
the medium, and the effect of the reagent upon the products of hydrolysis. Substituted amides of comparatively low molecular weight (e.g. acetonilide) may be hydrolysed by boiling either with 10 per cent sodium hydroxide solution or with 10 per cent sulphuric acid for 2–3 hours. Other substituted amides are so insoluble in water that little reaction occurs when they are refluxed with dilute acid or dilute alkali for several hours. These include such substances as benzanilide or the benzotoluidides. For these substances satisfactory results may be obtained with 70 per cent sulphuric acid*: this hydrolysis medium is a much better solvent for the substituted amide than is water or more dilute acid; it also permits a higher reaction temperature.

\[ R'\cdot\text{CONHR}^2 + H_2O \xrightarrow{\text{HSO}_4^-} R'\cdot\text{CO}_2H + R^2\cdot\text{NH}_3\text{HSO}_4^- \]

**Nitriles.** These are best hydrolysed by boiling either with 30–40 per cent sodium hydroxide solution or with 50–70 per cent sulphuric acid during several hours, but the reaction takes place less readily than for primary amides. Indeed the latter are intermediate products in the hydrolysis:

\[ R\cdot\text{CN} + H_2O \xrightarrow{\text{OH}} R\cdot\text{CONH}_2 \xrightarrow{\text{OH}} R\cdot\text{CO}_2^- + NH_3 \]

Nitriles and simple amides differ in physical properties: the former are liquids or low-melting solids, while the latter are generally solids. If the amide is a solid and insoluble in water, it may be readily prepared from the nitrile by dissolving in concentrated sulphuric acid and pouring the solution into water:

\[ R\cdot\text{CN} \xrightarrow{\text{HSO}_4^-} [R\cdot\text{C}=\text{NH}]\text{HSO}_4^- \xrightarrow{\text{H}_2\text{O}} R\cdot\text{CONH}_2 \]

**Oximes, hydrazones and semicarbazones.** The hydrolysis products of these compounds, i.e. aldehydes and ketones, may be sensitive to alkali (this is particularly so for aldehydes): it is best, therefore, to conduct the hydrolysis with strong mineral acid. After hydrolysis the aldehyde or ketone may be isolated by distillation with steam, extraction with ether or, if a solid, by filtration, and then identified. The acid solution may be examined for hydroxylamine or hydrazine or semicarbazide; substituted hydrazones of the aromatic series are precipitated as oils or solids upon the addition of alkali.

\[ R^1R^2\text{C}=\text{NOH} + H_2O \xrightarrow{\text{HCl}} R^1R^2\text{C}=\text{O} + \text{NH}_2\text{OH} \]

**Imides.** Imides are generally water-soluble, consequently they are much more readily hydrolysed in an alkaline medium, e.g. by refluxing with 10 per cent sodium hydroxide solution:

\[ (R\cdot\text{CO})_2\text{NH} \xrightarrow{\text{OH}} 2R\cdot\text{CO}_2^- + NH_3 \]

**Sulphonamides.** Sulphonamides are very resistant to the normal reagents for hydrolysis. Heating with 80 per cent sulphuric acid at 160–170°C results in rapid hydrolysis.

\[ \text{Ar} \cdot \text{SO}_2\text{NR}^1\text{R}^2 + H_2O \xrightarrow{\text{H}_2\text{SO}_4} \text{Ar} \cdot \text{SO}_3\text{H} + R^1R^2\cdot\text{NH}_2\text{HSO}_4^- \]

* Prepared by adding 40 ml of concentrated sulphuric acid cautiously and with stirring and cooling to 30 ml of water.

1228
The following methods represent typical procedures for the reduction or hydrolysis of these nitrogen-containing compounds.

(a) **Reduction of a nitro compound to a hydroxylamine.** Dissolve 0.5 g of the compound in 10 ml of 50 per cent ethanol, add 0.5 g of solid ammonium chloride and about 0.5 g of zinc powder. Heat to boiling and allow the ensuing chemical reaction to proceed for 5 minutes. Filter from the excess of zinc powder and test the filtrate with Tollen’s reagent (see p. 1219). An immediate black or grey precipitate or a silver mirror indicates the presence of a hydroxylamine formed by the reduction of the nitro compound. Alternatively, warm the filtrate with Fehling’s solution: a hydroxylamine will precipitate red copper(1) oxide. (A blank test should be performed with the original compound.)

(b) **Reduction of a nitro compound to a primary amine.** In a 50-ml round-bottomed flask fitted with a reflux condenser, place 1 g of the nitro compound and 2 g of granulated tin. Measure out 10 ml of concentrated hydrochloric acid and add it in three equal portions to the mixture; shake thoroughly after each addition. When the vigorous reaction subsides, heat under reflux on a water bath until the nitro compound has completely reacted (20–30 minutes). Shake the reaction mixture from time to time; if the nitro compound appears to be very insoluble, add 5 ml of ethanol. Cool the reaction mixture, and add 20–40 per cent sodium hydroxide solution until the precipitate of tin hydroxide dissolves. Extract the resulting amine from the cooled solution with ether, and remove the ether by distillation. Examine the residue with regard to its solubility in 5 per cent hydrochloric acid and its reaction with acetyl chloride or benzenesulphonyl chloride.

(c) **Reduction of a nitrosamine to a secondary amine.** Proceed as for a nitro compound. Determine the solubility of the residue after evaporation of the ether and also its behaviour towards benzenesulphonyl (or toluene-p-sulphonyl) chloride.

(d) **Hydrolysis of simple (primary) amides in alkaline solution.** Boil 0.5 g of the compound with 5 ml of 10 per cent sodium hydroxide solution and observe whether ammonia is evolved.

(e) **Hydrolysis of a substituted amide.** 1. **With 10 per cent sulphuric acid.** Reflux 1 g of the compound (e.g. acetyl anilide) with 20 ml of 10 per cent sulphuric acid for 1–2 hours. Distil the reaction mixture and collect 10 ml of distillate: this will contain any volatile organic acids which may be present. Cool the residue, render it alkaline with 20 per cent sodium hydroxide solution, cool and extract with ether. Distil off the ether and examine the ether-soluble residue for an amine.

2. **With 70 per cent sulphuric acid.** Reflux 1 g of the substance (e.g. benzanilide) with 10–15 ml of 70 per cent sulphuric acid (4 : 3 by volume) for 30 minutes. Allow to cool and wash down any acid which has sublimed into the condenser with hot water. Filter off the acid, wash it with water and examine for solubility, etc. Render the filtrate alkaline with 10–20 per cent sodium hydroxide solution, cool and extract with ether. Examine the residue, after evaporation of the ether, for an amine.

(f) **Hydrolysis of a nitrile to an acid.** Reflux 1 g of the nitrile with 5 ml of 30–40 per cent sodium hydroxide solution until ammonia ceases to be evolved (2–3 hours). Dilute with 5 ml of water and add, with cooling, 7 ml of 50 per cent sul-
phric acid. Isolate the acid by ether extraction, and examine its solubility and other properties.

(g) Hydrolysis of a nitrile to an amide. Warm a solution of 1 g of the nitrile in 4 ml of concentrated sulphuric acid to 80–90 °C, and allow the solution to stand for 5 minutes. Cool and pour the solution cautiously into 40 ml of cold water. Filter off the precipitate; stir it with 20 ml of cold 5 per cent sodium hydroxide solution and filter again. Recrystallise the amide from dilute ethanol, and determine its m.p. Examine the solubility behaviour and also the action of warm sodium hydroxide solution upon the amide.

(h) Hydrolysis of a sulphonamide. Mix 2 g of the sulphonamide with 3.5 ml of 80 per cent sulphuric acid* in a test tube and place a thermometer in the mixture. Heat the test tube, with frequent stirring by means of the thermometer, at 155–165 °C until the solid passes into solution (2–5 minutes). Allow the acid solution to cool and pour it into 25–30 ml of water. Render the resulting solution alkaline with 20 per cent sodium hydroxide solution in order to liberate the free amine. Two methods may be used for isolating the base. If the amine is volatile in steam, distil the alkaline solution and collect about 20 ml of distillate: extract the amine with ether, dry the ethereal solution with anhydrous potassium carbonate and distil off the solvent. If the amine is not appreciably steam-volatile, extract it from the alkaline solution with ether. The sulphonic acid (as sodium salt) in the residual solution may be identified by conversion into a suitable derivative (Section 9.6.26, p. 1284).

For further methods for the characterisation of these nitrogen-containing compounds see Sections 9.6.18, p. 1270, 9.6.20, p. 1271, and 9.6.24, p. 1281 and 9.6.27, p. 1286.

α-Amino acids. These are in general insoluble (or very sparingly soluble) in organic solvents such as ether or toluene, sparingly soluble in ethanol, usually soluble in water and neutral in reaction. They have no true melting points, but decompose on heating at temperatures between 120 and 300 °C; the apparent melting points vary considerably according to the conditions of heating and are therefore of no great value for purposes of identification. The following tests may be used to confirm the presence of an α-amino acid.

The ninhydrin test. Heat a solution of the compound with a few drops of a 0.25 per cent aqueous solution of ninhydrin (Expt 5.99). α-Amino acids give a blue-violet coloration. This highly sensitive test is also given by some β-amino acids and by some peptides and proteins, particularly on warming. The colour test is of great value in the characterisation of the α-amino acids separated by t.l.c., and the \( R_F \) values are useful aids to identification.

Copper complex formation. Add a few drops of aqueous copper(II) sulphate solution to an aqueous solution of the amino acid. A deep blue coloration is obtained. The deep blue copper derivative may be isolated by boiling a solution of the amino acid with precipitated copper(II) hydroxide or with copper(II) carbonate, filtering and concentrating the solution. These blue complexes are co-ordination compounds of the structure:

* Prepared by cautiously adding 3 vol. of concentrated sulphuric acid to 1 vol. of water.
Nitrous acid test. The conditions of the test are similar to those described for the classification of primary amines (Section 9.5.2, p. 1215), but using acetic acid in place of hydrochloric acid. An α-amino acid yields nitrogen and an α-hydroxy acid.

For the preparation of derivatives of α-amino acids, see Section 9.6.23, p. 1279.

COMPounds CONTAINING SULPhUR

The neutral sulphur compounds include sulphides or thioethers, disulphides, sulfoxides and sulphones, sulphate and sulphonate esters, and isothiocyanates. Acidic sulphur compounds, i.e. sulphonic and sulphinic acids, thiols and thio-phenols, and the primary sulphonamides have already been discussed. The sulphates of amines are converted by aqueous sodium hydroxide into the free bases; the sulphate anion can be detected in the resulting aqueous solution as barium sulphate in the usual manner.

Those compounds which contain the highly polar S=O group exhibit characteristic strong adsorption bands in the fingerprint region of the i.r. spectra. Two such bands originate from the symmetrical and asymmetrical stretching vibrations of the S=O groups (see Sections 5.17 and 6.4).

Sulphides (thioethers). The organic sulphides are usually liquids with penetrating and disagreeable odours. In contrast to the oxygen analogues (ethers), they are readily oxidised; thus sulfoxides are produced with hydrogen peroxide, and sulphones with nitric acid or with potassium permanganate in glacial acetic acid solution (see Section 5.17.3, p. 791).

\[
\begin{align*}
R^1_S-S+H_2O_2 & \rightarrow R^1_S=O \\
R^2_S & \rightarrow R^2_S=O
\end{align*}
\]

Thioethers usually yield sulphonium salts when warmed with ethyl iodide and allowed to cool. The physical properties (b.p. density and refractive index) are useful for identification purposes.

Disulphides. Disulphides are liquids or low m.p. solids and have unpleasant odours, particularly if liquid. They are reduced by zinc and dilute acids to the thiols.

\[
R_S-S+2[H] \rightarrow 2RSH
\]

Sulfoxides. These are usually solids of low m.p. They may be oxidised in glacial acetic acid solution by potassium permanganate to the corresponding sulphones, and reduced to the sulphides by boiling with tin or zinc and hydrochloric acid.

Sulphones. Sulphones are usually crystalline solids, and are extremely stable to most oxidising, reducing and hydrolytic reagents.

Esters of sulphuric acid. These compounds are generally water-insoluble liquids
and are saponified by boiling with water or dilute alkali to the corresponding alcohols and sulphuric acid:

\[ \text{R}_2\text{SO}_4 + 2\text{H}_2\text{O} \rightarrow 2\text{ROH} + \text{H}_2\text{SO}_4 \]

The simple dialkyl sulphates, in particular dimethyl sulphate, are markedly toxic (see Section 4.2.24, p. 430). They may be characterised as the alkyl 2-naphthyl ethers (cf. alkyl halides, Section 9.6.8, p. 1251; and also Expt 6.111).

The alkyl esters of sulphonic acids exhibit properties similar to those of the alkyl sulphates, and are hydrolysed, by boiling with aqueous alkalis, to the corresponding alcohols and sulphonic acids. Thus with ethyl toluene-p-sulphonate:

\[ p\text{-MeC}_6\text{H}_4\text{SO}_2\text{OEt} + \text{H}_2\text{O} \rightarrow p\text{-MeC}_6\text{H}_4\text{SO}_3\text{H} + \text{EtOH} \]

The salts of monoalkyl sulphates are frequently encountered as commercial detergents: these are usually sodium salts, the alkyl components contain 12 or more carbon atoms, and they give colloidal solutions. They are hydrolysed by boiling with dilute sodium hydroxide solution:

\[ \text{ROSO}_2\text{ONa} + \text{NaOH} \rightarrow \text{ROH} + \text{NaSO}_4 \]

**Isothiocyanates.** These compounds, also known as mustard oils are oils or low melting point solids, and usually possess irritating odours. Upon boiling with acids, for example with concentrated hydrochloric acid, they are hydrolysed to the primary amines and hydrogen sulphide is evolved:

\[ \text{R\cdotNCS} + \text{HCl} + 2\text{H}_2\text{O} \rightarrow \text{R}\text{NH}_3\text{Cl} + \text{CO}_2 + \text{H}_2\text{S} \]

They react with amines to form substituted thioureas:

\[ \text{R}^1\text{NCS} + \text{R}^2\text{NH}_2 \rightarrow \text{R}^1\text{NH\cdotCS\cdotNHR}^2 \]

This reaction is also employed for the characterisation of amines (see Section 9.6.21, p. 1273).

**COMPOUNDS CONTAINING HALOGEN**

The spectroscopic features (i.e., p.m.r., and m.s.) of aliphatic and aromatic halogen-containing compounds are summarised in Section 5.5 and 6.3 respectively.

**Reactivities of halogen compounds.** A halogen substituent in an organic compound is an inert functional group in the sense that it has relatively little effect on the solubility characteristics of the parent compound or upon the properties of other functional groups which may be present. For the purposes of classification and characterisation therefore the presence of the halogen is to a certain extent immaterial. Halogen may of course be present in the ionic form (i.e. in a salt), and then may readily be detected in the usual way with aqueous silver nitrate. Highly reactive halogen compounds, typically acid halides, will also respond to this test. With other, neutral, halogen compounds, it is useful to examine their behaviour towards ethanolic silver nitrate, and to categorise their reactivity in the following way:

**Reaction with ethanolic silver nitrate.** Treat 2 ml of a 2 per cent solution of silver nitrate in ethanol with 1 or 2 drops (or 0.05 g) of the compound. If no appre-
ciable precipitate appears at the laboratory temperature, heat in a boiling water bath for a few minutes. Some organic acids give insoluble silver salts, hence it is advisable to add 1 drop of dilute (5%) nitric acid at the conclusion of the test: most silver salts of organic acids are soluble in aqueous nitric acid. (CAUTION: On no account should concentrated nitric acid be used; a dangerous explosion may result.)

Organic compounds containing halogen react with ethanolic silver nitrate in the following order of decreasing reactivity:

1. Water-soluble compounds containing ionisable halogen or compounds such as acyl halides of low molecular weight which readily yield ionisable compounds with water will react immediately, even with aqueous silver nitrate.
2. Acyl and sulphonyl halides, α-halogeno-ethers and alkyl iodides react rapidly.
3. Alkyl chlorides and bromides, aromatic compounds containing halogen in the side chain, or nuclear-halogenated aromatic compounds with nitro groups in the ortho and/or para position, do not usually react readily at room temperature but react fairly rapidly on heating. The order of reactivity of alkyl halides is tertiary > secondary > primary, and indeed some tertiary halides may react in the cold.
4. Aromatic compounds in which the halogen is attached directly to the aromatic nucleus and polyhalogenated compounds with three or more halogens on the same carbon atom do not react even on heating.

Further classification of halogen compounds. Two further reactions aid the classification of halogen compounds.

Reaction with ethanolic potassium hydroxide. Boil 0.5 ml of the compound with 4 ml of 0.5 M ethanolic potassium hydroxide under reflux for 15 minutes. Most alkyl halides and benzyl halides give a crystalline precipitate of the potassium halide. Dilute with 5 ml of water, acidify with dilute nitric acid and test with silver nitrate solution.

The 0.5 M ethanolic potassium hydroxide solution is prepared by dissolving 16 g of potassium hydroxide pellets in 500 ml of ethanol in a bottle closed with a cork. After standing for 24 hours, the clear solution is decanted and filtered from the residue of potassium carbonate. It is said that a solution in methanol has better keeping qualities than that in ethanol.

Halogen exchange reaction. This is based upon the fact that sodium chloride and sodium bromide are sparingly soluble in pure acetone:

$$\text{RCI(Br)} + \text{NaI} \rightarrow \text{RI} + \text{NaCl(Br)}$$

The test consists in treating a solution of sodium iodide in pure acetone with the organic compound. The reaction is probably of the S_N2 type involving a bimolecular attack of the iodide ion upon the carbon atom carrying the chlorine or bromine; the order of reactivities of halides is: primary > secondary > tertiary and Br > Cl.

Primary bromides give a precipitate of sodium bromide within 3 minutes at 25 °C; chlorides react only when heated at 50 °C for up to 6 minutes. Secondary and tertiary bromides must be heated at 50 °C for up to 6 minutes, but tertiary chlorides do not react within this time.

1,2-Dichloro and dibromo compounds give a precipitate with the reagent and also liberate free iodine:
R\(^1\)CHBr·CHBr·R\(^2\) + 2NaI \(\rightarrow\) R\(^1\)CHI·CHI·R\(^2\) + 2NaBr

\[\text{Polybromo compounds (bromoform, s-tetribromoethane) react at 50 °C, but simple polychloro compounds (chloroform, carbon tetrachloride and trichloroacetic acid) do not.}

Sulphonyl chlorides give an immediate precipitate and also liberate iodine:

\[\text{Ar·SO}_2\text{Cl} + \text{NaI} \xrightarrow{\text{NaCl}} \text{Ar·SO}_2\text{I} \xrightarrow{\text{NaI}} \text{Ar·SO}_2\text{Na} + \text{I}_2\]

Acid chlorides and bromides, allyl halides, and \(\alpha\)-halo-ketones, -esters, -amides and -nitriles react at 25 °C within 3 minutes. Vinyl and aryl halides are inert.

Prepare the reagent by dissolving 7.5 g of sodium iodide in 50 ml of AnaIAR acetone. The colourless solution gradually acquires a yellow colour. Keep it in a dark bottle. When a red-brown colour develops, it should be discarded.

For the preparation of derivatives of alkyl and aryl halides see Sections 9.6.8, p. 1251 and 9.6.9, p. 1253 respectively.

### 9.6 PREPARATION OF DERIVATIVES

Before the development and widespread application of spectroscopic methods for the elucidation of structure, confirmation of the class type of an unknown organic compound was completed by the preparation of two or more crystalline functional derivatives. If the compounds had been previously reported in the literature, agreement between the published physical constants of the derivatives with those prepared by the worker was accepted as proof of identity. In many cases, and particularly in natural product chemistry, functional group recognition led to oxidative, reductive, or hydrolytic breakdown into smaller carbon-containing fragments. These were, if necessary, separated, characterised and identified by derivative preparation. The reassembly of the ‘jig-saw’ of fragments inferred by the identity of the fission products, then led to postulated structures.

Derivative preparation provides the developing organic chemist with an important area of study for the following reasons.

Firstly, the combination of spectroscopic information and reactivity tests enables the classification of the compound to be made with greater certainty, leading to derivative selection to be made with greater confidence. The requirements of a satisfactory derivative include the following:

1. The derivative should be easily and quickly prepared in good yield by an unambiguous reaction, and be easily purified. In practice, this generally means that the derivative must be a solid, because of the greater ease of manipulation of small quantities of solids, and the fact that melting points are more accurately and more easily determined than boiling points. The melting point should preferably be above 50 °C, but below 250 °C; compounds which melt below 50 °C are frequently difficult to recrystallise.
2. The derivative should be prepared preferably by a general reaction, which under the same experimental conditions would yield a definite derivative with
the other likely compounds. Rearrangements and side reactions should be avoided.

3. The properties (physical and chemical) of the derivatives should be markedly different from those of the original compound.

4. It should be borne in mind that when a compound has several functional groups, that functional group should be chosen for the preparation of the derivative which gives the least ambiguous reaction.

Secondly, the description of the general procedures given below, as distinct from the specific experimental procedures of the preparations described in earlier chapters, provides an excellent opportunity for the student to explore on the small scale the optimum reaction conditions, the chromatographic monitoring of the reaction, the methods of isolation and purification procedures (solvent extraction, recrystallisation, etc.) for the successful completion of the preparation. The small-scale nature of the experiments is of particular importance in providing experience of those techniques of reaction work-up in which mechanical loss is frequently the reason for failure. Such experience is vital to the synthetic chemist since many of the new chemo-, regio- and stereo-specific reagents are expensive and used in small-scale reactions.

Thirdly, some of the derivatives provide protection of the functional group, and their preparation, chemical reactivity, and deprotection procedures may be of value in the design of synthetic strategies.

The methods of preparation of some of the more important derivatives of a number of classes of organic compounds are described in the following sections. These sections are cross-referenced with tables incorporating the melting points and boiling points of the compounds themselves, and also the melting points of selected derivatives. For convenience, the references to the various derivative preparations and tables are collected in Table 9.2.

9.6.1 SATURATED ALIPHATIC HYDROCARBONS

Because of the chemical inertness of the saturated aliphatic hydrocarbons and of the closely related cycloalkanes, no satisfactory crystalline derivatives can be prepared. A pure sample may be characterised by consideration of such physical properties such as the boiling point, the refractive index (and/or the density), and these physical constants are listed in Table 10.1. If required, confirmation of structure should be sought from a more detailed study of appropriate spectra, particularly $^{13}$C-n.m.r., and mass spectra.

9.6.2 UNSATURATED ALIPHATIC HYDROCARBONS

DERIVATIVES OF ALKENES

The alkenes are distinguished from the alkanes by their solubility in concentrated sulphuric acid and their characteristic reactions with dilute potassium permanganate solution and with bromine. Characterisation may be based upon the determination of their physical and/or spectral properties. Characterisation by way of solid adducts with nitrosyl chloride has been quite widely used in the terpene field; the preparation of adducts with 2,4-dinitrobenzenesulphenyl chloride is described below (see also Section 8.1.1, p. 1128).

</table>
ADDITIONS WITH 2,4-DINITROBENZENESULPHENYL CHLORIDE

2,4-Dinitrobenzenesulphenyl chloride reacts in polar solvents (acetone, 1,2-dichloroethane, acetic acid and dimethylformamide) with alkenes to yield crystalline adducts, the $\beta$-chloroalkyl-2,4-dinitrophenyl sulphides, e.g.:

$$\text{R\cdot CH=CH_2 + 2,4-(NO_2)_2C_6H_3SCl} \rightarrow \text{R\cdot CHCl\cdot CH_2-S\cdot C_6H_3(NO_2)_2}$$

Addition of the reagent is stereospecific ($\text{trans}$ addition) and one can thus differentiate between $\text{cis}$ and $\text{trans}$ isomers: thus $\text{cis}$-butene and $\text{trans}$-butene give products of m.p. 129 and 77 °C respectively.

Heat a solution of 0.2 g of the reagent and 0.2–0.3 g of the alkene in glacial acetic acid on the steam bath for 15 minutes or until the potassium iodide test shows that the reaction is complete. Cool the mixture in ice. If a solid separates, filter it off; if not, pour the reaction mixture on to 5–10 g of crushed ice. Recrystallise the resulting solid or oil from ethanol. Test: Add a drop of the reaction solution to a drop of potassium iodide solution on a spot plate; the presence of unreacted reagent is revealed by the liberation of iodine:

$$2\text{RSCl} + 2\text{I}^\ominus \rightarrow \text{RSSR} + \text{I}_2 + 2\text{Cl}^\ominus$$

DERIVATIVES OF ALKYNES

ADDITION PRODUCTS WITH 2,4-DINITROBENZENESULPHENYL CHLORIDE

The reagent reacts with symmetrical alkenes as follows:

$$\text{R\cdot C≡C\cdot R} + \text{ArSCl} \rightarrow \text{R\cdot C(Cl)≡C(SAr)\cdot R; Ar = 2,4-(NO_2)_2C_6H_3}$$

Dissolve 1.60 g of the reagent in 15 ml of 1,2-dichloroethane at 0 °C and add 3.0 ml of the ice-cold alkene. Keep at 0 °C for 2 hours, remove the solvent by aspiration and keep the clear yellow oil in a refrigerator until crystallisation occurs. Dissolve the crystals in 25 ml of absolute ethanol, decolourise with charcoal and filter. Concentrate the filtrate, collect the crystals which separate and recrystallise from ethanol.

MERCURIDES OF MONOSUBSTITUTED ALKYNES

Monosubstituted alkenes form mercurides which are suitable for identification purposes:

$$2\text{R\cdot C≡CH} + \text{K}_2[\text{HgI}_4] + 2\text{KOH} \rightarrow (\text{R\cdot C≡C})_2\text{Hg} + 4\text{KI} + 2\text{H}_2\text{O}$$

The procedure consists in adding a dilute solution of the alkyn in ethanol to an excess of an alkaline mercury(II) iodide reagent: a white or greyish-white precipitate forms immediately, which is filtered off, washed with dilute ethanol and recrystallised. The yield of mercuride is 85–95 per cent.

The mercury(II) iodide reagent is prepared by dissolving 6.6 g of mercury(II) chloride (POISONOUS) in a solution of 16.3 g of potassium iodide in 16.3 ml of water and adding 12.5 ml of 10 per cent sodium hydroxide solution.

Into a cooled dilute solution of 2 equivalents of alkaline mercury(II) iodide reagent, drop slowly, with mechanical stirring, a solution of 1 equivalent of the monosubstituted alkyn in 20 volumes of 95 per cent ethanol. A white crystalline
precipitate separates at once. Stir for 2–3 minutes, filter rapidly with suction and wash with 50 per cent ethanol. Recrystallise from ethanol or benzene.

Data for a selection of alkenes and alkynes are collected in Table 10.2.

### 9.6.3 AROMATIC HYDROCARBONS

For characterisation, aromatic hydrocarbons can be sulphonated, chlorosulphonated, carboxybenzoylated and nitrated. Polynuclear aromatic hydrocarbons, and many of their derivatives, yield crystalline adducts with picric acid, styphnic acid, 1,3,5-trinitrobenzene and 2,4,7-trinitrofluorenone.

#### SULPHONAMIDES

Aromatic hydrocarbons react with chlorosulphonic acid to yield the corresponding sulphonyl chlorides (the process is known as chlorosulphonation). These do not usually crystallise well and are therefore converted into the sulphonamides by treatment with concentrated ammonia solution or with solid ammonium carbonate. (See also Section 6.4.2, p. 877.)

\[
\begin{align*}
\text{ArH} + 2\text{HOSO}_2\text{Cl} &\rightarrow \text{ArSO}_2\text{Cl} + \text{H}_2\text{SO}_4 + \text{HCl} \\
\text{ArSO}_2\text{Cl} + (\text{NH}_4)_2\text{CO}_3 &\rightarrow \text{ArSO}_2\text{NH}_2 + \text{NH}_4\text{Cl} + \text{CO}_2 + \text{H}_2\text{O}
\end{align*}
\]

Dissolve 1.0 g of the compound in 5 ml of dry (CaCl₂) chloroform in a dry test tube, cool it in a beaker of ice and add 3–5 ml of chlorosulphonic acid (CAUTION) dropwise. When the evolution of hydrogen chloride has subsided, remove the test tube from the ice bath and allow to stand at room temperature for 20–30 minutes; then pour on to crushed ice (30 g). Separate the chloroform layer, wash it with water, dry (CaCl₂), and evaporate the solvent.

Boil the arenesulphonyl chloride (0.5 g) with 5 ml of aqueous ammonia (d 0.88) for 10 minutes (fume cupboard). Cool the reaction mixture and dilute it with 10 ml of water. Filter off the sulphonamide, wash it with water and recrystallise from dilute ethanol.

Alternatively, heat a mixture of 0.5 g of the arenesulphonyl chloride with 2.8 g of dry powdered ammonium carbonate at 100 °C during 30 minutes. Wash the residue with several portions (10 ml) of cold water, filter and recrystallise from dilute ethanol.

If the presence of a sulphone is suspected (cf. Aromatic halogen compounds, Section 9.6.9, p. 1256), treat the product with 6 M sodium hydroxide solution (only the sulphonamide dissolves), filter and reprecipitate the sulphonamide with 6 M hydrochloric acid.

### o-AROYLBENZOIC ACIDS

Aromatic hydrocarbons react with phthalic anhydride in the presence of anhydrous aluminium chloride producing aroylbenzoic acids in good yields. The process is termed carboxybenzoylation. See formulation on p. 1008.

Place a mixture of 1.0 g of the hydrocarbon, 10 ml of dry dichloromethane or 1,2-dichloroethane, 2.5 g of powdered anhydrous aluminium chloride and 1.2 g of pure phthalic anhydride in a 25-50 ml round-bottomed flask fitted with a reflux condenser (127 mm jacket). Heat on a water bath for 30 minutes (or until no more hydrogen chloride fumes are evolved). Cool in ice and add 10 ml of concentrated hydrochloric acid cautiously and with constant shaking. When the reaction has subsided, add 20 ml of water and shake vigorously. (All the solid
material should pass into solution.) Transfer the two-phase system to a separatory funnel, add 25 ml of ether and shake. Discard the lower aqueous phase. Wash the ethereal layer with 25 ml of 2.5 M hydrochloric acid to ensure removal of any aluminium salts present. Shake the ethereal solution cautiously with 25 ml of M sodium carbonate solution, and run the aqueous phase slowly into 30 ml of M hydrochloric acid. Collect the aroylbenzoic acid by suction filtration, wash it with 25-50 ml of water and recrystallise it from dilute ethanol or from acetic acid. The derivatives prepared from benzene and toluene crystallise with water of crystallisation; the latter is removed by drying at 100 °C.

**NITRO DERIVATIVES**

No general experimental details for the preparation of nitro derivatives can be given, as the ease of nitrations and the product formed frequently depend upon the exact experimental conditions. Moreover some organic compounds react violently so that nitrations should *always be conducted on a small scale*. Typical procedures for benzene hydrocarbons are illustrated by the following concise notes for the nitrations of benzene and toluene to yield the solid dinitro compounds. (Full experimental details are given in Expts 6.17 and 6.18).

**Benzene.** Add 0.5 ml of benzene slowly and with shaking and cooling to a mixture of 4 ml each of concentrated sulphuric and nitric acids. Heat the mixture carefully until it just boils, cool and pour into excess of cold water. Filter off the precipitate, wash it free from acid and recrystallise it from dilute alcohol. *m*-Dinitrobenzene, m.p. 90 °C, is formed.

**Toluene.** Proceed as for *benzene* but use 0.5 ml of toluene and a mixture of 3 ml of concentrated sulphuric acid and 2 ml of fuming nitric acid. Gently warm the mixture over a free flame for 1-2 minutes, cool and pour into 20 ml of ice-water. Recrystallise the product from dilute alcohol. 2,4-Dinitrotoluene, m.p. 71 °C, is obtained.

Conditions for the mononitration of *naphthalene*, typical of the more reactive polynuclear aromatic hydrocarbons, are to be found in Expt 6.17. Naphthalene can also be nitrated by a mixture of nitric acid and glacial acetic acid, a reagent also suitable for some polyalkylated benzenes.

**OXIDATION OF A SIDE CHAIN BY ALKALINE PERMANGANATE**

Aromatic hydrocarbons containing side chains may be oxidised to the corresponding acids: the results are generally satisfactory for compounds with one side chain (e.g. toluene or ethylbenzene → benzoic acid) or with two side chains (e.g. *o*-xylene → phthalic acid).

Suspend in a round-bottomed flask 1 g of the substance in 75-80 ml of boiling water to which about 0.5 g of sodium carbonate crystals have been added, and introduce slowly 4 g of finely powdered potassium permanganate. Heat under reflux until the purple colour of the permanganate has disappeared (1-4 hours). Allow the mixture to cool and carefully acidify with dilute sulphuric acid. Heat the mixture under reflux for a further 30 minutes and then cool. Remove any excess of manganese dioxide by the addition of a little sodium metabisulphite. Filter the precipitated acid and recrystallise it from a suitable solvent (e.g. toluene, ethanol, dilute ethanol or water). If the acid does not separate from the solution, extract it with ether, toluene, or dichloromethane.
PICRATES
Many polynuclear aromatic hydrocarbons form 1:1 molecular compounds (π-complexes) with picric acid, for example, naphthalene picrate C\textsubscript{10}H\textsubscript{8}·C\textsubscript{6}H\textsubscript{2}(NO\textsubscript{2})\textsubscript{3}OH. Some picrates, e.g. anthracene picrate, are so unstable as to be decomposed by many, particularly hydroxylic, solvents; they therefore cannot be easily recrystallised but may be washed with a little ether and dried on a porous title. Their preparation may often be accomplished in such non-hydroxylic solvents as chloroform, benzene or ether. The picrates of hydrocarbons can be readily separated into their constituents by warming with dilute ammonia solution and filtering (if the hydrocarbon is a solid) through a moist filter paper. The filtrate contains the picric acid as the ammonium salt, and the hydrocarbon is left on the filter paper.

Picrates are usually prepared by adding a hot solution of the compound in ethanol to a cold saturated ethanolic solution of picric acid, warming and allowing to cool; the derivative separates in a crystalline condition. It is filtered off, washed with a little ether and pressed on a porous tile. If the picrate is stable, it is recrystallised from ethanol, ethyl acetate, benzene or ether. Do not mistake the recrystallised reagent (m.p. 122 °C) for a picrate.

The following are typical experimental details for the preparation of naphthalene picrate. Dissolve 0.1 g of naphthalene in the minimum of hot ethanol and add to 1 ml of a saturated solution of picric acid in ethanol. Warm the mixture and then cool to allow the product to crystallise.

OTHER ADDITION COMPOUNDS
Suitably reactive aromatic hydrocarbons also form crystalline 1:1 π-complexes ('stypnates') with styphnic acid (2,4,6-trinitroresorcinol). These derivatives do not crystallise quite so well as the corresponding picrates, but are frequently of great value. Benzene and its simple homologues do not give stable derivatives.

Dissolve equimolecular amounts of the hydrocarbon and styphnic acid in the minimum volume of hot acetic acid and allow to cool. Filter off the crystalline derivative which separates, wash it with a little acetic acid and dry in the air. Determine the m.p. Recrystallise from acetic acid and again determine the m.p.

Other π-complexing reagents are 1,3,5-trinitrobenzene and 2,4,7-trinitro-9-fluorenone (1). The crystalline adducts are usually formed in ethanol, glacial acetic acid, or toluene solution and recrystallised from similar solvents. They are useful both for the characterisation and also for the isolation of appropriately reactive aromatic hydrocarbons.

Data for a number of typical aromatic hydrocarbons are collected in Table 10.3.
9.6.4 ALCOHOLS AND POLYHYDRIC ALCOHOLS

OXIDATION WITH 'CHROMIC ACID'
A primary alcohol is oxidised by 'chromic acid' to the corresponding aldehyde while a secondary alcohol yields a ketone: tertiary alcohols are generally unaffected or are decomposed into non-ketonic products. Oxidation therefore provides a method for distinguishing between primary, secondary and tertiary alcohols and characterisation of the carbonyl compound provides a means of identifying the alcohol:

$$R\cdot CH_2OH \xrightarrow{\text{IO}_3} R\cdot CHO \quad R^1\cdot CH(OH)\cdot R^2 \xrightarrow{\text{IO}_3} R^1\cdot CO\cdot R^2$$

To an ice-cold mixture of 1.0 ml of concentrated sulphuric acid and 5 ml of saturated aqueous potassium dichromate solution, add 2 ml of the alcohol or its concentrated aqueous solution. If the alcohol is not miscible with the reagent, shake the reaction mixture vigorously. After 5 minutes, dilute with an equal volume of water, distil and collect the first few ml of the aqueous distillate in a test tube cooled in ice. (Aldehydes and ketones are volatile in steam.) Test a portion of the distillate for a carbonyl compound with 2,4-dinitrophenylhydrazine reagent (p. 1218). If a solid derivative is obtained, indicating that the compound was a primary or secondary alcohol, test a further portion with Schiff's reagent (p. 1291) to distinguish between the two possibilities. The derivative may be recrystallised; the m.p. may give a preliminary indication of the identity of the alcohol.

3.5-DINITROBENZOATES
3.5-Dinitrobenzoyl chloride reacts with alcohols to form solid esters which possess sharp melting points and are therefore admirably suited for purposes of characterisation:

$$3,5-(\text{NO}_2)_2C_6H_3\cdot \text{COCl} + ROH \rightarrow 3,5-(\text{NO}_2)_2C_6H_3\cdot \text{CO}_2R + \text{HCl}$$

The acid chloride is available commercially, but it is preferable to prepare it from the acid as and when required since 3.5-dinitrobenzoyl chloride tends to undergo hydrolysis if kept for long periods, particularly if the stock bottle is frequently opened. The substance may, however, be stored under dry light petroleum.

Prepare the reagent in a fume cupboard in the following way. Mix 1.0 g of 3.5-dinitrobenzoic acid with 1.5 g of phosphorus pentachloride in a small, dry test tube. Warm the mixture gently over a small smoky flame to start the reaction; when the reaction has subsided (but not before), boil for 1–2 minutes or until the solid matter has dissolved. Pour the mixture while still liquid on a dry watch glass (CAUTION: the fumes are irritating to the eyes). When the product has solidified, remove the liquid by-product (phosphorus oxychloride) by transferring the pasty mixture to a pad of several thicknesses of filter paper or to a small piece of porous tile. Spread the material until the liquid has been absorbed and the residual solid is dry and transfer the 3,5-dinitrobenzoyl chloride to a test tube. Add 0.5–1 ml of the alcohol, cork the tube loosely and heat on a boiling water bath for 10 minutes: secondary and tertiary alcohols require longer heating (up to 30 minutes). Cool the mixture, add 10 ml of 5 per cent (or saturated) sodium hydrogen carbonate solution, break up the resulting solid ester with a
stirring rod (alternatively, stir until crystalline) and filter at the pump; wash with a little sodium hydrogen carbonate solution, followed by water, and then suck as dry as possible. Recrystallise the crude ester from light petroleum (of suitable b.p. range) or from aqueous ethanol. Collect the crystals, dry and determine the melting point.

The above procedure may also be carried out in the presence of 1 ml of dry pyridine; with some alcohols improved yields may be obtained by this modification.

**p-NITROBENZOATES**

Alcohols react readily with p-nitrobenzoyl chloride to yield p-nitrobenzoates:

\[
\text{p-NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{COCl} + \text{ROH} \rightarrow \text{p-NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{R} + \text{HCl}
\]

The melting points of these esters are usually much lower than those of the corresponding 3,5-dinitrobenzoates: their preparation, therefore, offers no advantages over the latter except for alcohols of high molecular weight and for polyhydroxy compounds. The reagent is, however, cheaper than 3,5-dinitrobenzoyl chloride; it hydrolyses in the air so that it should either be stored under light petroleum or be prepared from the acid, when required, by the phosphorus pentachloride method.

The experimental technique is similar to that given under 3,5-**dinitrobenzoates** above.

**BENZOATES**

Alcohols react with benzoyl chloride in the presence of pyridine or of sodium hydroxide solution to produce esters of benzoic acid:

\[
\text{Ph-COCl} + \text{ROH} \rightarrow \text{Ph-CO}_2\text{R} + \text{HCl}
\]

These derivatives are generally liquids and hence are of little value for characterisation; the polyhydric alcohols, on the other hand, afford solid benzoates. Thus the benzoates of ethylene glycol, trimethylene glycol and glycerol melt at 73, 58 and 76 °C respectively.

Mix together 0.5–0.8 ml of the polyhydroxy compound, 5 ml of pyridine and 2.5 ml of redistilled benzoyl chloride in a 50-ml flask, and heat under reflux for 30–60 minutes. Add 25 ml of 5 per cent sodium hydrogen carbonate solution to the cold reaction mixture and cool in ice until the precipitate solidifies. Filter and wash with a little water. Recrystallise from dilute ethanol.

**PHENYL- AND 1-NAPHTHYL-URETHANS (PHENYL- AND 1-NAPHTHYL-CARBAMATES)**

Both phenyl isocyanate and 1-naphthyl isocyanate (CAUTION: see p. 51) react with alcohols to yield phenyurethans and 1-napthylurethans respectively:

\[
\text{Ph-N}=\text{C}==\text{O} + \text{ROH} \rightarrow \text{Ph-NH-CO}_2\text{R}
\]

\[
\text{C}_{10}\text{H}_{7.1}\cdot\text{N}=\text{C}==\text{O} + \text{ROH} \rightarrow \text{C}_{10}\text{H}_{7.1}\cdot\text{NH-CO}_2\text{R}
\]

If the alcohol is not anhydrous, reaction also occurs between the water and the reagent to produce diphenylurea (m.p. 238 °C) and di-1-naphthylurea (m.p. 297 °C) respectively, for example:

\[
2\text{Ph-N}=\text{C}==\text{O} + \text{H}_2\text{O} \rightarrow \text{Ph-NH-CO-NH-Ph} + \text{CO}_2
\]
The ureas are less soluble than the corresponding urethans, but their separation is not always easy. For this reason the urethans are generally prepared from alcohols which are insoluble in water and can therefore be easily obtained in the anhydrous condition.

1-Naphthyl isocyanate is usually preferred to phenyl isocyanate for the following reasons: (a) it is much less lachrymatory; (b) it is not so readily decomposed by cold water and thus possesses better keeping qualities; and (c) the melting points of the 1-naphthylurethans are generally higher than those of the corresponding phenylurethans. Furthermore, with primary alcohols, which react readily in the cold, only small amounts of the urea are produced and these may be removed by taking advantage of the extreme insolubility of di-1-naphthylurea in hot ligroin. (See also Section 9.6.8, p. 1251.)

Place 1 g of the anhydrous alcohol in a dry test tube and add 0.5 ml of 1-naphthyl isocyanate* (if the molecular weight is known, use a 10% excess of the reagent); insert a loose plug of cotton wool in the mouth of the tube. If no solid separates after shaking and standing for 5 minutes, warm on a water bath for 5–10 minutes, and then cool in ice. If no solid is now obtained, 'scratch' the sides of the tube with a glass rod to induce crystallisation. Extract the solid with 5–10 ml of boiling light petroleum (b.p. 100–120 °C); this rapidly dissolves the 1-naphthylurethan but not the di-1-naphthylurea. Remove the urea (if any) by filtration and allow the hot solution to cool. If the urethan does not crystallise out, evaporate the solution to half its original volume, and allow to cool. Collect the crystals on a filter, dry and determine the melting point. If the latter is not sharp, recrystallise from light petroleum (b.p. 100–120 °C), ethanol, chloroform or dichloromethane.

**HYDROGEN 3-NITROPHTHALATES**

3-Nitrophthalic anhydride, a yellow crystalline powder of m.p. 163–164 °C, reacts with alcohols to yield monoesters of 3-nitrophthalic acid. Although two isomeric esters are theoretically possible, the main product is the 2-ester; traces of the isomeric 1-ester are eliminated during purification.

\[
\begin{align*}
\text{CO} & \quad \text{O} \\
\text{CO} & \quad \text{CO}_2R \\
\text{NO}_2 & \quad \text{CO}_2H
\end{align*}
\]

The reagent must be carefully protected from moisture as it is comparatively easily hydrated to the acid, m.p. 216–218 °C (sealed capillary tube). Dilute aqueous solutions of an alcohol should be treated with solid potassium carbonate and the alcohol layer used for the test.

Phthalic anhydride reacts similarly (see Section 5.19, p. 809), but the acid phthalates are somewhat more difficult to isolate and the melting points are considerably lower.

For alcohols of b.p. below 150 °C, mix 0.5 g of 3-nitrophthalic anhydride (Expt 6.162) and 0.5 ml (0.4 g) of the alcohol in a test tube fitted with a short condenser, and heat under reflux for 10 minutes after the mixture liquefies. For alco-

* The procedure for phenyl isocyanate is similar, but great care must be taken to protect both the reagent and the reaction mixture from moisture.
hols boiling above 150 °C, use the same quantities of reactants, add 5 ml of dry toluene, heat under reflux until all the anhydride has dissolved and then for 20 minutes more: remove the toluene under reduced pressure (suction with water pump). The reaction product usually solidifies upon cooling, particularly upon rubbing with a glass rod and standing. If it does not crystallise, extract it with dilute sodium hydrogen carbonate solution, wash the extract with ether and acidify. Recrystallise from hot water, or from 30 to 40 per cent ethanol or from toluene. It may be noted that the m.p. of 3-nitrophthalic acid is 218 °C.

3,4,5-TRIODOBENZOATES
The derivatives enumerated above are unsatisfactory for hydroxy ethers, e.g. the mono-ethers of ethyleneglycol (‘cellosolves’) and the mono-ethers of diethylenglycol (‘carbitols’) (see Table 10.4). Crystalline derivatives of hydroxy ethers are readily obtained with 3,4,5-triiodobenzoyle chloride, for example:

\[ 3,4,5-\text{I}_3\text{C}_6\text{H}_2\text{COCl} + \text{HOCH}_2\text{CH}_2\text{OR} \xrightarrow{\text{HCl}} 3,4,5-\text{I}_3\text{C}_6\text{H}_2\text{CO}_2\text{CH}_2\text{CH}_2\text{OR} \]

Place 0.5 g of 3,4,5-triiodobenzoyle chloride in a small test tube, add 0.25 ml of the hydroxy ether and heat the mixture gently over a micro burner until the evolution of hydrogen chloride ceases (3–5 minutes). Pour the molten mass into 10 ml of 20 per cent ethanol to which crushed ice has been added. Some derivatives solidify instantly; those which separate as oils change to solids in a few minutes without further manipulation. Recrystallise from rectified spirit (use 50% ethanol for esters of methyl and butyl carbitol).

3,4,5-Triiodobenzoyle chloride is prepared by refluxing 5 g of 3,4,5-triiodobenzoic acid (Expt 6.70) with 10 ml of thionyl chloride for 2 hours. The excess thionyl chloride is removed by distillation and the residue recrystallised from carbon tetrachloride–light petroleum. The acid chloride has m.p. 138 °C; the yield is 3.8 g. It should be kept in a well-stoppered bottle.

PSEUDOSACCHARIN ETHERS
Pseudosaccharin chloride (Expt 6.42) reacts with alcohols to give ethers (O-alkyl derivatives of saccharin):

\[ \text{S}_2\text{NCCl} + \text{HOR} \xrightarrow{} \text{S}_2\text{NCO} + \text{HCl} \]

Heat a little pseudosaccharin chloride with excess of the anhydrous alcohol in a test tube until hydrogen chloride is no longer evolved. Recrystallise from ethanol or other organic solvent.

With the lower primary alcohols, heating at 100 °C for 10 minutes suffices; for higher alcohols, a temperature of 125 °C is preferable. Secondary alcohols require longer heating at 125 °C. A large excess of alcohol should be used when identifying the lower alcohols and the excess removed by evaporation; for the higher alcohols, it is better to employ an excess of pseudosaccharin chloride and the product washed free from the reagent with dilute aqueous alkali.

The melting points of derivatives of selected aliphatic alcohols and polyhydric alcohols are collected in Tables 10.4 and 10.8 respectively.

The melting points of some derivatives of aromatic alcohols are collected in Table 10.5.
9.6.5 CARBOHYDRATES

The melting points (more accurately termed the decomposition points) of sugars and some of their derivatives, e.g. osazones, are not so definite as those of other classes of organic compounds: they vary with the rate of heating and the differences between individual members are not always large. There are, however, a number of reactions and derivatives which will assist in the characterisation of the simple sugars.

OSAZONE FORMATION

The carbohydrates containing a potential aldehyde or keto group in their cyclic form react with one molecular proportion of phenylhydrazine in the cold to form the corresponding phenylhydrazones (compare Aldehydes and ketones, Section 9.6.13, p. 1257); these are usually soluble in water and consequently are of little value for purposes of separation and identification. If, however, the carbohydrate is heated in the presence of excess (3–4 moles) of phenylhydrazine, the >CHOH in an aldose or the —CH₂OH in a ketose adjacent to the phenylhydrazone group is effectively oxidised by one molecule of phenylhydrazine to the corresponding carbonyl group, which then reacts with a further molecule of phenylhydrazine to give a bisphenylhydrazone or osazone; aniline and ammonia are by-products of the reaction.
Glucose and fructose (and also mannose) form the same osazone. The osazones are usually yellow, well-defined crystalline compounds and are sparingly soluble in cold water. The characteristic crystalline forms of the osazones of the commonly occurring sugars, when examined under the microscope, may be employed for their identification (Fig. 9.1); the melting or decomposition
points are less satisfactory since these depend to a marked degree on the rate of heating.

Certain carbohydrates (sugars) may be identified by the length of time required to form osazones upon treatment with phenylhydrazine under standard experimental conditions. Monosaccharides give precipitates at 100°C within 20 minutes. The disaccharides maltose and lactose give no osazone at 100°C even after 2 hours, but osazones are obtained on cooling after 10–15 minutes heating. With sucrose an osazone commences to separate after about 30 minutes, due to gradual hydrolysis into glucose and fructose, but no osazone is produced on cooling after heating for 10–15 minutes.

Place 0.20 g of the carbohydrate, 0.40 g of pure white phenylhydrazine hydrochloride, e.g. of AnalaR quality; (CAUTION: handle with great care), 0.60 g of crystallised sodium acetate and 4.00 ml of water in a dry test tube. (Weigh the quantities within an accuracy of 0.01 g.) Stopper the tube loosely with a cork, and stand or clamp it upright in a beaker containing boiling water. Note the time of immersion and the time when the osazone first separates. Shake the tube occasionally (without removing it from the boiling water) in order to prevent supersaturation. The precipitate separates quite suddenly: duplicate experiments should agree within 0.5 minute. Note whether the precipitate is white (mannose), yellow or orange yellow, and whether it is crystalline or ‘oily’.

The approximate times of osazone formation in minutes are given in Table 10.9. The product from mannose is the simple hydrazone and is practically white. Arabinose osazone separates first as an oil, while that from galactose is highly crystalline. Lactose and maltose give no precipitate from hot solution.

**p-NITROPHENYLHYDRAZONES**

This reagent has been used in the characterisation of a number of monosaccharides.

Heat 0.25 g of the compound with 3 ml of ethanol, add 0.25 g of *p*-nitrophenylhydrazine and heat the suspension until the reaction appears complete. The *p*-nitrophenylhydrazone soon separates. Filter, preferably after standing overnight, wash with a little cold ethanol and then recrystallise from ethanol.

**ACETATES**

Complete acetylation of all the hydroxyl groups is desirable in order to avoid mixtures. In some cases, the completely acetylated sugars may be obtained in the α- or β-forms depending upon the catalyst, e.g. zinc chloride or sodium acetate, that is employed in the acetylation. The experimental details for acetylation may be easily adapted from those already given for α- and β-glucose penta-acetates (Expts 5.106 and 5.107 respectively).

**BENZOATES**

Benzoyl chloride has a limited application as a reagent in the sugar series. Details for the benzoylation of D-glucose are given in Expt 5.108.

**TRIMETHYLSILYLATION**

The conversion of monosaccharides and the smaller oligosaccharides (di, tri, and tetra-) into their trimethylsilyl derivatives, which are sufficiently volatile to be analysed by g.l.c., has greatly simplified the problem of sugar identification. The method described in Section 2.31 uses hexamethyldisilazane and chlorotri-
methylsilane in pyridine solution, and may conveniently be applied to a sample size down to 1 mg; the trimethylsilylation reaction is complete within about 20 minutes.

$$\text{CHOH} + [\text{Me}_3\text{Si}]_2\text{NH}/\text{Me}_3\text{SiCl} \xrightarrow{\text{pyridine}} \text{CHO} \cdot \text{SiMe}_3$$

The melting points of some derivatives of carbohydrates are included in Table 10.9.

9.6.6 PHENOLS

ACETATES
The acetates of monohydric phenols are usually liquids, but those of di- and trihydric phenols and also of many substituted phenols are frequently crystalline solids.

Acetates may be prepared by adding acetic anhydride to somewhat dilute solutions of compounds containing hydroxyl (or amino) groups in aqueous caustic alkalies. The amount of alkali used should suffice to leave the liquid slightly basic at the end of the operation, so much ice should be added that a little remains unmelted, and the acetic anhydride should be added quickly.

Dissolve 0.01 mol (or 1 g if the molecular weight is unknown) of the compound in 5 ml of 3 m sodium hydroxide solution, add 10–20 g of crushed ice followed by 1.5 g (1.5 ml) of acetic anhydride. Shake the mixture vigorously for 30–60 seconds. The acetate separates in a practically pure condition either at once or after acidification by the addition of a mineral acid. Collect the acetyl derivative, and recrystallise it from hot water or from dilute ethanol.

BENZOATES
The benzoates of a few phenols (e.g. o-cresol) are liquids. Many phenols do, however, yield crystalline benzoyl derivatives: these are useful for purposes of characterisation.

The Schotten–Baumann method of benzoylation with benzoyl chloride in the presence of aqueous sodium hydroxide may be used. Full details are given under Primary and secondary amines, Section 9.6.21, p. 1273. Alternatively, dissolve 1.0 g of the phenol in 3 ml of dry pyridine and add 0.5 g of benzoyl chloride. After the initial reaction has subsided, warm the mixture over a small flame for a minute or two and pour, with vigorous stirring, into 10–15 ml of water. Allow the precipitate to settle, decant the supernatant liquid, stir the residue thoroughly with 5–10 ml of m sodium carbonate solution, filter and recrystallise from ethanol or from light petroleum.

TOLUENE-p-SULPHONATES
Toluene-p-sulphonyl chloride reacts readily with phenols to yield toluene-p-sulphonates:

$$p\cdot\text{Me} \cdot C_6\text{H}_4\cdot \text{SO}_2\text{Cl} + \text{ArOH} \rightarrow p\cdot\text{Me} \cdot C_6\text{H}_4\cdot \text{SO}_2\text{OAr} + \text{HCl}$$

Mix 1.0 g of the phenol with 2.5 ml of pyridine, add 2 g of toluene-p-sulphonyl chloride and heat on a water bath for 15 minutes. Pour into 25 ml of cold water and stir until the oil solidifies. Filter, wash with cold dilute hydrochloric acid (to remove pyridine), with cold dilute sodium hydroxide solution (to remove any
phenol present), and then with cold water. Recrystallise from methanol or ethanol.

**p-NITROBENZOATES AND 3,5-DINITROBENZOATES**

Both p-nitrobenzoyl chloride and 3,5-dinitrobenzoyl chloride react with phenols, best in pyridine solution, to yield crystalline p-nitrobenzoates and 3,5-dinitrobenzoates respectively:

\[
p-\text{NO}_2\text{C}_6\text{H}_4\text{COCl} + \text{ArOH} \rightarrow p-\text{NO}_2\text{C}_6\text{H}_4\text{COAr} + \text{HCl} \\
3,5-(\text{NO}_2)_2\text{C}_6\text{H}_3\text{COCl} + \text{ArOH} \rightarrow 3,5-(\text{NO}_2)_2\text{C}_6\text{H}_3\text{COAr} + \text{HCl}
\]

For properties of these reagents and their preparation from the corresponding acids, see under *Alcohols and polyhydric alcohols*, Section 9.6.4, p. 1241.

Dissolve 0.5 g of the phenol in 4–5 ml of dry pyridine, add 1.3 g of 3,5-dinitrobenzoyl chloride and reflux for 25–30 minutes. Pour the cold reaction mixture into 40 ml of c. 2 m-hydrochloric acid. Decant the supernatant aqueous liquid from the precipitated solid or oil and stir it vigorously with about 10 ml of sodium carbonate solution. Filter off the solid derivative and wash it with water. Recrystallise from ethanol, dilute ethanol, toluene-acetone or toluene-light petroleum (b.p. 60–80 °C).

**ARYLOXACETIC ACIDS**

Phenols, in the presence of alkali, react with chloroacetic acid to give arylxooxetic acids, which are generally crystalline compounds with sharp melting points. (See also Expt 6.110.)

\[
\text{Ar} \cdot \text{O}^- + \text{Cl} \cdot \text{CH}_2 \cdot \text{CO}_2^- \xrightarrow{\text{Cl}^-} \text{Ar} \cdot \text{O} \cdot \text{CH}_2 \cdot \text{CO}_2^- \xrightarrow{\text{H}^+} \text{Ar} \cdot \text{O} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H}
\]

To a mixture of 1.0 g of the compound and 3.5 ml of 33 per cent sodium hydroxide solution in a test tube, add 2.5 ml of 50 per cent chloroacetic acid solution. If necessary, add a little water to dissolve the sodium salt of the phenol. Stopper the test tube loosely and heat on a gently boiling water bath for an hour. After cooling, dilute with 10 ml of water, acidify to Congo red with dilute hydrochloric acid and extract with 30 ml of ether. Wash the ethereal extract with 10 ml of water, and extract the arylxooxetric acid by shaking with 25 ml of 5 per cent sodium carbonate solution. Acidify the sodium carbonate extract (to Congo red) with dilute hydrochloric acid, collect the arylxooxetric acid which separates and recrystallise it from water or from aqueous ethanol.

**DIPHENYLURETHANS**

Phenols react with diphenylcarbamoyl chloride to yield diphenylurethans (or aryl N,N-diphenylcarbamates):

\[
\text{Ph}_2\text{N} \cdot \text{COCl} + \text{HOAr} \xrightarrow{\text{C}_6\text{H}_5\text{N}} \text{Ph}_2\text{N} \cdot \text{COAr} + \text{HCl}
\]

The reagent is unsuitable for a number of phenolic acids.

Dissolve 0.5 g of the phenol in 2.5 ml of pyridine, and add one equivalent of diphenylcarbamoyl chloride (or 0.4–0.5 g if the molecular weight is uncertain). Reflux the mixture for 30–60 minutes on a boiling-water bath, and then pour into about 25 ml of water. Filter the derivative, wash with a little sodium hydrogen carbonate solution and recrystallise from ethanol, toluene, light petroleum (b.p. 60–80 °C) or dichloromethane.
1-NAPHTHYLURETHANS

1-Naphthyl isocyanate reacts smoothly with monohydric, but not with poly-
hydric, phenols to give 1-naphthylurethans (or N-1-naphthylcarbamates):

\[ C_{10}H_7N\equiv C=O + ArOH \rightarrow C_{10}H_7NH\cdot CO_2Ar \]

(compare Alcohols and polyhydric alcohols, Section 9.64, p. 1242). Some phenols,
e.g. nitrophenols and halogeno-phenols, react with difficulty with the reagent
alone; the addition of a few drops of pyridine or 1 drop of an ethereal solution of
trimethylamine or triethylamine generally results in the rapid formation of the
urethan.

Place 0.25 g of the phenol together with an equal weight of 1-naphthyl iso-
cyanate in a dry test tube closed with a stopper carrying a calcium chloride
guard-tube. If a spontaneous reaction does not occur, boil the mixture gently for
2–3 minutes, and cool; if the reaction mixture does not solidify, rub the walls of
the tube vigorously with a glass rod. If no crystalline solid is obtained, add 2
drops of dry pyridine or 1 drop of an ethereal solution of triethylamine, and
warm on a water bath for 5 minutes. Extract contents of the tube with boiling
light petroleum (b.p. 80–100 °C or 100–120 °C) to separate any insoluble di-1-
naphthyl urea. Recrystallise the crystals which separate on cooling from the
same solvent.

The following alternative method may be used. Dissolve 0.01 mol of the phe-
nol and 0.01 mol of 1-naphthyl isocyanate in 20 ml of light petroleum (b.p. 60–
80 °C), add 2 drops of triethylamine (or, less satisfactorily, 2 drops of pyridine),
reflux for 5 minutes and allow to crystallise. Filter off the crystalline solid
through a sintered glass funnel.

2,4-DINITROPHENYL ETHERS

1-Chloro-2,4-dinitrobenzene reacts with the sodium salts of phenols to yield
crystalline 2,4-dinitrophenyl ethers:

\[ C_6H_4Cl+ArONa \rightarrow (NO_2)_2C_6H_3\cdot O\cdot Ar + NaCl \]

Dissolve 1 g (or 0.01 mol) of the phenol in a solution of 0.40 g of sodium
hydroxide in 5 ml of water. Add the resulting solution to 2.0 g of 1-chloro-2,4-
dinitrobenzene dissolved in 30 ml of 95 per cent ethanol; add more ethanol, if
necessary, to effect solution. Heat the solution under reflux on a water bath until
the colour (usually red) is discharged and a copious precipitate of sodium chloride
appears (30–60 minutes). Dilute the reaction mixture with an equal volume of
water, filter off the precipitated 2,4-dinitrophenyl ether, wash with water and
recrystallise from ethanol.

Note. The chlorodinitrobenzene must be handled cautiously (use disposable gloves). If
any touches the skin, wash it with industrial spirit and then copiously with water.

PSEUDOSACCHARIN ETHERS

When pseudosaccharin chloride is heated with an excess of a phenol, O-aryl
derivatives of saccharin are produced (compare Section 9.64, p. 1244).

Heat 0.5 g of pseudosaccharin chloride with an excess of the phenol to 125–
140 °C for 15–20 minutes; hydrogen chloride is evolved. Wash the product with
dilute sodium hydroxide solution and then with water. Recrystallise the derivat-
ive from ethanol.
BROMO DERIVATIVES
The presence of the hydroxyl group in phenols facilitates the substitution of the nuclear hydrogen atoms by halogen; the number and position of the substituent atoms varies with the nature of the phenol. This method is an indirect means of identification, as the formation of a substitution derivative is not a characteristic reaction of the phenol group but of the benzene nucleus. Phenol reacts with bromine to give 2,4,6-tribromophenol:

\[ \text{PhOH} + 3\text{Br}_2 \rightarrow 2,4,6\text{-Br}_3\text{C}_6\text{H}_3\text{OH} + 3\text{HBr} \]

Bromo derivatives are often difficult to prepare, particularly in the case of polyhydroxy phenols which oxidise easily.

Dissolve 1.0 g of the compound in 10–15 ml of glacial acetic acid, cautiously add a solution of 3–4 ml of liquid bromine in 10–15 ml of glacial acetic acid until the colour of bromine persists and allow the mixture to stand for 15–20 minutes. Pour into 50–100 ml of water, filter off the bromo compound at the pump and wash with a little cold water. Recrystallise from dilute ethanol. Alternatively dissolve 1.0 g of the phenol in water, ethanol or acetone and add slowly, with constant shaking, just sufficient of a bromine solution (prepared by adding 5 g of bromine to a solution of 7.5 g of potassium bromide in 50 ml of water) to impart a yellow colour to the mixture. Allow to stand for 5 minutes. Add about 50 ml of water, and shake vigorously to break up any lumps. Filter and wash the bromo derivative with a dilute solution of sodium metabisulphite. Recrystallise from ethanol or from dilute ethanol.

The melting points of the derivatives of a number of selected phenols are collected in Table 10.6.

9.6.7 ENOLS
\(\beta\)-Keto esters and some 1,3-diketones may be characterised by conversion into semicarbazones (see Aldehydes and ketones, Section 9.6.13, p. 1258).

Heating with an equivalent amount of phenylhydrazine often yields characteristic derivatives. Thus \(\beta\)-keto esters afford 1-phenylpyrazalones (cf. Expt 8.15), while 1,3-diketones yield 1-phenylpyrazalones (cf. Expt 8.14).

Heat a mixture of 0.5 g. of the \(\beta\)-keto ester and an equivalent amount of phenylhydrazine in an oil bath at 100–110 °C for 2 hours. Water and alcohol vapours are evolved. Cool and recrystallise the product from ethanol.

For 1,3-diketones, excellent results are obtained by refluxing the reactants in ethanolic solution for 2–3 hours; the product separates on cooling.

The physical properties as well as the melting points of the derivatives of a number of enols (\(\beta\)-keto esters and 1,3-diketones) are given in Table 10.7.

9.6.8 ALIPHATIC HALOGEN COMPOUNDS
ANILIDES AND 1-NAPHTHALIDES
The Grignard reagents prepared from alkyl halides react with phenyl isocyanate or with 1-naphthyl isocyanate to yield addition products that are converted by hydrolysis into anilides and naphthalides respectively:

\[ \text{Ar} \cdot \text{NCO} + \text{RMgX} \rightarrow \text{Ar} \cdot \text{N} = \text{C(OMgX)}\text{R} \quad \text{H}_2\text{O} \rightarrow \text{Ar} \cdot \text{N} = \text{C(OH)}\text{R} \quad \text{Ar} \cdot \text{NH} \cdot \text{CO} \cdot \text{R} \]
Phenyl isocyanate is a colourless liquid, b.p. 164°C or 55°C/13 mmHg; its vapour is lachrymatory. The liquid reacts readily with water, yielding diphenyl urea, m.p. 238°C, and hence must be protected from atmospheric moisture:

\[ \text{Ph} \cdot \text{NCO} + \text{H}_2\text{O} \rightarrow \text{Ph} \cdot \text{NHCONH} \cdot \text{Ph} + \text{CO}_2 \]

1-Naphthyl isocyanate, b.p. 269–270°C or 153°C/18 mmHg, is not quite so irritant and is somewhat more stable towards water (di-1-naphthyl urea has m.p. 297°C). It is therefore to be preferred as a reagent; furthermore the 1-naphthalides are less soluble than the corresponding anilides.

In a small dry flask, fitted with a short reflux condenser and a calcium chloride guard-tube, place 0.4 g of dry magnesium turnings, a minute crystal of iodine and a solution of 1 ml (or 0.01 mol) of the alkyl halide in 10–15 ml of anhydrous ether. If the reaction does not start immediately (as indicated by the disappearance of the iodine colour), warm for a short period in a beaker of warm water; allow the reaction to proceed spontaneously, moderating it if necessary by immersing the flask in cold water. When the reaction has ceased, decant the nearly clear liquid from any solid material into another flask, and fit the reflux condenser into it. Add, portionwise, through the condenser a solution of 0.5 ml of phenyl or 1-naphthyl isocyanate in 15 ml of anhydrous ether, shaking the flask after each addition. Allow the mixture to stand for 10 minutes and then add 30 ml of m hydrochloric acid dropwise and with vigorous shaking and cooling in ice. (Alternatively, pour the reaction mixture cautiously into 20 ml of ice water containing 1 ml of concentrated hydrochloric acid, and shake the mixture well.) Transfer to a separatory funnel, shake well, then discard the lower aqueous layer. Dry the ethereal solution with a little magnesium sulphate and distil off the ether. Recrystallise the residue: methanol, ethanol, light petroleum, ether or hot water are suitable recrystallisation solvents.

**ALKYL MERCURY(II) HALIDES**

Grignard reagents, prepared from alkyl halides, react with a mercury(II) halide that contains the same halogen as the reagent to form alkyl mercury(II) halides:

\[ \text{RMgX} + \text{HgX}_2 \rightarrow \text{RHgX} + \text{MgX}_2 \]

The reaction is applicable to primary and secondary halides only; tertiary halides do not react.

Filter the Grignard solution, prepared as in *Anilides and 1-naphthalides*, rapidly through a little glass wool into a test tube containing 4–5 g of mercury(II) chloride, bromide or iodide (CAUTION), depending upon the halogen in the original alkyl halide. Shake the reaction mixture vigorously for a few minutes and then evaporate the ether. Boil the residue with 20 ml of rectified spirit, filter the solution, dilute it with 10 ml of distilled water, reheat to dissolve any precipitated solid and allow to cool. Recrystallise the alkyl mercury(II) halide from dilute ethanol.

**S-ALKYLISOTHIOURIUM PICRATES**

Alkyl bromides or iodides react with thiourea in ethanolic solution to produce S-alkylisothiouronium salts, which yield picrates of sharp melting point:
RX + S═C<sub>NH₂</sub><br>\[ \text{R} \cdot \text{S} \cdot C \equiv \text{NH}_2 \]\( ^{\ominus} \) \[ \text{X}^{\ominus} \xrightarrow{\text{HOC}_6\text{H}_2(\text{NO}_2)_3} \]

\[ \text{R} \cdot \text{S} \cdot C \equiv \text{NH}_2 \]^\( ^{\ominus} \) \[ \text{OC}_6\text{H}_2(\text{NO}_2)_3 \]

Alkyl chlorides react slowly and the yield of the derivative is poor. Tertiary halides give anomalous results.

Place a mixture of 0.5 g of finely powdered thiourea (CAUTION), 0.5 g of the alkyl halide and 5 ml of ethanol in a test tube or small flask equipped with a reflux condenser. Reflux the mixture for a period depending upon the nature of the halide: primary alkyl bromides and iodides, 10–20 minutes (according to the molecular weight); secondary alkyl bromides or iodides, 2–3 hours; alkyl chlorides, 3–5 hours; polymethylene dibromides or di-iodides, 20–50 minutes. Then add 0.5 g of picric acid, boil until a clear solution is obtained and cool. If no precipitate is obtained, add a few drops of water. Recrystallise the resulting S-alkyl isothiouronium picrate from ethanol.

**PICRATES OF ALKYL 2-NAPHTHYL ETHERS**

Alkyl halides react with the sodium or potassium derivative of 2-naphthol in alcoholic solution to yield the corresponding alkyl 2-naphthyl ethers (which are usually low m.p. solids) and the latter are converted by picric acid into the crystalline picrates:

RX + 2-C<sub>10</sub>H<sub>7</sub>ONa \( \rightarrow \) 2-C<sub>10</sub>H<sub>7</sub>OR + NaX

Mix together 1.0 g of pure 2-naphthol and the theoretical quantity of 50 per cent potassium hydroxide solution, add 0.5 g of the halide, followed by sufficient rectified spirit to produce a clear solution. For alkyl chlorides, the addition of a little potassium iodide is recommended. Heat the mixture under reflux for 15 minutes, and dissolve any potassium halide by the addition of a few drops of water. The 2-naphthyl ether usually crystallises out on cooling; if it does not, dilute the solution with 10 per cent sodium hydroxide solution until precipitation occurs. Dissolve the 2-naphthyl ether in the minimum volume of hot ethanol and add the calculated quantity of picric acid dissolved in hot ethanol. The picrate separates out on cooling. Recrystallise it from rectified spirit.

The 2-naphthyl ethers from methylene halides have m.p. 133 °C, from ethylene halides 217 °C and trimethylene halides 148 °C.

Table 10.10, deals with a number of aliphatic halogen compounds together with their crystalline derivatives.

**9.6.9 AROMATIC HALOGEN COMPOUNDS**

**NITRATION PRODUCTS**

Although no general method of nitration can be given, the following procedure is widely applicable.

* Alkyl chlorides often react more rapidly (50–60 minutes) upon adding 0.5 g of potassium iodide to the original reaction mixture, followed by sufficient water or ethanol to produce a clear solution at the boiling point. After refluxing, 0.5 g of picric acid is added, etc.
Add 1 g of the compound to 4 ml of concentrated sulphuric acid and cautiously introduce, drop by drop, 4 ml of fuming nitric acid. Warm the mixture on a water bath for 10 minutes, then pour it on to 25 g of crushed ice (or 25 ml of ice-water). Collect the precipitate by filtration at the pump, and recrystallise it from dilute ethanol.

Twenty per cent oleum may be substituted for the concentrated sulphuric acid for compounds which are difficult to nitrate.

**REACTION WITH CHLOROSULPHONIC ACID – SULPHONAMIDES**

Many aryl halides, either alone or in chloroform solution, when treated with excess of chlorosulphonic acid afford the corresponding sulphonyl chlorides in good yield (use the experimental details given in Section 9.6.3, p. 1238); the latter may be readily converted into the aryl sulphonamides by reaction with concentrated ammonia solution or with solid ammonium carbonate.

The following give abnormal results when treated with chlorosulphonic acid alone, preferably at 50°C for 30–60 minutes: fluorobenzene (4,4'-difluorodiphenylsulphone, m.p. 98°C); iodobenzene (4,4'-diiododiphenylsulphone, m.p. 202°C); o-dichlorobenzene (3,4,3',4'-tetrachlorodiphenylsulphone, m.p. 176°C); and o-dibromobenzene (3,4,3',4'-tetrabromodiphenylsulphone, m.p. 176–177°C). The resulting sulphones may be crystallised from glacial acetic acid, toluene or ethanol, and are satisfactory for identification of the original aryl halide. In some cases sulphones accompany the sulphonyl chloride; they are readily separated from the final sulphonamide by their insolubility in cold 6 M sodium hydroxide solution; the sulphonamides dissolve readily and are reprecipitated by 6 M hydrochloric acid.

**OXIDATION OF SIDE CHAINS**

The oxidation of halogenated toluenes and similar compounds and of compounds with side chains of the type –CH₂Cl and –CH₂OH proceeds comparatively smoothly with alkaline permanganate solution (for experimental details, see under *Aromatic hydrocarbons*, Section 9.6.3, p. 1239 and also Expt 6.149). The resulting acid may be identified by a m.p. determination and by the preparation of suitable derivatives (see Section 9.6.15, p. 1261).

**PICRATES**

Some halogen derivatives of polynuclear aromatic hydrocarbons form picrates (for experimental details, see under *Aromatic hydrocarbons*, Section 9.6.3, p. 1240), for example, 1-chloronaphthalene (m.p. 137°C), 1-bromonaphthalene (m.p. 134°C) and 2-bromonaphthalene (m.p. 86°C).

The properties of a number of aromatic halogen compounds together with the melting points of their derivatives are collected in Table 10.11.

**9.6.10 ALIPHATIC ETHERS**

The low reactivity of aliphatic ethers renders the problem of the preparation of suitable crystalline derivatives a somewhat difficult one. There are, however, two reactions based upon the cleavage of the ethers which are useful for characterisation.
REACTION WITH 3,5-DINITROBENZOYL CHLORIDE

Ethers undergo cleavage with 3,5-dinitrobenzoyl chloride in the presence of zinc chloride:

\[
ROR + (NO_2)_2C_6H_3COCl \xrightarrow{\text{ZnCl}_2} (NO_2)_2C_6H_3CO_2R + RCl
\]

The resulting alkyl 3,5-dinitrobenzoate may be employed for the characterisation of the ether. The method is only applicable to symmetrical ethers; a mixed aliphatic ether \( R^1 OR^2 \) would yield a mixture of solid esters.

Add 1 ml of the ether to 0.1–0.15 g of finely powdered anhydrous zinc chloride and 0.5 g of pure 3,5-dinitrobenzoyl chloride (Section 9.6.4, p. 1241) contained in a test tube; attach a small water condenser and reflux gently for 1 hour. Treat the reaction product with 10 ml of 0.75 M sodium carbonate solution, heat and stir the mixture for 1 minute upon a boiling water bath, allow to cool and filter at the pump. Wash the precipitate with 5 ml of 0.75 M sodium carbonate solution and twice with 5 ml of ether. Dry on a porous tile or upon a pad of filter paper. Transfer the crude ester to a test tube and boil it with 10 ml of dichloromethane; filter the hot solution, if necessary. If the ester does not separate on cooling, evaporate to dryness on a water bath, and recrystallise the residue from 2–3 ml of either aqueous ethanol or light petroleum. Determine the melting point of the resulting 3,5-dinitrobenzoate (see Table 10.4).

CLEAVAGE OF ETHERS WITH HYDRIODIC ACID

Aliphatic ethers suffer fission when boiled with constant boiling point hydriodic acid. (See also Section 5.4.6, p. 550.)

\[
R^1 OR^2 + 2HI \rightarrow R^1 I + R^2 I + H_2O
\]

If the ether is a simple one (\( R^1 = R^2 \)), the identification of the resulting alkyl iodide presents no difficulties. If, however, it is a mixed aliphatic ether, the separation of the two alkyl iodides by fractional distillation is generally difficult unless \( R^1 \) and \( R^2 \) differ considerably in molecular weight and sufficient material is available.

Reflux 1 ml of the ether with 5 ml of freshly distilled, constant boiling point hydriodic acid (Section 4.2.32, p. 436), b.p. 126–128 °C, for 2–3 hours. Add 10 ml of water, distil and collect about 7 ml of liquid. Decolourise the distillate by the addition of a little sodium metabisulphite, and separate the two layers by means of a dropper pipette. Determine the b.p. of the resulting iodide by the Siwoloboff method (Section 2.34) and prepare a crystalline derivative (Section 9.6.8, p. 1251).

The physical properties of a number of aliphatic ethers, including cyclic ethers, are collected in Table 10.12.

9.6.11 AROMATIC ETHERS

Commonly encountered purely aromatic ethers (e.g. diphenyl ether) are limited in number; most aromatic ethers are of the mixed aliphatic–aromatic type. The following procedures may be used for their characterisation.

CLEAVAGE WITH A HYDRIODIC ACID

Aromatic ethers undergo fission when heated with constant boiling point hydriodic acid:
ArOR + HI $\rightarrow$ ArOH + RI

The cleavage products are a phenol and an alkyl iodide, which will serve to characterise the ether (see also Section 6.9.4, p. 988).

Experimental details can easily be adapted from those given under Aliphatic ethers, Section 9.6.10, p. 1254.

To isolate the phenol, treat the residue in the flask with aqueous sodium carbonate until alkaline and extract the mixture with ether. Wash the ethereal extract with saturated aqueous sodium carbonate, and then with 2 M sodium hydroxide solution. Acidify the sodium hydroxide solution (to Congo red paper) and extract the liberated phenol with ether. Characterise the phenol as in Section 9.6.6, p. 1248.

**PICRATES**

Ethers of many polynuclear aromatic systems are conveniently characterised as their picrates prepared by the method described for the corresponding derivates in Aromatic hydrocarbons, Section 9.6.3, p. 1238.

**DERIVATIVES BY NUCLEAR SUBSTITUTION**

**Nitration.** These may generally be prepared as detailed under Aromatic hydrocarbons, Section 9.6.3, p. 1238; the following experimental procedure for anisole may be regarded as typical. Add 0.5 g of anisole to a mixture of equal volumes of concentrated nitric acid and concentrated sulphuric acid keeping the temperature below 25 °C by cooling in an ice bath. Finally warm to 40 °C until dilution of a small portion with water gives a solid product. Pour the whole of the reaction mixture into water; collect the resulting 2,4-dinitroanisole and recrystallise from ethanol.

**Bromination.** These may be prepared as described under Phenols, Section 9.6.6, p. 1251, using glacial acetic acid as solvent. In some cases dichloromethane is a satisfactory solvent; the dichloromethane is separated by distillation and the residue is recrystallised from dilute ethanol.

**Formation of sulphonamides.** These may be prepared as described for Aromatic hydrocarbons, Section 9.6.3, p. 1238.

**OXIDATION OF SIDE CHAINS**

General conditions for the oxidation of an alkyl side chain attached to an aromatic ring are given under Aromatic hydrocarbons, Section 9.6.3, p. 1239. The following procedure for the oxidation of p-cresyl methyl ether to anisic acid is illustrative.

Prepare a solution of 6 g of potassium permanganate in a mixture of 20 ml of 5 per cent sodium hydroxide solution and 150 ml of water, add 2.0 g of p-cresyl methyl ether and heat under reflux for 2–3 hours. If any permanganate remains at the end of this period, destroy it by the addition of a few drops of ethanol. Remove the precipitated manganese dioxide by filtration at the pump, evaporate the filtrate to a volume of 25–30 ml and acidify it (to Congo red) with dilute sulphuric acid. Anisic acid, m.p. 183–184 °C, crystallises out on cooling.

Table 10.13 contains data referring to a number of selected aromatic ethers.
9.6.12 ACETALS

Acetals may be characterised by reference to the alcohol and aldehyde (or ketone if a ketal) which they yield readily when hydrolysed in dilute acid solution (e.g. with 3–5% acid):

\[ R'\cdot CH(OR)_2 + H_2O \xrightarrow{H^+} R'\cdot CHO + 2R^2OH \]

The rate of hydrolysis depends upon the solubility of the acetal in the hydrolysis medium. Acetals of low molecular weight are completely hydrolysed by refluxing for 5–10 minutes; those of higher molecular weight, and therefore of low solubility, may require 30–60 minutes, but the rate of hydrolysis may be increased by the addition of dioxane which increases the solubility of the acetal.

The experimental procedure to be followed depends upon the products of hydrolysis. If the alcohol and aldehyde are both soluble in water, the reaction product is divided into two parts. One portion is used for the characterisation of the aldehyde by the preparation of a suitable derivative (e.g. the 2,4-dinitrophenylhydrazone, semicarbazone or dimethone, see Aldehydes and ketones, Section 9.6.13, below). The other portion is employed for the preparation of a 3,5-dinitrobenzoate, etc. (see Alcohols and polyhydric alcohols, Section 9.6.4, p. 1241): it is advisable first to concentrate the alcohol by distillation or to attempt to salt out the alcohol by the addition of solid potassium carbonate. If one of the hydrolysis products is insoluble in the reaction mixture, it is separated and characterised. If both the aldehyde and the alcohol are insoluble, they are removed from the aqueous layer; separation is generally most simply effected with sodium metabisulphite solution (compare Expt 5.82), but fractional distillation may sometimes be employed.

The formulae and physical properties of a number of common acetals are collected in Table 10.14.

9.6.13 ALDEHYDES AND KETONES

2,4-DINITROPHENYLHYDRAZONES

Small quantities may be prepared with the class reagent described on p. 1218. The following procedure is generally more satisfactory.

Suspend 0.25 g of 2,4-dinitrophenylhydrazone in 5 ml of methanol and add 0.4–0.5 ml of concentrated sulphuric acid cautiously. Filter the warm solution and add a solution of 0.1–0.2 g of the carbonyl compound in a small volume of methanol or of ether. If no solid separates within 10 minutes, dilute the solution carefully with m sulphuric acid. Collect the solid by suction filtration and wash it with a little aqueous methanol. Recrystallise the derivative from ethanol, dilute ethanol, ethyl acetate, acetic acid, dioxane, nitromethane, nitrobenzene or xylene.

Alternatively, to the clear solution obtained by warming 0.5 g of 2,4-dinitrophenylhydrazone, 1 ml of concentrated hydrochloric acid and 8–10 ml of ethanol, add 0.25 g of the carbonyl compound and heat just to boiling. Allow to cool to room temperature, filter off the 2,4-dinitrophenylhydrazone and recrystallise it from ethanol or glacial acetic acid.

The following reagent, a 0.25 M solution of 2,4-dinitrophenylhydrazone, may be used for the preparation of derivatives of keto compounds. Dissolve 25 g of 2,4-
dinitrophenylhydrazine in 300 ml of 85 per cent phosphoric acid in a 600-ml beaker on a steam bath, dilute the solution with 200 ml of 95 per cent ethanol, allow to stand and filter through a sintered glass funnel. It must be emphasised that this reagent is not suitable for the routine detection of carbonyl compounds since it also gives a precipitate in the cold with certain amines, esters and other compounds: if, however, a dilute solution of the ketonic compound in ethanol is treated with a few drops of the reagent and the mixture diluted with water and heated, the precipitate produced with non-ketonic compounds generally dissolves.

For the preparation of 2,4-dinitrophenylhydrazones, dissolve the carbonyl compound (say, 0.5 g) in 5 ml of ethanol and add the calculated volume of the reagent. If a precipitate does not form immediately, dilute with a little water. Collect the derivative and recrystallise it as above.

**p-NITROPHENYLHYDRAZONES**

Reflux a mixture of 0.5 g of p-nitrophenylhydrazine, 0.5 g of the aldehyde (or ketone), 10–15 ml of ethanol and 2 drops of glacial acetic acid for 10 minutes. Add more ethanol if the boiling solution is not homogeneous. Cool the clear solution, filter off the p-nitrophenylhydrazone and recrystallise it from ethanol or acetic acid.

Alternatively, dissolve approximately equivalent amounts of the aldehyde (or ketone) and the solid reagent in the minimum volume of cold glacial acetic acid, and reflux for 15 minutes. The p-nitrophenylhydrazone separates on cooling or upon careful dilution with water.

**PHENYLHYDRAZONES**

Dissolve 0.5 g of colourless phenylhydrazine hydrochloride (CAUTION) and 0.8 g of sodium acetate in 5 ml of water, and add a solution of 0.2–0.4 g of the aldehyde (or ketone) in a little ethanol (free from aldehydes and ketones). Shake the mixture until a clear solution is obtained and add a little more ethanol, if necessary. Warm on a water bath for 10–15 minutes and cool. Filter off the crystalline derivative, and recrystallise it from dilute ethanol or water; sometimes benzene or light petroleum (b.p. 60–80 °C) may be used.

**SEMICARBAZONES**

Dissolve 1 g of semicarbazide hydrochloride and 1.5 g of crystallised sodium acetate in 8–10 ml of water, add 0.5 g of the aldehyde or ketone and shake. If the mixture is turbid, add alcohol (acetone-free) or water until a clear solution is obtained; shake the mixture for a few minutes and allow to stand. Usually the semicarbazone crystallises from the cold solution on standing, the time varying from a few minutes to several hours. The reaction may be accelerated, if necessary, by warming the mixture on a water bath for a few minutes and then cooling in ice-water. Filter off the crystals, wash with a little cold water and recrystallise from water or from methanol or ethanol either alone or diluted with water.

**Note.** When semicarbazide is heated in the absence of a carbonyl compound for long periods, condensation to biurea, NH₂CONH-NHCONH₂, m.p. 247–250 °C (decomp.), may result; occasionally this substance may be produced in the normal preparation of a semicarbazone that forms slowly. Biurea is sparingly soluble in alcohol and soluble in hot water, whereas semicarbazones with melting points in the same range are insoluble in water: this enables it to be readily distinguished from a semicarbazone.
OXIMES
The method given for semicarbazones (above) may be employed: use 1 g of hydroxylamine hydrochloride, 2 g of crystallised sodium acetate and 0.5 g of the aldehyde or ketone. It is usually advisable to warm on a water bath for 10 minutes.

For water-insoluble aldehydes or ketones, the following alternative procedure may be used. Reflux a mixture of 0.5 g of the aldehyde or ketone, 0.5 g of hydroxylamine hydrochloride, 5 ml of ethanol and 0.5 ml of pyridine on a water bath for 15–60 minutes. Remove the ethanol either by distillation (water bath) or by evaporation of the hot solution in a stream of air (water pump). Add 5 ml of water to the cooled residue, cool in an ice bath and stir until the oxime crystallises. Filter off the solid, wash it with a little water and dry. Recrystallise from ethanol (95% or more dilute), benzene or benzene–light petroleum (b.p. 60–80°C).

Note. All aldehydes, and also those ketones which have two different groups attached to the carbonyl grouping, are capable of yielding two stereoisomeric oximes, hydrazones or semicarbazones. As a general rule, however, one of the stereoisomerides is formed in much greater amount than the other, and no doubt therefore arises as to the purity of the ketonic compound under investigation; occasionally a mixture of stereoisomerides is obtained, which may be difficult to separate by recrystallisation. The formation, therefore, of one of the above derivatives having indefinite melting point and obvious heterogeneity does not necessarily imply the presence of an impure ketonic substance.

DIMEDONE DERIVATIVES (aldehydes only)
Dimedone (5,5-dimethylcyclohexane-1,3-dione) in saturated aqueous solution or in 10 per cent alcohol solution gives crystalline derivatives (2) with aldehydes, but not with ketones. The reaction is:

The condensation products (conveniently called alkylidene dimethones) are almost insoluble in water, but can be crystallised from dilute ethanol. Dimedone is therefore a good reagent for the detection and characterisation of aldehydes.
The alkylidene dimethone (2) upon boiling with glacial acetic acid, acetic anhydride, hydrochloric acid and other reagents frequently loses water and passes into the anhydride, or dimethone anhydride (3) (a substituted octahydro-xanthene) which often serves as another derivative. The derivatives (2) are soluble in dilute alkali and the resulting solutions give colorations with ferric chloride solution; on the other hand, the anhydrides (3) are insoluble in dilute alkali and hence can easily be distinguished from the alkylidene dimethones (2).

Add 0.1 g of the aldehyde in 5 ml of 50 per cent ethanol to 2 ml of a 10 per cent or saturated ethanolic solution of dimedone. If a precipitate does not form immediately, warm for 5 minutes; if the solution is still clear at the end of this period, add hot water until the mixture is just cloudy and cool to about 5 °C. Collect the crystalline derivative and recrystallise it from methanol–water or ethanol–water.

To prepare the anhydride, boil a solution of 0.1 g of the dimethone derivative (2) in 5 ml of 80 per cent ethanol to which 1 drop of concentrated hydrochloric acid has been added, for 5 minutes, then add hot water until the mixture is just turbid, cool and collect the anhydride by filtration. Recrystallise it from dilute methanol.

**BENZYLIDENE DERIVATIVES**

Compounds containing the ketomethylene group (—CH₂·CO—) react with benzaldehyde to yield benzylidene derivatives:

\[ R'\cdot CO\cdot CH₂\cdot R² + Ph\cdot CHO \rightarrow R'\cdot CO\cdot C(=CH\cdot Ph)R² + H₂O \]

\[ R'\cdot CH₂\cdot CO\cdot CH₂\cdot R² + 2Ph\cdot CHO \rightarrow R'\cdot C(=CH\cdot Ph)\cdot CO\cdot C(=CH\cdot Ph)R² + 2H₂O \]

Dissolve 1 g of the ketomethylene compound and 1.1 g or 2.2 g of pure benzaldehyde (according as to whether the compound may be regarded as R·CO·CH₂·R or as R·CH₂·CO·CH₂·R) in about 10 ml of rectified (or industrial) spirit, add 0.5 ml of 5 m sodium hydroxide solution, shake and allow the mixture to stand for about an hour at room temperature. The benzylidene derivative usually crystallises out or will do so upon ‘scratching’ the walls of the vessel with a glass rod. Filter off the solid, wash it with a little cold ethanol and recrystallise it from absolute ethanol. (See also Expt 6.135.)

**AZINES**

Aldehydes react with hydrazine to yield azines: the reaction cannot usually be arrested at the hydrazone stage. This reaction may be illustrated by the preparation of benzylideneazine from benzaldehyde:

\[ 2Ph\cdot CHO + N₂H₄·H₂SO₄ \xrightarrow{aq.\, NH₃/H₂SO₄} Ph\cdot CH=N\cdot N=CH\cdot Ph + 2H₂O \]

Stir a mixture of 2.4 g of powdered hydrazine sulphate, 18 ml of water and 2.4 ml of concentrated aqueous ammonia (d 0.88), and add 4.6 g (4.4 ml) of benzaldehyde (free from benzoic acid) dropwise, with stirring, over a period of 30–60 minutes. Stir the mixture for a further hour, collect the solid by suction filtration and wash it with water. Recrystallise from 8 ml of rectified spirit. The yield of benzylideneazine (yellow needles), m.p. 92–93 °C, is 3.6 g.

The physical constants of the various derivatives of aliphatic and aromatic aldehydes and ketones are given in Tables 10.15, 10.16, 10.17 and 10.18.
9.6.14 QUINONES

REDUCTION TO THE HYDROQUINONE
Dissolve, or suspend, 0.5 g of the quinone in 5 ml of ether or benzene and shake vigorously with a solution of 1.0 g of sodium dithionite (Na₂S₂O₄) in 10 ml of m sodium hydroxide until the colour of the quinone has disappeared. Separate the alkaline solution of the hydroquinone, cool it in ice and acidify with concentrated hydrochloric acid. Collect the product (extract with ether, if necessary) and recrystallise it from ethanol or water.

REDUCTIVE ACETYLATION
Suspend 0.5 g of the quinone in 2.5 ml of pure acetic anhydride, and add 0.5 g of zinc powder and 0.1 g of powdered, anhydrous sodium acetate. Warm the mixture gently until the colour of the quinone has largely disappeared and then boil for 1 minute. Add 2 ml of glacial acetic acid and boil again to dissolve the product and part of the precipitated zinc acetate. Decant the hot solution from the zinc acetate and zinc, and wash the residue with 3–4 ml of hot glacial acetic acid. Combine the solutions, heat to boiling, carefully add sufficient water to hydrolyse the acetic anhydride and to produce a turbidity. Cool the mixture in ice, filter off the diacetate of the hydroquinone and recrystallise it from dilute ethanol or from light petroleum.

THIELE ACETYLATION
Quinones, when treated with acetic anhydride in the presence of perchloric acid or of concentrated sulphuric acid (strong acid catalyst), undergo simultaneous reductive acetylation and substitution to yield triacetoxy derivatives, e.g. benzquinone gives 1,2,4-triacetoxybenzene (cf. Expt 6.130).

Add 0.1 ml of concentrated sulphuric acid or of 72 per cent perchloric acid cautiously to a cold solution of 0.01 mol (or 1.0 g) of the quinone in 3–5 ml of acetic anhydride. Do not permit the temperature to rise above 50 °C. Allow to stand for 15–30 minutes and pour into 15 ml of water. Collect the precipitated solid and recrystallise it from ethanol.

SEMICARBAZONES
The preparation of these derivatives is described on p. 1258.

QUINOXALINES FROM o-QUINONES
The preparation of these derivatives is described in Expt 8.44.

The melting points of the derivatives of a selection of quinones are collected in Table 10.19.

9.6.15 CARBOXYLIC ACIDS

AMIDES, ANILIDES AND p-TOLUIDIDES
The dry acid is first converted by excess of thionyl chloride into the acid chloride:

\[ R\cdot CO_2H + SOCl_2 \rightarrow R\cdot COCl + SO_2 + HCl \]

The by-products are both gaseous and the excess of thionyl chloride (b.p. 78 °C)
may be readily removed by distillation. Interaction of the acid chloride with ammonia solution, aniline or \( p \)-toluidine yields the amide, anilide or \( p \)-toluidide respectively:

\[
\begin{align*}
R \cdot \text{COCl} + 2\text{NH}_3 & \rightarrow R \cdot \text{CONH}_2 + \text{NH}_4\text{Cl} \\
R^1 \cdot \text{COCl} + 2R^2\text{NH}_2 & \rightarrow R^1 \cdot \text{CONHR}^2 + R^2\text{NH}_2\text{HCl}
\end{align*}
\]

Place 0.5–1.0 g of the dry acid (finely powdered if it is a solid) into a 25-ml flask fitted with a reflux condenser, add 2.5–5.0 ml of redistilled thionyl chloride and reflux gently for 30 minutes; it is advisable to place a plug of cotton wool* in the top of the condenser to exclude moisture. Rearrange the condenser and distil off the excess of thionyl chloride† (b.p. 78 °C). The residue in the flask consists of the acid chloride and can be converted into any of the derivatives given below.

**Amides.** Treat the acid chloride cautiously with about 20 parts of concentrated ammonia solution \((d 0.88)\) and warm for a few moments. If no solid separates on cooling, evaporate to dryness on a water bath. Recrystallise the crude amide from water or dilute ethanol.

Alternatively stir the acid chloride with an equivalent weight of ammonium acetate in 10 ml of acetone at room temperature for one hour, filter the mixture and evaporate the acetone, and crystallise the residual amide from water or from dilute ethanol.

**Anilides.** Dilute the acid chloride with 5 ml of pure ether (or benzene), and add a solution of 2 g of pure aniline in 15–20 ml of the same solvent until the odour of the acid chloride has disappeared; excess of aniline is not harmful. Shake with excess of dilute hydrochloric acid to remove aniline and its salts, wash the ethereal (or benzene) layer with 3–5 ml of water and evaporate the solvent **(CAUTION).** Recrystallise the anilide from water, dilute ethanol or toluene-light petroleum (b.p. 60–80 °C).

\( p \)-Bromoanilides are similarly prepared with \( p \)-bromoaniline.

**\( p \)-Toluidides.** Proceed as under Anilides, but substitute \( p \)-toluidine for aniline.

\( \text{Anilides and } p \text{-toluidides may also be prepared directly from the acids; } \)‡ by heating them with aniline or \( p \)-toluidine respectively:

\[
\begin{align*}
R^1 \cdot \text{CO}_2\text{H} + R^2\text{NH}_2 & \rightarrow R^1 \cdot \text{CONHR}^2 + \text{H}_2\text{O}
\end{align*}
\]

Place 1.0 g of the monobasic acid and 2 g of aniline or \( p \)-toluidine in a dry test tube, attach a short air condenser and heat the mixture in an oil bath at 140–160 °C for 2 hours; do not reflux too vigorously an acid that boils below this temperature range and only allow steam to escape from the top of the condenser. For a sodium salt, use the proportions of 1 g of salt to 1.5 g of the base. If the acid is dibasic, employ double the quantity of amine and a reaction temper-

* This is more convenient than the conventional calcium chloride guard-tube and possesses the advantages of cheapness and hence can easily be renewed for each experiment.

† If the boiling point of the acid chloride is too near that of thionyl chloride to render separation by distillation practicable, the excess of the reagent can be destroyed by the addition of pure formic acid:

\[
\text{HCO}_2\text{H} + \text{SOCl}_2 \rightarrow \text{CO} + \text{SO}_2 + 2\text{HCl}
\]

‡ Alternatively, the alkali metal salts of the acids may be heated with the hydrochloride of the appropriate base.
nature of 180–200°C; incidentally, this procedure is recommended for dibasic acids since the latter frequently give anhydrides with thionyl chloride. Powder the cold reaction mixture, triturate it with 20–30 ml of 10 per cent hydrochloric acid* and recrystallise from dilute ethanol.

**p-BROMOPHENACYL ESTERS**

*p*-Bromophenacyl bromide reacts with the alkali metal salts of acids to form crystalline *p*-bromophenacyl esters:

\[ R \cdot CO_2 Na + BrCH_2 \cdot CO \cdot C_6 H_4 Br (p) \xrightarrow{-NaBr} R \cdot CO_2 CH_2 \cdot CO \cdot C_6 H_4 Br (p) \]

Dissolve or suspend 0.5 g of the acid in 5 ml of water in a small conical flask, add a drop or two of phenolphthalein indicator, and then 4–5 per cent sodium hydroxide solution until the acid is just neutralised. Add a few drops of very dilute hydrochloric acid so that the final solution is faintly acid (litmus).† Introduce 0.5 g of *p*-bromophenacyl bromide (m.p. 109°C) dissolved in 5 ml of rectified (or industrial) spirit, and heat the mixture under reflux for 1 hour: if the mixture is not homogeneous at the boiling point or a solid separates out, add just sufficient ethanol to produce homogeneity. (Di- and tri-basic acids require proportionately larger amounts of the reagent and longer refluxing periods.) Allow the solution to cool, filter the separated crystals at the pump, wash with a little alcohol and then with water. Recrystallise from dilute ethanol: dissolve the solid in hot ethanol, add hot water until a turbidity just results, clear the latter with a few drops of ethanol and allow to cool. Acetone may sometimes be employed for recrystallisation.

**p-NITROBENZYL ESTERS**

*p*-Nitrobenzyl bromide (m.p. 100°C) reacts with the alkali metal salts of acids to give *p*-nitrobenzyl esters:

\[ R \cdot CO_2 Na + BrCH_2 \cdot C_6 H_4 \cdot NO_2 (p) \xrightarrow{-NaBr} R \cdot CO_2 CH_2 \cdot C_6 H_4 \cdot NO_2 (p) \]

It is important that the solution of the sodium salt be faintly acid in order that the formation of coloured by-products in the subsequent reaction may be prevented. If the molecular weight of the monobasic acid is known, it is desirable to employ a slight excess of the sodium salt, since excess of the latter is more easily removed than the unchanged reagent.

Use the procedure given above for *p*-bromophenacyl esters. If the ester does not crystallise out on cooling, reheat the reaction mixture, and add small portions of hot water to the point of incipient cloudiness and allow to cool.

**p-PHENYLPHENACYL ESTERS**

*p*-Phenylphenacyl bromide reacts with soluble salts of organic acids to yield crystalline *p*-phenylphenacyl esters.

* When the derivative is appreciably soluble in ether, the following alternative procedure may be employed. Dissolve the cold reaction mixture in about 50 ml of ether, wash it with 20–30 ml of 10 per cent hydrochloric acid (to remove the excess of base), followed by 20 ml of 10 per cent sodium hydroxide solution, separate the ether layer and evaporate the solvent (CAUTION). Recrystallise the residue from dilute ethanol.

† If the sodium salt of the acid is available, dissolve 0.5 g in 5 ml of water, add a solution of 0.5 g of the reagent in 5 ml of ethanol and proceed as detailed in the text after just acidifying (litmus) with dilute hydrochloric acid.
R·CO₂Na + BrCH₂·CO·C₆H₄·Ph(p) $\overset{NaBr}{\longrightarrow}$ R·CO₂CH₂·CO·C₆H₄·Ph(p)

The procedure is similar to that given under p-Bromophenacyl esters and p-Nitrobenzyl esters above. Add a weighed amount of acid (0.005 mol) to 5 ml of water in a small conical flask and neutralise it with 0.5 M sodium carbonate or M sodium hydroxide. The final solution should be faintly acid to litmus (add more of the organic acid or a few drops of dilute hydrochloric acid); unless this precaution is taken, coloured by-products are formed which are very difficult to remove. (If the alkali metal salt is available, dissolve 0.005 mol in 5 ml of water, and render the solution just acid to litmus by the addition of dilute hydrochloric acid.) Introduce 10 ml of ethanol, and if the salt of the organic acid is not thrown out of solution, add 0.005 mol of p-phenylphenacyl bromide. Dibasic and tribasic acids will require 0.01 and 0.015 mol respectively. Reflux the mixture for periods of up to 1, 2 or 3 hours according to the basicity of the acid. If the salt of the organic acid is precipitated by the ethanol, add more water until the salt dissolves. Some of the esters are sparingly soluble in the reaction mixture and crystallise from the boiling solution; in most cases, however, crystal formation does not occur until the mixture is cooled. In some instances it may be necessary to concentrate the solution before crystallisation occurs. Recrystallise the crude p-phenylphenacyl ester from ethanol, dilute ethanol, acetone or toluene.

Certain dibasic acids, of which the sodium or potassium salts are sparingly soluble in dilute ethanol, cause difficulty; these should be neutralised with ethylamine solution.

**S-BENZYLISOTHIOURIUM SALTS**

S-Benzylisothiouronium chloride reacts with the alkali metal salts of organic acids to produce crystalline S-benzylisothiouronium salts:

$$\left[\text{Ph} \cdot \text{CH}_2 \cdot \text{S} \cdot \text{C} \overset{\text{NH}_2}{\equiv} \text{NH}_2\right]^+ \text{Cl}^- + \text{R} \cdot \text{CO}_2^\ominus \text{Na}^\ominus \overset{\text{NaCl}}{\longrightarrow} \left[\text{Ph} \cdot \text{CH}_2 \cdot \text{S} \cdot \text{C} \overset{\text{NH}_2}{\equiv} \text{NH}_2\right]^\ominus \text{R} \cdot \text{CO}_2^\ominus$$

It is important not to allow the reaction mixture to become appreciably alkaline, since the free base then decomposes rapidly yielding phenylmethanethiol, which has an unpleasant odour.

Dissolve (or suspend) 0.25 g of the acid in 5 ml of warm water, add a drop or two of phenolphthalein indicator and neutralise carefully with c M sodium hydroxide solution. Then add 2–3 drops of c 0.1 M hydrochloric acid to ensure that the solution is almost neutral (pale pink colour). (Under alkaline conditions the reagent tends to decompose to produce the evil-smelling phenylmethanethiol.) If the sodium salt is available, dissolve 0.25 g in 5 ml of water and add 2 drops of c 0.1 M hydrochloric acid. Introduce a solution of 1 g of S-benzylisothiouronium chloride in 5 ml of water, and cool in ice until precipitation is complete. Recrystallise the crude derivative from dilute ethanol or from hot water.

With some acids (e.g. succinic acid and sulphanilic acid) more satisfactory results are obtained by reversing the order of mixing, i.e. by adding the solution of the sodium salt of the acid to the reagent. In view of the proximity of the melting points of the derivatives of many acids, the mixed m.p. test (Section 2.33) should be applied.
ANHYDRIDES
1,2-Dicarboxylic acids are readily converted into cyclic anhydrides when heated alone or in acetic anhydride. Heat 0.5 g of the acid in 2–3 ml of refluxing acetic anhydride for 30 minutes. Remove most of the excess reagent by distillation and crystallise the residual cyclic anhydride from chloroform or toluene. The melting points of aliphatic and aromatic anhydrides are to be found in Tables 10.23 and 10.24 respectively. For conversion of the anhydrides into anilic acids see Section 9.6.16, below.

FUSION WITH SODA-LIME
An additional useful test for aromatic carboxylic acids is to distil the acid or its sodium salt with soda-lime. Heat 0.5 g of the acid or its sodium salt with 0.5 g of soda-lime in an ignition tube to make certain that there is no danger of explosion. Then grind together 0.5 g of the acid with 3 g of soda-lime, place the mixture in a Pyrex test tube and cover it with an equal bulk of soda-lime. Fit a wide delivery tube dipping into an empty test tube. Clamp the tube near the mouth. Heat the soda-lime first and then the mixture gradually to a dull-red heat. Examine the product: this may consist of aromatic hydrocarbons or derivatives, e.g. phenol from salicylic acid, anisole from anisic acid, toluene from toluic acid, etc.

The melting points of the derivatives of aliphatic and aromatic carboxylic acids are collected in Tables 10.20 and 10.21.

9.6.16 CARBOXYLIC ACID CHLORIDES AND ANHYDRIDES

HYDROLYSIS TO THE ACIDS
A general procedure is to hydrolyse the acid chloride (or anhydride) by warming with dilute alkali and acidifying the resulting solution with dilute hydrochloric acid to Congo red. If the acid is sparingly soluble, filter it off and characterise it in the usual way. If no precipitate of carboxylic acid is obtained, adjust the pH of the solution to neutrality to phenolphthalein and evaporate to dryness. Use the mixture of the sodium salt of the acid and sodium chloride thus obtained for the preparation of a suitable derivative (e.g. the p-bromophenacyl ester).

CONVERSION INTO ANILIDES
Acid chlorides are converted directly to the corresponding anilides by reaction with aniline, as described in Section 9.6.15, p. 1261. For anhydrides, heat a mixture of 1 g of the anhydride and 1 g of aniline in a boiling water bath for 5 minutes, add 5 ml of water, boil and cool. Crystallise the resulting product from water or from aqueous ethanol.

ANILIC ACIDS FROM CYCLIC ANHYDRIDES
Dissolve 0.5 g of the anhydride in 15 ml of toluene by heating on a water bath, and add a solution of 0.5 ml of aniline in 3 ml of toluene. If the anilic acid does not separate after a short time, cool the solution, wash it with a little dilute hydrochloric acid to remove the excess of aniline and evaporate the solvent; the anilic acid will then usually crystallise. Recrystallise from aqueous ethanol. When heated above their melting points, anilic acids dehydrate to form cyclic imides, e.g.
The melting points of the derivatives of some dicarboxylic acids are:

Succinic; anilic acid 148 °C, imide 156 °C.
Phthalic; anilic acid 169 °C, imide 205 °C.
3-Nitrophthalic; — , imide 136 °C.

The physical properties of a number of carboxylic acid chlorides and anhydrides are given in Tables 10.22, 10.23 and 10.24.

9.6.17 ESTERS

HYDROLYSIS

Esters are usually characterised by hydrolysis followed by identification of the alcoholic and acidic components, although it is possible to prepare derivatives of both these components directly from the ester.

In the routine examination of esters it is often a good plan to carry out two hydrolysies, [(A) and (B) below] one for the isolation and characterisation of the parent acid, and the other for the isolation and identification of the parent alcohol.

A. Drop 1 g of sodium into 10 ml of methanol in a small flask provided with a small water condenser; heat the mixture until all the sodium has dissolved. Cool, and add 1 g of the ester and 0.5 ml of water. Frequently the sodium salt of the acid will be deposited either at once or after boiling for a few minutes. If this occurs, filter off the solid at once, wash it with a little methanol and convert it into the p-bromophenacyl ester, p-nitrobenzyl ester or S-benzyl isothiouronium salt (for experimental details, see Section 9.6.15, p. 1261). If no solid separates, continue the boiling for 30–60 minutes, boil off the alcohol, allow to cool, render the product just neutral to phenolphthalein with dilute sulphuric or hydrochloric acid, convert the sodium salt present in solution into a crystalline derivative (Section 9.6.15, p. 1261) and determine its melting point.

B. Boil 2 g of the ester with 30 ml of 10 per cent sodium or potassium hydroxide solution under reflux for at least 1 hour. If the alcohol formed is water (or alkali) soluble, the completion of the hydrolysis will be indicated by the disappearance of the ester layer. Distil off the liquid through the same condenser and collect the first 3–5 ml of distillate. If a distinct layer separates on standing (or upon saturation of half the distillate with potassium carbonate), remove this layer with a capillary dropper, dry it with a little anhydrous potassium carbonate or anhydrous calcium sulphate and determine the b.p. by the Siwoloboff method (Section 2.34). Whether an insoluble alcohol separates out or not, prepare a crystalline derivative (e.g. the 3,5-dinitrobenzoate, Section 9.6.4, p. 1241) and determine its m.p.

The residue in the flask will contain the sodium (or potassium) salt of the acid together with excess of alkali. Just acidify with dilute sulphuric acid and observe whether a crystalline acid separates; if it does, filter, recrystallise and identify (Section 9.6.15, p. 1261). If no crystalline solid is obtained, the solution may be just neutralised to phenolphthalein and the solution of the alkali salt used for the
preparation of a crystalline derivative. This will confirm, if necessary, the results of hydrolysis by method A. If the time factor is important, either method A or the product of the caustic alkali hydrolysis may be used for the identification of the acid.

The following notes may be useful:

1. Some esters, e.g. methyl formate, dimethyl oxalate, dimethyl succinate, dimethyl and diethyl tartrate, are appreciably soluble in water. These are usually easily hydrolysed by alkali.
2. If the original ester is a fat or oil and produces an odour of acrolein when heated, it may be a glyceride. Esters of ethylene glycol and of glycerol with simple fatty acids are viscous and of high b.p. They are hydrolysed (method A) and the alcohol distilled off. The residue is diluted (a soap may be formed) and acidified with hydrochloric acid (Congo red paper). The acid is filtered or extracted with ether. If no acid can be isolated by these methods, it must be simple and volatile, and should be separated by distillation. The residual aqueous solution of glycol or glycerol is neutralised, evaporated to a syrup on a water bath and extracted with ethanol or with ethyl acetate; the solvent is evaporated and the glycol or glycerol in the residue is identified as usual.
3. β-Keto esters (e.g. ethyl acetoacetate) are soluble in solutions of caustic alkalis but not in sodium carbonate solution. They give colours with freshly prepared ferric chloride solution; a little ethanol should be added to bring the ester into solution. Sodium ethoxide solution reacts to yield sodio compounds, which usually crystallise out in the cold. They are hydrolysed by boiling sulphuric acid to the corresponding ketones, which can be identified as usual (Section 9.6.13, p. 1257).

A slight modification in the procedure for isolating the products of hydrolysis is necessary for phenolic (or phenyl) esters since the alkaline solution will contain both the alkali phenate and the alkali salt of the organic acid: upon acidification, both the phenol and the acid will be liberated. Two methods may be used for separating the phenol and the acid.

(i) Acidify the cold alkaline reaction mixture with dilute sulphuric acid (use litmus or Congo red paper) and extract both the acid and the phenol with ether. Remove the acid by washing the ethereal extract with saturated sodium hydrogen carbonate solution until effervescence ceases; retain the aqueous washings. Upon evaporating the ether, the phenol remains; it may be identified by its action upon ferric chloride solution, by the formation of a crystalline derivative with bromine water, or by any of the methods given in Section 9.6.6, p. 1248. Acidify the aqueous washings with dilute sulphuric acid while stirring steadily, and investigate the organic acid (Section 9.6.15, p. 1261).

(ii) Add dilute sulphuric acid, with stirring, to the cold alkaline solution until the solution is acid to litmus or Congo red paper, and the acid, if a solid, commences to separate as a faint permanent precipitate. Now add dilute sodium carbonate solution until the solution is alkaline (litmus paper) and any precipitate has completely redissolved. Extract the clear solution twice with ether; evaporate or distil the ether from the ethereal solution on a water bath, and identify the residual phenol as under (i). Remove the dissolved ether from the aqueous solution by boiling, acidify with dilute sulphuric acid and identify the organic acid present (see Section 9.6.15, p. 1261).
DIRECT IDENTIFICATION OF THE ALCOHOLIC COMPONENT OF AN ESTER

The alcohol components of many simple esters may be identified as the crystalline 3,5-dinitrobenzoates (compare Section 9.6.15, p. 1261) by heating them with 3,5-dinitrobenzoic acid in the presence of a little concentrated sulphuric acid:

$$ R^1\cdot CO_2R^2 + 3,5-(NO_2)_2C_6H_3CO_2H \rightleftharpoons R^1\cdot CO_2H + 3,5-(NO_2)_2C_6H_3CO_2R^2 $$

The reaction does not appear to be applicable if either of the groups R¹ or R² reacts readily with concentrated sulphuric acid; esters of molecular weight in excess of about 250 react with difficulty.

Dissolve 2 drops of concentrated sulphuric acid in 2 ml of the ester and add 1.5 g of 3,5-dinitrobenzoic acid. If the b.p. is above 150 °C heat the mixture, with frequent shaking at first, in an oil bath at about 150 °C. If the 3,5-dinitrobenzoic acid dissolves within 15 minutes, heat the mixture for 30 minutes, otherwise 60 minutes heating is required. Allow the reaction mixture to cool, dissolve it in 25 ml of ether and extract thoroughly with 5 per cent sodium carbonate solution (c. 25 ml). Wash the ethereal solution with water, and remove the ether. Dissolve the residue (which is usually an oil) in 5 ml of hot ethanol, add hot water cautiously until the 3,5-dinitrobenzoate commences to separate, cool and stir. Recrystallise the derivative from dilute ethanol: the yield is 0.1–0.2 g.

DIRECT IDENTIFICATION OF THE ACIDIC COMPONENT OF AN ESTER

The following procedures may be regarded as alternative to that described above involving hydrolysis of the ester.

Anilides or p-toluidides of acids from esters. Esters are converted into the corresponding anilides or p-toluidides by treatment with anilino- or with p-toluidinomagnesium bromide, which are readily obtained from any simple Grignard reagent and aniline or p-toluidine:

$$ \text{ArNH}_2 + \text{RMgX} \longrightarrow \text{ArNHMgX} + \text{RH} $$

$$ 2\text{ArNHMgX} + R^1\cdot \text{CO}_2R^2 \longrightarrow R^1\cdot \text{C(O\text{MgX})(NH\text{Ar})}_2 + \text{Mg(OR^2)}X \xrightleftharpoons{2\text{H}_2\text{O}} R^1\cdot \text{CONH\text{Ar}} + \text{ArNH}_2 + \text{Mg(OH)}X + R^2\text{OH} $$

This procedure is speedy, economical and employs materials which are readily available. It is not satisfactory for esters of dibasic acids.

Add 4.0 g (4.0 ml) of pure aniline dropwise to a cold solution of ethylmagnesium bromide prepared from 1.0 g of magnesium, 5.0 g (3.5 ml) of ethyl bromide and 30 ml of pure, sodium-dried ether. When the vigorous evolution of ethane has ceased, introduce 0.02 mol of the ester in 10 ml of anhydrous ether, and warm the mixture on a water bath for 10 minutes; cool. Add dilute hydrochloric acid to dissolve the magnesium compounds and excess of aniline. Separate the ethereal layer, dry it with magnesium sulphate and evaporate the ether. Recrystallise the residual anilide, which is obtained in almost quantitative yield, from dilute ethanol or other suitable solvent.

Alternatively, add a solution of 4.5 g of p-toluidine in dry ether to the Grignard reagent prepared from 1.0 g of magnesium as detailed above. Then introduce 1.0 g (or 0.02 mol) of the ester and proceed as described for anilides.
**N-Benzylamides of acids from esters.** Esters are converted into the N-benzylamides of the corresponding acids by heating with benzylamine in the presence of a little ammonium chloride as catalyst:

\[ R'\cdot CO_2R^2 + \text{Ph} \cdot CH_2NH_2 \rightarrow R'\cdot CONHCH_2\cdot \text{Ph} + R^2OH \]

The reaction (which is essentially the direct aminolysis of esters with benzylamine) proceeds readily when \( R^2 \) is methyl or ethyl. Esters of higher alcohols should preferably be subjected to a preliminary methanolation by treatment with sodium methoxide in methanol:

\[ R'\cdot CO_2R^2 + \text{MeOH} \xrightarrow{\text{MeCO}_2\text{Na}} R'\cdot CO_3\text{Me} + R^2OH \]

N-Benzylamides are recommended when the corresponding acid is liquid and/or water-soluble so that it cannot itself serve as a derivative. The benzylamides derived from the simple fatty acids or their esters are not altogether satisfactory since they are often low melting; those derived from most hydroxy acids and from polybasic acids or their esters are formed in good yield and are easily purified. The esters of aromatic acids yield satisfactory derivatives but the method must compete with the equally simple process of hydrolysis and precipitation of the free acid, an obvious derivative when the acid is a solid. The procedure fails with esters of keto acids, sulphonic acids and inorganic acids and some halogenated aliphatic esters.

Reflex a mixture of 1 g of the ester, 3 ml of benzylamine and 0.1 g of powdered ammonium chloride for 1 hour in a Pyrex test tube fitted with a short condenser. Wash the cold reaction mixture with water to remove the excess of benzylamine. If the product does not crystallise, stir it with a little water containing a drop or two of dilute hydrochloric acid. If crystallisation does not result, some unchanged ester may be present: boil with water for a few minutes in an evaporating dish to volatilise the ester. Collect the sold N-benzylamide on a filter, wash it with a little petroleum, b.p. 100–120 °C, and recrystallise it from dilute ethanol, ethyl acetate or acetone.

If the ester does not yield a benzylamide by this procedure, convert it into the methyl ester by refluxing 1 g for 30 minutes with 5 ml of absolute methanol in which about 0.1 g of sodium has been dissolved. Remove the methanol by distillation and treat the residual ester as above.

The melting points of the N-benzylamides are collected in Tables 10.20 and 10.21.

**Acid hydrazides from esters.** Methyl and ethyl esters react with hydrazine to give acid hydrazides:

\[ R\cdot CO_2\text{Me} + H_2\text{NNH}_2 \rightarrow R\cdot CONHNH_2 + \text{MeOH} \]

The hydrazides are often crystalline and then serve as useful derivatives. Esters of higher alcohols should be converted first to the methyl esters by boiling with sodium methoxide in methanol (see under N-benzylamides).

Place 1.0 ml of hydrazine hydrate (CAUTION: corrosive chemical) in a test tube fitted with a short reflux condenser. Add 1.0 g of the methyl or ethyl ester dropwise (or portionwise) and heat the mixture gently under reflux for 15 minutes. Then add just enough absolute ethanol through the condenser to produce a clear solution, reflux for a further 2–3 hours, distil off the ethanol and
cool. Filter off the crystals of the acid hydrazide, and recrystallise from ethanol, dilute ethanol or from water.

The melting points of the hydrazides of some aliphatic and aromatic acids are collected in Tables 10.20 and 10.21.

Tables 10.25 and 10.26 list the boiling points, densities and refractive indices of a number of selected esters.

9.6.18 PRIMARY AMIDES

HYDROLYSIS

Amides may be hydrolysed by boiling with 10 per cent sodium hydroxide solution to the corresponding acid (as the sodium salt). The alkaline solution should be acidified with dilute hydrochloric acid; the liberated acid if sparingly water-soluble is isolated by filtration, otherwise any water-soluble acidic component may be isolated by extraction with ether or by distillation from the acidic aqueous solution. The procedure is illustrated by the following experimental details for benzamide. Place 1.5 g of benzamide and 25 ml of 10 per cent sodium hydroxide solution in a 100-ml conical or round-bottomed flask equipped with a reflux condenser. Boil the mixture gently for 30 minutes; ammonia is freely evolved. Detach the condenser and continue the boiling in the open flask for 3-4 minutes to expel the residual ammonia. Cool the solution in ice, and add concentrated hydrochloric acid until the mixture is strongly acid; benzoic acid separates immediately. Leave the mixture in ice until cold, filter at the pump, wash with a little cold water and drain well. Recrystallise the benzoic acid from hot water.

Hydrolysis may also be effected (but usually rather less readily) with 20 per cent sulphuric acid.

XANTHYLAMIDES

Xanthhydrol reacts with primary amides with the formation of crystalline xanthylamides or 9-acylaminoxanthens.

![Chemical structure of xanthylamide]

Dissolve 0.25 g of xanthhydrol* in 3.5 ml of glacial acetic acid; if an oil separates (as is sometimes the case with commercial material), allow to settle for a

* Best results are obtained with reagent freshly prepared by the reduction of xanthone with sodium amalgam. Prepare an amalgam from 0.9 g of clean sodium and 75 g (5.5 ml) of mercury as described in Section 4.2.70, p. 464, and then warm it in a stoppered Pyrex reagent bottle to 50 °C. Add a cold suspension of 2.5 g of commercial xanthone in 20 ml of rectified spirit, stopper the flask and shake vigorously releasing the pressure from time to time. The temperature rises rapidly to 60-70 °C, the xanthone passes into solution and a transient blue colour develops. After 5 minutes the solution is clear and colourless; after a further 10 minutes shaking, separate the mercury and wash it with 3 ml of ethanol. Filter the warm solution into 200 ml of cold distilled water with shaking. Filter the xanthhydrol under suction, wash with water and dry. The yield of xanthhydrol, m.p. 122-123 °C, is 2.4 g. The product may be recrystallised from ethanol; it is comparatively unstable but may be kept in an alcoholic solution.
short time and decant the supernatant solution. Add 0.25 g of the amide, shake and allow to stand. If a crystalline derivative does not separate in about 10 minutes, warm on a water bath for a period not exceeding 30 minutes, and allow to cool. Filter off the solid xanthylamide (9-acylaminoxanthen) and recrystallise it from dioxane-water or from acetic acid–water, dry at 80 °C for 15 minutes and determine the m.p.

Some amides do not dissolve in glacial acetic acid; in such cases a mixture of 2 ml of glacial acetic acid and 3 ml of water may be used as a solvent for the reaction. Urea may be characterised as the di-xanthyl derivative (m.p. 274 °C) prepared in acetic acid. Di- and tri-chloroacetamide, oxamide, and salicylamide do not give satisfactory results.

The melting points of aliphatic and aromatic primary carboxylic acid amides and those of the corresponding xanthylamides are collected in Tables 10.27 and 10.28.

9.6.19 SUBSTITUTED AMIDES

HYDROLYSIS
Substituted aromatic carboxylic acid amides of the type Ar·CONHR and Ar·CONR₂ are only slowly attacked by aqueous alkali and are characterised by hydrolysis under acidic conditions; 70 per cent sulphuric acid (prepared by carefully adding 4 parts of acid to 3 parts of water) is the preferred reagent. Use the general procedure which has been outlined on p. 1229; characterise the acidic and basic components.

FUSION WITH SODA-LIME
The basic component is liberated upon fusion with sode-lime and at the same time the aroyl group yields a hydrocarbon. Use the experimental details described for carboxylic acids, Section 9.6.15, p. 1261; characterise the base by the preparation of a suitable derivative.

The melting points of some typical substituted aromatic amides are collected in Table 10.29. Other examples will be found in the appropriate columns of Tables 10.20, 10.33 and 10.34.

9.6.20 NITRILES

HYDROLYSIS TO THE CARBOXYLIC ACID
Hydrolysis with alkali. When nitriles are treated with 20–40 per cent sodium or potassium hydroxide solution, there is no reaction in the cold; upon prolonged boiling hydrolysis proceeds comparatively slowly (compare primary amides which are rapidly hydrolysed) to the sodium salt of the acid and ammonia. The reaction is complete when ammonia is no longer evolved:

\[ R\cdot CN + H_2O + NaOH \rightarrow R\cdot CO_2Na + NH_3 \]

The excess of alkali is then neutralised to phenolphthalein or to Congo red with dilute hydrochloric acid and the solution is evaporated to dryness on the water bath. The acid may then be characterised as the S-benzylisothiouronium salt or as the p-bromophenacyl ester (Section 9.6.15, p. 1263). In many instances the derivative may be prepared directly from the neutralised solution.
Hydrolysis with acid. Most nitriles are hydrolysed by boiling with 5–8 times the weight of 50–75 per cent sulphuric acid under reflux for 2–3 hours:

\[ 2R\cdot CN + H_2SO_4 + 4H_2O \rightarrow 2R\cdot CO_2H + (NH_4)_2SO_4 \]

If the acid is a simple aliphatic monobasic acid it can usually be distilled directly from the reaction mixture. If this procedure is not possible, the reaction mixture is poured into excess of crushed ice, and the acid is isolated by ether extraction or by other suitable means. The acid is then characterised (Section 9.6.15, p. 1261). The addition of hydrochloric acid (as sodium chloride; say, 5% of the weight of sulphuric acid) increases the rate of the reaction.

A mixture of 50 per cent sulphuric acid and glacial acetic acid may be used with advantage in the case of difficultly-hydrolysable aromatic nitriles. The reaction product is poured into water, and the organic acid is separated from any unchanged nitrile or from amide by means of sodium carbonate solution.

Those nitriles which yield water-insoluble amides (e.g. the higher alkyl cyanides), conversion to the amide often leads to a satisfactory derivative. The hydration if effected by warming a solution of the nitrile in concentrated sulphuric acid for a few minutes, cooling and pouring into water. For experimental details see p. 1229.

REDUCTION TO A PRIMARY AMINE AND CONVERSION INTO A SUBSTITUTED PHENYLTHIOUREA.

Reduction of a nitrile with sodium and ethanol yields the primary amine, which may be identified by direct conversion into a substituted phenylthiourea.

\[ R\cdot CN + 2H_2 \xrightarrow{\text{Na}_\text{ROH}} R\cdot CH_2NH_2 \xrightarrow{\text{PhNCS}} R\cdot CH_2NH\cdot CS\cdot NH\cdot Ph \]

Dissolve 1.0 g of the nitrile in 20 ml of absolute ethanol in a dry 200-ml round-bottomed flask fitted with a reflux condenser. Add through the top of the condenser 1.5 g of clean sodium (previously cut into small pieces) at such a rate that the reaction, although vigorous, remains under control. When all the sodium has reacted (10–15 minutes), cool the reaction mixture to about 20 °C, and add 10 ml of concentrated hydrochloric acid dropwise through the condenser while swirling the contents of the flask vigorously: the final solution should be acid to litmus. Connect the flask to a still-head and condenser, and distil off about 20 ml of liquid (dilute ethanol). Cool the flask and fit a small dropping funnel into the top of the still-head. Place 15 ml of 40 per cent sodium hydroxide solution in the dropping funnel, attach an adapter to the end of the condenser and so arrange it that the end dips into about 3 ml of water contained in a 50-ml conical flask. Add the sodium hydroxide solution dropwise and with shaking: a vigorous reaction ensues. When all the alkali has been added, separate the amine by distillation until the contents of the flask are nearly dry.

Add 0.5 ml of phenyl isothiocyanate to the distillate and shake the mixture vigorously for 3–4 minutes. If no derivative separates, crystallisation may be induced by cooling the flask in ice and 'scratching' the walls with a glass rod. Filter off the crude product, wash it with a little 50 per cent ethanol and recrystallise from hot dilute ethanol.
\(\alpha\)-IMINOALKYLMERCAPTOACETIC ACID HYDROCHLORIDES

Mercaptoacetic acid (thioglycollic acid) reacts with nitriles in the presence of hydrogen chloride to give \(\alpha\)-iminoalkylmercaptoacetic acid hydrochlorides:

\[
R \cdot \text{CN} + \text{HSCH}_2 \cdot \text{CO}_2\text{H} + \text{HCl} \rightarrow R \cdot \text{C}^{\text{NH}_2} \text{SCH}_2 \cdot \text{CO}_2\text{H} + \text{C}_2\text{H}_4\text{Cl}
\]

These salts have sharp and reproducible decomposition temperatures but no true melting points. They act as dibasic acids when titrated with standard alkali, thymol blue being used as indicator.

Dissolve 1.0 g of the nitrile and 2.0 g of mercaptoacetic acid in 25 ml of sodium-dried ether in a dry test tube or small flask. Cool the solution in ice and saturate it with dry hydrogen chloride (5–10 minutes). Stopper the test tube or flask and keep it at 0 °C until crystallisation is complete (15–60 minutes). Collect the crystals by suction filtration, wash with anhydrous ether and dry in a vacuum desiccator over potassium hydroxide pellets (to remove hydrogen chloride) and paraffin wax shavings (to remove ether).

ACYL PHLOROGLUCINOLS

Crystalline derivatives of aliphatic nitriles may be prepared by an application of the Hoesch reaction. Equimolecular proportions of phloroglucinol and the nitrile react in dry ethereal solution in the presence of anhydrous zinc chloride and hydrogen chloride to give an imine hydrochloride, which is converted into a solid alkyl trihydroxyphenyl ketone by hydrolysis. The alkyl 2,4,6-trihydroxyphenyl ketones are usually highly crystalline solids of sharp melting point and are purified by recrystallisation from hot water. Many contain water of crystallisation which can be removed by drying in vacuo at about 100 °C; the melting points of both the hydrated and anhydrous compound should be determined.

A detailed preparative procedure is described in Expt 6.125, where the reaction is formulated. The following concise general instructions are suitable for small-scale working.

Add 0.4 g of powdered, anhydrous zinc chloride to a solution of 1.1 g of anhydrous phloroglucinol in 25 ml of sodium-dried ether, and introduce the nitrile (0.01 mol) dissolved in 5 ml of dry ether. Pass a steady stream of dry hydrogen chloride through the solution for 25–30 minutes; it becomes turbid after 2–3 minutes but the turbidity subsequently disappears. Decant the supernatant liquid, dissolve the residual oil or crystals in 25 ml of water and shake the aqueous solution with two 20 ml portions of ether. Concentrate the aqueous layer to about 10–12 ml. The hydroxy ketone separates upon cooling; recrystallise it from hot water and dry in the air. The hydrate is thus produced.

Physical data for aliphatic and aromatic nitriles are collected in Tables 10.30 and 10.31 respectively.

9.6.21 PRIMARY AND SECONDARY AMINES

ACETYL DERIVATIVES

Primary and secondary amines are best acetylated with acetic anhydride:

\[
\text{RHN}_2 + (\text{Me} \cdot \text{CO})_2\text{O} \rightarrow \text{Me} \cdot \text{CO} \cdot \text{NHR} + \text{Me} \cdot \text{CO}_2\text{H}
\]

\[
\text{R}^1\text{R}^2\text{NH} + (\text{Me} \cdot \text{CO})_2\text{O} \rightarrow \text{Me} \cdot \text{CO} \cdot \text{NR}^1\text{R}^2 + \text{Me} \cdot \text{CO}_2\text{H}
\]
Acetyl chloride is not so satisfactory since an equivalent quantity of the amine hydrochloride is simultaneously produced:

$$2RNH_2 + \text{Me} \cdot \text{COCl} \rightarrow \text{Me} \cdot \text{CO} \cdot \text{NHR} + \text{RNH}_3\text{Cl}$$

Reflux gently in a test tube under a short air condenser 1 g of the base with 2.5 moles [or 3.0 g (3.0 ml) if the molecular weight is unknown] of acetic anhydride for 10–15 minutes. Cool the reaction mixture and pour it into 20 ml of cold water. Boil to decompose the excess of acetic anhydride. When cold, filter the residual insoluble acetyl derivative and wash it with a little cold water. Recrystallise from water or from dilute ethanol.

Certain ortho-substituted derivatives of aromatic amines are difficult to acetylate under the above conditions owing to steric hindrance. The process is facilitated by the addition of a few drops of concentrated sulphuric acid (compare Expt 6.59), which acts as a catalyst, and by the use of a large excess of acetic anhydride.

Excellent results may be obtained by conducting the acetylation in aqueous solution. Dissolve 0.5 g of the amine in 2 ml hydrochloric acid, and add a little crushed ice. Introduce a solution of 5 g of hydrated sodium acetate in 25 ml of water, followed by 5 ml of acetic anhydride. Shake the mixture in the cold until the smell of acetic anhydride disappears. Collect the solid acetyl derivative, and recrystallise it from water or dilute ethanol.

**BENZOYL DERIVATIVES**

Both primary and secondary amines form benzoyl derivatives under the conditions of the Schotten–Baumann reaction (see Section 6.6.2, p. 916, for a discussion).

Suspend 1 g (or 1 ml) of the substance in 20 ml of 5 per cent sodium hydroxide solution in a well-corked boiling tube or small conical flask, and add 2 ml of benzoyl chloride, c. 0.5 ml at a time, with constant shaking, and cooling in water (if necessary). Shake vigorously for 5–10 minutes until the odour of the benzoyl chloride has disappeared. Make sure that the mixture has an alkaline reaction. Filter off the solid benzoyl derivative, wash it with a little cold water and recrystallise it from ethanol or dilute ethanol.

If the benzoyl derivative is soluble in alkali, precipitate it together with the benzoic acid derived from the reagent by the addition of hydrochloric acid; filter and extract the product with cold ether or light petroleum (b.p. 40–60 °C) to remove the benzoic acid.

The following alternative procedure is sometimes useful.

To a solution of 0.5 g of the amine in 4 ml of dry pyridine and 10 ml of dry benzene (CAUTION), add dropwise 0.5 ml of benzoyl chloride. Heat the mixture under reflux on a water bath at 60–70 °C for 20–30 minutes and then pour into 80–100 ml of water. Separate the benzene layer and extract the aqueous layer with 10 ml of benzene. Wash the combined benzene solutions with 5 ml of 5 per cent sodium carbonate solution, followed by 5 ml of water, and dry with magnesium sulphate. Filter off the desiccant through a small fluted filter paper and concentrate the benzene solution to a small volume (3–4 ml). Stir 15–20 ml of hexane into the residue: the crystalline product separates. Filter and wash with a little hexane. Recrystallise from a mixture of cyclohexane with hexane or with ethyl acetate; alternatively use ethanol or dilute ethanol for recrystallisation.
BENZENESULPHONYL AND TOLUENE-\(p\)-SULPHONYL DERIVATIVES

Treat 1 g (1 ml) of the amine with 4 molar equivalents of 10 per cent sodium or potassium hydroxide solution (say, 20 ml), and add 1.5 moles (or 3g if the molecular weight is unknown) of benzenesulphonyl or toluene-\(p\)-sulphonyl chloride in small portions with constant shaking. To remove the excess of acid chloride, either shake vigorously or warm gently. Acidify with dilute hydrochloric acid and filter off the sulphonamide. Recrystallise it from ethanol or dilute ethanol.

If the presence of a disulphonyl derivative from a primary amine is suspected (e.g. formation of a precipitate in alkaline solution even after dilution), reflux the precipitate, obtained after acidifying, with a solution of 1 g of sodium in 20 ml of rectified spirit for 15 minutes. Evaporate the ethanol, dilute with water and filter if necessary; acidify with dilute hydrochloric acid. Collect the sulphonyl derivative and recrystallise it from ethanol or dilute ethanol.

It is generally more convenient to employ the solid toluene-\(p\)-sulphonyl chloride (m.p. 69 °C) rather than the liquid benzenesulphonyl chloride. Moreover, the benzenesulphonamides of certain secondary amines are oils or low melting point solids that may be difficult to crystallise: the toluene-\(p\)-sulphonamides usually have higher melting points and are more satisfactory as derivatives.\(^*\)

Feebly basic amines, e.g. the nitroanilines, generally react so slowly with benzenesulphonyl chloride that most of the acid chloride is hydrolysed by the aqueous alkali before a reasonable yield of the sulphonamide is produced; indeed, \(o\)-nitroaniline gives little or no sulphonamide under the above conditions. Excellent results are obtained by carrying out the reaction in pyridine solution:

\[
o\text{-NO}_2\cdot \text{C}_6\text{H}_4\cdot \text{NH}_2 + \text{Ph}\cdot \text{SO}_2\text{Cl} \xrightarrow{\text{pyridine, HCl}} o\text{-NO}_2\cdot \text{C}_6\text{H}_4\cdot \text{NH}\cdot \text{SO}_2\cdot \text{Ph}
\]

Reflux a mixture of 1 g (1 ml) of the amine, 2–3 g of benzenesulphonyl chloride and 6 ml of pyridine (CAUTION) for 30 minutes. Pour the reaction mixture into 10 ml of cold water and stir until the product crystallises. Filter off the solid and recrystallise it from ethanol or dilute ethanol.

Most amines react so rapidly in pyridine solution that the reaction is usually complete after refluxing for 10–15 minutes.

FORMYL DERIVATIVES

Formic acid condenses with primary and secondary amines to yield formyl derivatives:

\[
\text{Ar\cdot NHR} + \text{H\cdot CO}_2\text{H} \rightarrow \text{Ar\cdot N(R)\cdot CHO} + \text{H}_2\text{O}
\]

Reflux 0.5 g of the amine with 5 ml of 90 per cent formic acid (CAUTION: in handling) for 10 minutes, and dilute the hot solution with 10 ml of cold water. Cool in ice and, in some cases, saturate with salt if the derivative does not separate immediately. Filter, wash with cold water and recrystallise from water, ethanol or light petroleum (b.p. 60–80 °C).

\(^*\) For the separation of mixtures of primary, secondary and tertiary amines using benzenesulphonyl or toluene-\(p\)-sulphonyl chloride (Hinsberg's method), see p. 1288.
DERIVATIVES WITH 3-NITROPHTHALIC ANHYDRIDE

3-Nitrophthalic anhydride reacts with primary and secondary amines to yield nitrophthalamic acids; it does not react with tertiary amines. The phthalamic acid derived from a primary amine undergoes dehydration when heated to 145 °C to give a neutral N-substituted 3-nitrophthalimide. The phthalamic acid from a secondary amine is stable to heat and is, of course, soluble in alkali. The reagent therefore provides a method for distinguishing between, and separating a mixture of, primary and secondary amines.

\[
\text{CO}_2\text{H} \quad \xrightarrow{145 \degree C} \quad \text{CO} \cdot \text{NHR}
\]

Heat 0.5 g (or 0.5 ml) of the amine with 0.5 g of pure 3-nitrophthalic anhydride (Expt 6.162) in an oil bath at 145–150 °C for 10–20 minutes, pour the reaction mixture into a small mortar or Pyrex dish and allow it to solidify. Recrystallise from ethanol, aqueous ethanol or ethanol–acetone.

N-SUBSTITUTED PHTHALIMIDES (FROM PRIMARY AMINES)

Phthalic anhydride reacts with primary amines similarly to yield \( N \)-substituted phthalimides.

\[
\text{2,4-}(\text{NO}_2)\text{C}_6\text{H}_3\text{Cl} + \text{R-NH}_2 \rightarrow 2,4-\text{(NO}_2)\text{C}_6\text{H}_3\text{NH-R} + \text{HCl}
\]

Dissolve 0.5 g of the primary amine and 0.5 g of phthalic anhydride in 5 ml of glacial acetic acid and reflux for 20–30 minutes. (If the amine salt is used, add 1 g of sodium acetate.) The \( N \)-substituted phthalimide separates out on cooling. Recrystallise it from ethanol or from glacial acetic acid.

2,4-DINITROPHENYL DERIVATIVES

The halogen atom in 1-chloro-2,4-dinitrobenzene is reactive and coloured crystalline compounds (usually yellow or red) are formed with primary and with secondary amines:

\[
\text{2,4-}(\text{NO}_2)\text{C}_6\text{H}_3\text{Cl} + \text{R-NH}_2 \rightarrow 2,4-\text{(NO}_2)\text{C}_6\text{H}_3\text{NH-R} + \text{HCl}
\]

Dissolve 1.0 g (or 1.0 ml) of the amine and 1.0 g of 1-chloro-2,4-dinitrobenzene in 5–10 ml of ethanol, add a slight excess of anhydrous potassium carbonate or of powdered fused sodium acetate, reflux the mixture on a water bath for 20–30 minutes and then pour into water. Wash the precipitated solid with dilute sodium carbonate solution, followed by dilute hydrochloric acid. Recrystallise from ethanol, dilute ethanol or glacial acetic acid.

Note. Chlorodinitrobenzene must be handled with care (use disposable gloves). It if touches the skin, wash it off with industrial spirit and then copiously with water.
PHENYLTHIOUREAS
Primary and secondary amines react with phenyl isothiocyanate to yield phenylthioureas:

\[
\text{Ph-N} = \text{C} + \text{S} + \text{R} \text{NH}_2 \rightarrow \text{Ph-NH-CS-NHR}
\]

\[
\text{Ph-N} = \text{C} + \text{S} + \text{R}_2 \text{NH} \rightarrow \text{Ph-NH-CS-NR}_2
\]

Phenyl isothiocyanate is not sensitive to water; the reaction may be carried out with an aqueous solution of an amine.

Dissolve equivalent quantities of the reagent and of the amine in a small amount of rectified spirit. If no reaction appears to take place in the cold, reflux the mixture for 5–15 minutes. Upon cooling (and ‘scratching’ with a glass rod, if necessary) the crystalline thiourea separates. Recrystallise it from rectified spirit or from 60–80 per cent ethanol.

Alternatively, mix equal amounts (say, 0.2 g of each) of the amine and phenyl isothiocyanate in a test tube and shake for 2 minutes. If no reaction occurs, heat the mixture gently for 2 minutes and then cool in ice until the mass solidifies. Powder the solid, wash it with a little light petroleum (b.p. 100–120 °C) and recrystallise from rectified spirit.

1-Naphthyl isothiocyanate yields crystalline 1-naphthylthioureas and is similarly applied.

PICRATES
Picric acid combines with amines to yield salts (picrates), which usually possess characteristic melting points. Most picrates have the composition 1 mol amine: 1 mol picric acid. The picrates of the amines, particularly of the more basic ones, are generally more stable than the molecular \( \pi \)-complexes formed between picric acid and the hydrocarbons (compare Section 9.6.3, p. 1238).

If the amine is soluble in water, mix it with a slight excess (about 25%) of a saturated solution of picric acid in water (the solubility in cold water is about 1%). If the amine is insoluble in water, dissolve it by the addition of 2–3 drops of dilute hydrochloric acid (1:1) for each 2–3 ml of water, then add a slight excess of the reagent. If a heavy precipitate does not form immediately after the addition of the picric acid solution, allow the mixture to stand for some time and then shake vigorously. Filter off the precipitated picrate and recrystallise it from boiling water, ethanol or dilute ethanol, boiling 10 per cent acetic acid, chloroform, or, best, toluene.

The following alternative procedure may sometimes be employed. Dissolve 0.5 g of the amine in 5 ml of rectified spirit and add 5 ml of a cold saturated solution of picric acid in ethanol. Warm on a water bath for 5 minutes and allow to cool. Collect the precipitated picrate and recrystallise it as above.

BENZYLIDENE DERIVATIVES
Primary aromatic amines generally condense directly with benzaldehyde to form benzylidene derivatives (Schiff's bases or anils).

\[
\text{R-NH}_2 + \text{Ph-CHO} \rightarrow \text{R-N=CH-Ph + H}_2\text{O}
\]

These are often crystalline and therefore useful for the characterisation of primary amines. Diamines may, of course, yield di-benzylidene derivatives.

Heat the amine with 1 or 2 moles of redistilled benzaldehyde (according to whether the base is a monamine or diamine) to 100 °C for 10 minutes; if the
molecular weight is unknown, use 1 g of the base and 1 or 2 g of benzaldehyde. Sometimes a solvent, such as methanol (5 ml) or acetic acid, may be used. Recrystallise from ethanol, dilute ethanol or toluene.

The melting points of the derivatives of a number of aliphatic and aromatic primary and secondary amines are collected in Tables 10.32, 10.33 and 10.34.

9.6.22 TERTIARY AMINES

PICRATES
Experimental details are given under Primary and secondary amines, Section 9.6.21, above.

METHIOIDIDES
Methyl iodide (CAUTION) reacts with tertiary amines to form the crystalline quaternary ammonium iodide (methiodide):

$$\text{R}^1\text{R}^2\text{R}^3\text{N} + \text{MeI} \rightarrow \text{R}^1\text{R}^2\text{R}^3\text{NMe}^+\text{I}^-$$

Some of these derivatives are hygroscopic.

Allow a mixture of 0.5 g of the tertiary amine and 0.5 ml of colourless methyl iodide* to stand for 5 minutes. If reaction has not occurred, warm under reflux for 5 minutes on a water bath and then cool in ice-water. The mixture will generally set solid: if it does not, wash it with a little dry ether and 'scratch' the sides of the tube with a glass rod. Recrystallise the solid product from absolute ethanol or methanol, ethyl acetate, glacial acetic acid or ethanol–ether.

Alternatively, dissolve 0.5 g of the tertiary amine and 0.5 ml of methyl iodide in 5 ml of dry ether or toluene, and allow the mixture to stand for several hours. The methiodide precipitates, usually in a fairly pure state. Filter, wash with a little of the solvent and recrystallise as above.

The ethiodide is prepared similarly, using ethyl iodide.

METHOTOLUENE-\(p\)-SULPHONATES
Methyl toluene-\(p\)-sulphonate combines with many tertiary amines to yield crystalline derivatives:

$$\text{R}^1\text{R}^2\text{R}^3\text{N} + \text{p-MeC}_6\text{H}_4\text{SO}_3\text{Me} \rightarrow \text{R}^1\text{R}^2\text{R}^3\text{NMe}^+\text{p-MeC}_6\text{H}_4\text{SO}_3^-$$

Dissolve 2–3 g of methyl toluene-\(p\)-sulphonate in 10 ml of dry toluene, add 1 g of the amine and boil the mixture for 20–30 minutes. Cool, and filter the precipitated quaternary salt. Recrystallise by dissolving the solid in the minimum volume of boiling ethanol and then adding ethyl acetate until crystallisation commences. Filter the cold mixture, dry rapidly on a porous plate and determine the m.p. immediately.

The benzyltrialkylammonium salts \((\text{R}_3\text{N}\cdot\text{CH}_2\cdot\text{Ph})^+\text{Cl}^-\) are prepared similarly; 3 g of redistilled benzyl chloride replaces the methyl toluene-\(p\)-sulphonate.

REACTION WITH NITROUS ACID
\(N,N\)-Dialkylanilines yield green solid \(p\)-nitroso derivatives on treatment with

* Keep a coil of copper wire (prepared by winding copper wire round a glass tube) or a little silver powder in the bottle, which should be of brown or amber glass; the methyl iodide will remain colourless indefinitely. Ethyl iodide may sometimes give more satisfactory results.
nitrous acid (see p. 1215). Illustrative preparative details for \( p \)-nitrosodimethyl- 
aniline are as follows. Dissolve 1.0 g of dimethylaniline in 10 ml of dilute hydro- 
chloric acid (1:1), cool to 0–5°C and slowly add, with stirring, a solution of 
0.70 g of sodium nitrite in 4 ml of water. After 20–30 minutes, filter off the pre- 
cipitated yellow hydrochloride,* and wash it with a little dilute hydrochloric 
acid. Dissolve the precipitate in the minimum volume of water, add a solution of 
sodium carbonate or sodium hydroxide to decompose the hydrochloride (i.e. 
until alkaline) and extract the free base with ether. Evaporate the ether, and 
recrystallise the residual green crystals of \( p \)-nitrosodimethylaniline from light 
petroleum (b.p. 60–80°C) or from toluene. The pure compound has m.p. 85°C. 
The melting points of the derivatives of a number of aliphatic and aromatic 
tertiary amines are collected in Table 10.35.

9.6.23 \( \alpha \)-AMINO ACIDS

2,4-DINITROPHENYL DERIVATIVES 
The reaction between 1-fluoro-2,4-dinitrobenzene and amino acids leads to 
2,4-dinitrophenyl derivatives: these are often crystalline and possess relatively 
sharp melting points.

\[
2,4-(\text{NO}_2)_2\text{C}_6\text{H}_3\text{F} + \text{NH}_2\cdot\text{CHR} \cdot \text{CO}_2\text{H} \overset{(i) \text{NaHCO}_3}{\rightarrow} \overset{(ii) \text{HCl}}{\rightarrow} 2,4-(\text{NO}_2)_2\text{C}_6\text{H}_3\cdot\text{NH} \cdot \text{CHR} \cdot \text{CO}_2\text{H}
\]

To a solution or suspension of 0.25 g of the amino acid in 5 ml of water and 
0.5 g of sodium hydrogen carbonate, add a solution of 0.4 g of 1-fluoro-2,4- 
dinitrobenzene in 3 ml of ethanol. Shake the reaction mixture vigorously and 
allow to stand for 1 hour with intermittent vigorous shaking. Add 3 ml of satu- 
rated sodium chloride solution and extract with ether (2 \( \times \) 5 ml) to remove 
unchanged reagent. Pour the aqueous layer into 12 ml of cold 5 per cent hydro- 
chloric acid with vigorous agitation: this mixture should be distinctly acid to 
Congo red indicator paper. If the product separates as an oil, try to induce crys- 
tallisation by 'scratching' or stirring. Collect the derivative by suction filtration 
and recrystallise it from 50 per cent ethanol.

BENZOYL DERIVATIVES 
Dissolve 0.5 g of the amino acid in 10 ml of 10 per cent sodium hydrogen carbon- 
ate solution and add 1 g of benzoyl chloride. Shake the mixture vigorously in a 
stoppered test tube; remove the stopper from time to time since carbon dioxide 
is evolved. When the odour of benzoyl chloride has disappeared, acidify with 
dilute hydrochloric acid to Congo red and filter. Extract the solid with a little 
cold ether to remove any benzoic acid which may be present. Recrystallise the 
benzoyl derivative which remains from hot water or from dilute ethanol.

3,5-DINITROBENZOYL DERIVATIVES 
The following experimental details are for glycine (aminoacetic acid) and may 
be easily adapted for any other amino acid. Dissolve 0.75 g of glycine in 20 ml of

* The hydrochloride may not separate with other dialkylanilines. Add a slight excess of sodium car- 
bonate or sodium hydroxide to the solution, extract the free base with ether, etc.
m sodium hydroxide solution and add 2.32 g of finely powdered 3,5-dinitrobenzoyl chloride. Shake the mixture vigorously in a stoppered test tube; the acid chloride soon dissolves. Continue the shaking for 2 minutes, filter (if necessary) and acidify with dilute hydrochloric acid to Congo red. Recrystallise the derivative immediately from water or 50 per cent ethanol.

Excess of the reagent should be avoided, if possible. If excess of dinitrobenzoyl chloride is used, this appears as the acid in the precipitate obtained upon acidification: the acid can be removed by shaking in the cold with a mixture of 5 volumes of light petroleum (b.p. 40–60 °C) and 2 volumes of ethanol. The glycine derivative is insoluble in this medium. For some amino acids (leucine, valine and phenylalanine) acetic acid should be used for acidification.

TOLUENE- p -SULPHONYL DERIVATIVES
Amino acids react with toluene- p -sulphonyl chloride (compare Section 9.6.21, p. 1275) under the following experimental conditions to yield, in many cases, crystalline toluene- p -sulphonylamino acids.

Dissolve 0.01 g equivalent of the amino acid in 20 ml of m sodium hydroxide solution and add a solution of 2 g of toluene- p -sulphonyl chloride in 25 ml of ether; shake the mixture mechanically or stir vigorously for 3–4 hours. Separate the ether layer: acidify the aqueous layer to Congo red with dilute hydrochloric acid. The derivative usually crystallises out rapidly or will do so on standing in ice. Filter off the crystals and recrystallise from 4–5 ml of 60 per cent ethanol.

With phenylalanine and tyrosine, the sodium salt of the derivative is sparingly soluble in water and separates during the initial reaction. Acidify the suspension to Congo red: the salts pass into solution and the mixture separates into two layers. The derivative is in the ethereal layer and crystallises from it within a few minutes. It is filtered off and recrystallised.

2,4-DICHLOROPHENOXYACETYL DERIVATIVES
Amino acids react with 2,4-dichlorophenoxyacetyl chloride to give crystalline derivatives:

\[ 2,4\text{-Cl}_2\text{C}_6\text{H}_3\text{.O\text{-CH}_2\cdot COCl + H}_2\text{N\cdotCHR\cdot CO_2H} \xrightarrow{\text{HCl}} 2,4\text{-Cl}_2\text{C}_6\text{H}_3\text{.O\text{-CH}_2\cdot CO\cdot NH\cdotCHR\cdot CO_2H} \]

Dissolve 0.01 mol of the amino acid in 30 ml of m sodium hydroxide solution and cool to 5 °C in a bath of ice. Add, with rapid stirring, 0.01 mol of 2,4-dichlorophenoxyacetyl chloride dissolved in 5 ml of dry toluene at such a rate (5–10 minutes) that the temperature of the mixture does not rise above 15 °C, if the reaction mixture gels after the addition of the acid chloride, add water to thin it. Remove the ice bath and stir for 2–3 hours. Extract the resulting mixture with ether, and acidify the aqueous solution to Congo red with dilute hydrochloric acid. Collect the precipitate by filtration and recrystallise it from dilute ethanol.

Commercial 2,4-dichlorophenoxyacetic acid may be recrystallised from toluene; m.p. 139–140 °C. Reflux 10 g of the acid with 15 ml of thionyl chloride on a steam bath for 1 hour, distil off the excess of thionyl chloride at atmospheric pressure and the residue under reduced pressure: 2,4-dichlorophenoxyacetyl chloride (8 g) passes over at 155–157 °C/22–23 mmHg. It occasionally crystallises (m.p. 44.5–45.5 °C), but usually tends to remain as a supercooled liquid.
**PHTHALOYL DERIVATIVES**

Many amino acids condense with phthalic anhydride at 180–185°C to yield crystalline phthaloyl derivatives (N-substituted phthalimides).

\[
\text{H}_2\text{N}\cdot\text{CHR}\cdot\text{CO}_2\text{H} + \text{CO} + \text{CO} \xrightarrow{\text{H}_2\text{O}} \text{N}\cdot\text{CHR}\cdot\text{CO}_2\text{H}
\]

Place 0.5 g of the amino acid and 1.0 g of phthalic anhydride in a Pyrex test tube and immerse the lower part of the tube in an oil bath, which has previously been heated to 180–185°C. Stir the mixture occasionally during the first 10 minutes and push down the phthalic anhydride which sublimes on the walls into the reaction mixture with a glass rod. Leave the mixture undisturbed for 5 minutes. After 15 minutes, remove the test tube from the bath: when the liquid mass solidifies, invert the test tube and scrape out the excess of phthalic anhydride on the walls. Recrystallise the residue from 10 per cent ethanol or from water.

**1-NAPHTHYLUREIDO ACIDS (or 1-naphthylhydantoic acids)**

Amino acids react in alkaline solution with 1-naphthyl isocyanate to yield the sodium salts of the corresponding 1-naphthylureido acids, which remain in solution: upon addition of a mineral acid, the ureido acid is precipitated.

\[
\text{1-C}_{10}\text{H}_7\cdot\text{NCO} + \text{H}_2\text{N}\cdot\text{CHR}\cdot\text{CO}_2\text{Na} \rightarrow \text{1-C}_{10}\text{H}_7\cdot\text{NH}\cdot\text{CO}\cdot\text{NH}\cdot\text{CHR}\cdot\text{CO}_2\text{Na}
\]

Dissolve 0.5 g of the amino acid in slightly more than the equivalent quantity of 1 m sodium hydroxide solution in a stoppered flask. Add a quantity of 1-naphthyl isocyanate just equivalent to the alkali (if the molecular weight of the compound is not known, use 1 g of the reagent and the corresponding quantity of alkali), stopper the flask and shake vigorously until the odour of the reagent has disappeared. Filter off any insoluble di-1-naphthylurea (resulting from the action of water on any excess reagent), and acidify the filtrate to Congo red with dilute hydrochloric acid. Filter the naphthylureido acid at the pump, wash it with a little cold water and recrystallise from hot water or dilute ethanol.

The phenylureido acid is prepared similarly, using phenyl isocyanate. The latter is more sensitive to water than 1-naphthyl isocyanate and therefore does not keep so well.

The melting points of the derivatives of a number of amino acids are collected in Table 10.36. Most α-amino acids decompose on heating so that the melting points would be more accurately described as decomposition points: the latter vary somewhat with the rate of heating and the figures given are those obtained upon rapid heating.

**9.6.24 NITRO COMPOUNDS**

**REDUCTION TO THE PRIMARY AMINE**

Add 10 ml of concentrated hydrochloric acid in small portions to a mixture of 1.0 g of the nitro compound and 3 g of granulated tin contained in a small (say, 50-ml) flask fitted with a reflux condenser. Shake the flask well to ensure thorough mixing during the addition of the acid. After 10 minutes warm under
reflux at 100 °C with vigorous shaking until the nitro compound has dissolved and its odour is no longer apparent. (If the nitro compound dissolves slowly, add a few ml of ethanol.) Cool the reaction mixture thoroughly and cautiously make it alkaline with 20–40 per cent sodium hydroxide solution. Isolate the liberated amine by steam distillation or by ether extraction. Characterise the amine by the preparation of a suitable crystalline derivative (see Primary and secondary amines, Section 9.6.21, p. 1273).

Some aromatic dinitro compounds, e.g. m-dinitrobenzene, may be characterised by partial reduction to the nitroamine. Experimental details using sodium polysulphide as the reducing agent are to be found in Expt 6.51.

**OXIDATION OF SIDE CHAINS**

Aromatic nitro compounds that contain a side chain (e.g. nitro derivatives of alkylbenzenes) may be oxidised to the corresponding acids either by alkaline potassium permanganate (Aromatic hydrocarbons, Section 9.6.3, p. 1238) or, preferably, with a sodium dichromate–sulphuric acid mixture in which medium the nitro compound is more soluble.

Mix 1.0 g of the nitro compound with 4 g of sodium dichromate and 10 ml of water in a 50-ml flask, then attach a reflux condenser to the flask. Add slowly and with shaking 7 ml of concentrated sulphuric acid. The reaction usually starts at once; if it does not, heat the flask gently to initiate the reaction. When the heat of reaction subsides, boil the mixture, cautiously at first, under reflux for 20–30 minutes. Allow to cool, dilute with 30 ml of water and filter off the precipitated acid. Purify the crude acid by extraction with sodium carbonate solution, precipitation with dilute mineral acid and recrystallisation from hot water, toluene, etc.

**NITRATION TO A POLY-NITRO COMPOUND**

Aromatic mononitro compounds may sometimes be characterised by conversion into the corresponding dinitro or trinitro derivatives. It may be noted that many poly-nitro compounds form characteristic addition compounds with naphthalene.

The nitration of an aromatic compound, especially if its composition is unknown, must be conducted with great care, preferably behind a safety screen, since many aromatic compounds react violently.

A. Add about 0.5 g of the compound to 2.0 ml of concentrated sulphuric acid. Introduce 2.0 ml of concentrated nitric acid drop by drop, with shaking after each addition. Attach a small reflux condenser to the flask and heat in a beaker of water at 50 °C for 5 minutes. Pour the reaction mixture on to 15 g of crushed ice and collect the precipitated solid by suction filtration. Recrystallise from dilute ethanol.

B. Proceed as in A, but use 2.0 ml of fuming nitric acid instead of the concentrated nitric acid, and warm the mixture on a boiling water bath for 5–10 minutes.

The physical constants of a number of selected aromatic and aliphatic nitro compounds are collected in Tables 10.37 and 10.38 respectively. It will be noted that a few nitro aromatic esters have been included in the tables.
9.6.25 THIOLS

2,4-DINITROPHENYL SULPHIDES AND SULPHONES

Thiols react with 1-chloro-2,4-dinitrobenzene in alkaline solution to yield crystalline thioethers (2,4-dinitrophenyl sulphides) (1). These sulphides (1) can be readily oxidised in glacial acetic acid solution by potassium permanganate to the corresponding sulphones (2); the latter exhibit a wide range of melting points and are therefore particularly valuable for the characterisation of thiols. (See also Expt 5.208.)

$$2,4-(NO_2)_2C_6H_3Cl + RNH \xrightarrow{NaCl} 2,4-(NO_2)_2C_6H_3SR \xrightarrow{KMnO_4} 2,4-(NO_2)_2C_6H_3 \cdot SO_2R$$

(1)  
(2)

Preparation of 2,4-dinitrophenyl sulphides. Dissolve about 0.5 g (or 0.005 mol) of the thiol in 10–15 ml of rectified spirit (or in the minimum volume necessary for solution; warming is permissible) and add 2 ml of 10 per cent sodium hydroxide solution. Mix the resulting solution with a solution of 1 g of 1-chloro-2,4-dinitrobenzene (CAUTION: see Section 9.6.21, p. 1276) in 5 ml of rectified spirit. Reaction may occur immediately with precipitation of the thioether. In any case reflux the mixture for 10 minutes on a water bath in order to ensure the completeness of the reaction. Filter the hot solution rapidly; allow the solution to cool when the sulphide will crystallise out. Recrystallise from ethanol.

Preparation of the sulphones. Dissolve the 2,4-dinitrophenyl sulphide (0.005 mol) in the minimum volume of warm glacial acetic acid and add 3 per cent potassium permanganate solution with shaking as fast as decolourisation occurs. Use a 50 per cent excess of potassium permanganate: if the sulphide tends to precipitate, add more acetic acid. Just decolourise the solution with sulphur dioxide (or with sodium metabisulphite or ethanol) and add 2–3 volumes of crushed ice. Filter off the sulphone, dry and recrystallise from ethanol.

3,5-DINITROTHIOPHTHALATES

Thiols react with 3,5-dinitrobenzoyl chloride in the presence of pyridine as a catalyst to yield 3,5-dinitrothiobenzaldehydes (compare Alcohols and polyhydric alcohols, Section 9.6.4, p. 1241).

$$3,5-(NO_2)_2C_6H_3 \cdot COCl + RSH \xrightarrow{\text{pyridine}} 3,5-(NO_2)_2C_6H_3 \cdot COSR$$

Mix 0.2 g of 3,5-dinitrobenzoyl chloride, 6 drops of the thiol and 1–3 drops of pyridine in a test tube, and heat the mixture in a beaker of boiling water until fumes of hydrogen chloride cease to appear (10–15 minutes). Add a few drops of water, followed by a drop or two of pyridine to eliminate the excess of the reagent. The product solidifies upon stirring with a glass rod. Add water, filter and recrystallise from dilute ethanol or dilute acetic acid.

HYDROGEN 3-NITROTHIOPHTHALATES

Thiols react with 3-nitrophthalic anhydride to yield hydrogen 3-nitrothiophthalates (compare Section 9.6.4, p. 1243).
Mix 3-nitrophthalic anhydride (0.005 mol or 1.0 g) and the thiol (0.0075 mol, or 1.0 g if the molecular weight it not known) in a test tube and heat gently over a free flame for about 30 seconds. Allow the mixture to cool, and add 0.5 ml of 2 m sodium hydroxide solution dropwise and with cooling in an ice bath. Then add about 0.3 ml of 2 m hydrochloric acid and shake the reaction mixture vigorously. Collect the solid which separates by suction filtration and dry it upon a porous tile. Recrystallise from dilute acetic acid or from aqueous acetone.

The melting points are determined using a bath preheated to about 100°C. The compounds decompose slightly at the m.p. The melting points of the derivatives of the more commonly occurring thiols are collected in Table 10.39.

9.6.26 SULPHONIC ACIDS

SULPHONAMIDES
Mix together 1.0 g of the dry acid of 1.2 g of the anhydrous salt with 2.5 g of phosphorus pentachloride and heat under a reflux condenser in an oil bath at 150°C for 30 minutes. Cool the mixture, add 20 ml of dry benzene (CAUTION), warm in a steam bath (fume cupboard) and stir the solid mass well to extract the sulphonyl chloride: filter.* Add the benzene solution slowly and with stirring to 10 ml of concentrated ammonia solution. If the sulphonamide precipitates, separate it by filtration; if no solid is obtained, evaporate the benzene on a steam bath. Wash the sulphonamide with a little cold water, and recrystallise from water, aqueous ethanol or ethanol to constant m.p.

The procedure is not usually applicable to aminosulphonic acids owing to the interaction between the amino group and the phosphorus pentachloride. If, however, the chlorosulphonic acid is prepared by diazotisation and treatment with a solution of cuprous chloride in hydrochloric acid, the crystalline chlorosulphonamide and chlorosulphonanilide may be obtained in the usual way. With some compounds, the amino group may be protected by acetylation. Sulphonic acids derived from a phenol or naphthol cannot be converted into the sulphonyl chlorides by the phosphorus pentachloride method.

The sulphonanilides may be prepared by either of the following methods:

1. Reflux the solution of the sulphonyl chloride in benzene obtained as above, with 2.5 g of aniline for 1 hour. Concentrate the benzene solution to half its volume and cool in ice. Collect the solid which separates on a filter, wash with hot water and recrystallise from ethanol or dilute ethanol.

2. Treat the crude sulphonyl chloride (isolated by evaporating the solvent after extraction with benzene (or ether or chloroform) as above) with 1 g of p-toluidine and 30 ml of c. 2 m sodium hydroxide solution. Shake for 10–15 minutes.

* The sulphonyl chloride may be isolated by evaporating the benzene solution and recrystallising the residue from chloroform–light petroleum (b.p. 40–60°C) or toluene–light petroleum (b.p. 40–60°C).
Extract the alkaline solution with ether to remove excess of p-toluidine, acidify, filter and recrystallise the residue as in (1).

\[ R\cdot SO_2ONa + PCl_3 \longrightarrow R\cdot SO_2Cl + POCI_3 + NaCl \]
\[ R\cdot SO_2Cl + 2NH_3 \longrightarrow R\cdot SO_2NH_2 + NH_4Cl \]
\[ R\cdot SO_2Cl + 2Ph-NH_2 \longrightarrow R\cdot SO_2NH\cdot Ph + Ph\cdot NH_3\cdot Cl\]

**S-BENZYLISOTHIOURONIUM SALTS**

(See *Carboxylic acids*, Section 9.6.15, p. 1264.) If the substance is the free sulphonic acid, dissolve 0.5 g of it in 5–10 ml of water, add a drop or two of phenolphthalein indicator and neutralise with c. m sodium hydroxide solution. Then add 2–3 drops of 0.1 m hydrochloric acid to ensure that the solution is almost neutral (*pale* pink colour); under alkaline conditions the reagent tends to decompose to produce the evil-smelling phenylmethanethiol.

To a solution of 0.5 g of the salt in 5 ml of water and 2–3 drops of 0.1 m hydrochloric acid (or to a solution of the acid treated as above), add a slight excess of a cold, 15 per cent aqueous solution of S-benzylisothiouronium chloride (if the molecular weight of the compound is not known, use a solution of 1 g of the reagent in 5 ml of water), and cool in ice. Filter off the crystalline derivative and recrystallise it from 5 per cent ethanol.

**SULPHONACETAMIDES**

Sulphonacetamides are derivatives of sulphonamides (Section 9.6.27, p. 1286), but since the latter are readily prepared from the sulphonic acids or their salts, sulphonacetamides may be employed for the characterisation of sulphonic acids; for this reason they are included in this Section.

Sulphonamides upon heating with acetyl chloride are converted into the N-acetyl derivatives or sulphonacetamides:

\[ Ar\cdot SO_2NHR + Me\cdot COCl \xrightarrow{HCl} Ar\cdot SO_2N(R)\cdot CO\cdot Me \quad (R = H \text{ or alkyl}) \]

The sulphonacetamides (R=H) are freely soluble in sodium hydrogen carbonate solution thus rendering purification facile. Sulphonacetamides are moderately strong acids, and can generally be titrated in aqueous or aqueous–alcoholic solution with phenolphthalein as indicator. The acidic properties of sulphonacetamides may be used to effect a separation of a sulphonamide from an N-alkylsulphonamide. Acetylation of such a mixture gives a sulphonacetamide and an N-alkylsulphonacetamide, of which only the former is soluble in sodium hydrogen carbonate solution. Both sulphonacetamides and N-alkylsulphonacetamides are readily hydrolysed by boiling with excess of 5 per cent potassium hydroxide solution for about 1 hour, followed by acidification with dilute hydrochloric acid, giving the corresponding sulphonamides and N-alkylsulphonamides respectively.

Reflux 1 g of the sulphonamide with 2.5 ml of acetyl chloride for 30 minutes; if solution is not complete within 5 minutes, add up to 2.5 ml of glacial acetic acid. Remove the excess of acetyl chloride by distillation on a water bath, and pour the cold reaction mixture into water. Collect the product, wash with water and dissolve it in warm sodium hydrogen carbonate solution. Acidify the filtered solution with glacial acetic acid; filter off the precipitated sulphonacetamide and recrystallise it from aqueous ethanol.
p-TOLUIDINE SALTS OF SULPHONIC ACIDS
These are prepared by the interaction of the sulphonic acid or its sodium salt with p-toluidine hydrochloride in aqueous solution:

\[ R\cdot SO_3^+Na^+ + p\text{-Me} \cdot C_6H_4\cdot NH_2 + HCl \rightarrow (p\text{-Me} \cdot C_6H_4NH_3)^+ (R\cdot SO_3)^- + NaCl \]

Dissolve 1.0 g of the alkali metal salt of the sulphonic acid in the minimum volume of hot water and add 0.5 g of p-toluidine and 2 ml of concentrated hydrochloric acid. If a solid separates or the p-toluidine does not dissolve completely, add more hot water and a few drops of concentrated hydrochloric acid until a clear solution is obtained at the boiling point. Cool the solution; if crystallisation does not occur immediately, 'scratch' the walls of the test tube to induce crystallisation. Collect the product by suction filtration, and recrystallise it from hot water containing a drop of concentrated hydrochloric acid, or from dilute ethanol.

The melting points of the derivatives of a number of selected sulphonic acids are collected in Table 10.40; the melting points of the corresponding sulphonyl chlorides are included for purposes of reference. The acids do not possess sharp melting points; the sulphonic acids are therefore arranged in groups of related compounds. In a subsidiary Table (10.40A), a number of sulphonic acids are arranged in the order of increasing melting points of the S-benzylisothiouronium salts.

9.6.27 SULPHONAMIDES

HYDROLYSIS
Sulphonamides are most readily identified by hydrolysis with 80 per cent sulphuric acid (for experimental details see p. 1230).

\[ R'\cdot SO_2\cdot NH_2 + H_2O \rightarrow R'\cdot SO_3H + R'\cdot NH_2 \]

The amine is liberated by the addition of alkali and then characterised by a suitable derivative; the sulphonic acid may then be recovered as the sodium salt and converted into a suitable crystalline derivative, e.g. the S-benzylisothiouronium salt.

XANTHYLSULPHONAMIDES
Primary sulphonamides (R\cdot SO_2NH_2) may be most simply characterised by reaction with xanthhydrol to yield the corresponding N-xanthylsulphonamides (cf. Primary amides, Section 9.6.18, p. 1270). Dissolve 0.25 g of xanthhydrol and 0.25 g of the primary sulphonamide in 10 ml of glacial acetic acid. Shake for 2–3 minutes at the laboratory temperature and allow to stand for 60–90 minutes. Filter off the derivative, recrystallise it from dioxane–water (3:1) and dry at room temperature.

SULPHONACETAMIDES
Sulphonamides may also be characterised as sulphonacetamides: for experimental details see Section 9.6.26, above).
The melting points of sulphonamides, both aliphatic and aromatic, together with the melting points of some $N$-xanthylsulphonamides and sulphonacetamides are collected in Tables 10.41 and 10.40.

### 9.7 SEPARATION OF MIXTURES OF ORGANIC COMPOUNDS

#### 9.7.1 INTRODUCTION

The organic chemist is frequently faced with the task of separating mixtures of compounds. Since few organic reactions give a single product, this commonly occurs in the work-up stage of a reaction when it is desired to isolate a single pure compound from a mixture which may contain unreacted starting materials and reagents, inorganic material produced from reagents, and expected and unexpected by-products (Section 2.18). The chemist may also need to separate mixtures of naturally occurring substances obtained from plant or animal sources. Earlier chapters have illustrated many of the techniques used by the organic chemist to separate mixtures as part of a reaction work-up. The particular method used will depend on the chemical and physical properties of the substances involved. A simple, standard procedure is as follows. Pour the reaction mixture into water; extract the organic material with a low-boiling solvent such as ether or dichloromethane by shaking in a separatory funnel with several successive portions of the solvent; combine the organic solutions and dry with a suitable drying agent (Section 2.23); remove the solvent by distillation or by using a rotary evaporator; purify the residual organic product by distillation (Section 2.24) or recrystallisation (Section 2.20). The reaction work-up procedure may be modified to take advantage of particular physical or chemical properties of one or more components of the mixture, such as volatility, solubility characteristics and acidic or basic properties, and some of these methods are described in this section. The mixture may be examined by one or more chromatographic methods (Section 2.31), commonly thin-layer chromatography (t.l.c.), gas–liquid chromatography (g.l.c.) or high performance liquid chromatography to determine the number of components. The mixture may also be investigated by spectroscopic techniques (Section 9.4) and chemical methods (Section 9.5) to give an indication of the nature of the components. In the light of all this information the chemist can decide on the appropriate method of separation. The greater the similarity in chemical and physical properties, the more challenging does the task of separation become. Examples are included in earlier chapters of the separation of structural isomers (for example: toluene-$p$- and $o$-sulphonyl chlorides, Expt 6.41; $o$- and $p$-hydroxypropophenones, Expt 6.107; $o$- and $p$-hydroxybenzaldehydes, Expt 6.116; 3- and 4-nitrophthalic acids, Expt 6.162), geometric isomers (for example, $(E)$- and $(Z)$-azobenzenes, Section 2.31.2, p. 223) and optical isomers (for example: $(\pm)$-$\alpha$-methylbenzylamine, Expt 5.219; $(\pm)$-octan-2-ol, Expt 5.220; and $(\pm)$-alanine, Expt 5.221).

In order to gain an understanding of the principles involved and of the variety of methods which may be employed, it can be useful practice for the organic chemistry student to carry out exercises on the investigation and separation of given mixtures. It is impossible, however, to give a set of procedures which will be applicable, without modification, to the great variety of combinations which may be encountered. Advantage should be taken of any facts which
have emerged in the preliminary examination and to adapt, if necessary, the general schemes given below to the mixture under examination. The preliminary examination is therefore of fundamental importance.

Broadly speaking, the separation of the components of mixtures may be divided into three main groups.

SEPARATIONS BASED UPON DIFFERENCES IN THE CHEMICAL PROPERTIES OF THE COMPONENTS

A mixture of toluene and aniline may be separated by extraction with dilute hydrochloric acid: the aniline passes into the aqueous layer in the form of the salt, aniline hydrochloride, and may be recovered by neutralisation. Similarly, a mixture of phenol and toluene may be separated by treatment with dilute sodium hydroxide. The above examples are, of course, simple applications of the fact that the various components fall into different solubility groups (compare Section 9.2). Another example is the separation of a mixture of dibutyl ether and chlorobenzene: concentrated sulphuric acid dissolves only the dibutyl ether and it may be recovered from solution by distillation with water. With some classes of compounds, e.g. unsaturated compounds, concentrated sulphuric acid leads to polymerisation, sulphonation, etc., so that the original component cannot be recovered unchanged: this solvent, therefore, possesses limited application.

Phenols may be separated from acids (for example, o-cresol from benzoic acid) by a dilute solution of sodium hydrogen carbonate: the weakly acidic phenols (and also enols) are not converted into salts by this reagent and may be removed by ether extraction or by other means; the acids pass into solution as the sodium salts and may be recovered after acidification. For experimental details see Sections 2.22 and 9.6.17, p. 1266.

Mixtures of primary, secondary and tertiary amines can usually be separated by Hinsberg’s method. This is based on the fact that reaction with benzene-sulphonyl (or toluene-p-sulphonyl) chloride converts primary amines into alkali-soluble sulphonamides, secondary amines into alkali-insoluble sulphonamides and leaves tertiary amines unaffected.

\[
\text{Ph- SO}_2\text{Cl} + \text{H}_2\text{N-R} \xrightarrow{\text{NaOH}} [\text{Ph- SO}_2\text{N-R}]\text{Na}^+ \text{ (water-soluble)}
\]

\[
\xrightarrow{\text{HCl}} \text{Ph- SO}_2\text{NH-R} \text{ (water-insoluble)}
\]

\[
\text{Ph- SO}_2\text{Cl} + \text{NHR}_2 \xrightarrow{\text{NaOH}} \text{Ph- SO}_2\text{NR}_2 \text{ (insoluble in alkali)}
\]

The following experimental details illustrate how the Hinsberg separation of amines may be carried out in practice.

Treat 2.0 g of the mixture of amines with 40 ml of 10 per cent of sodium hydroxide solution and add 4 g (3 ml) of benzenesulphonyl chloride (or 4 g of toluene-p-sulphonyl chloride) in small portions. Warm on a water bath to complete the reaction. Acidify the alkaline solution with dilute hydrochloric acid when the sulphonamides of the primary and secondary amines are precipitated. Filter off the solid and wash it with a little cold water; the tertiary amine will be present in the filtrate. To convert any disulphonamide that may have been formed from the primary amine into the sulphonamide, boil the solid under reflux with 2.0 g of sodium dissolved in 40 ml of absolute ethanol for 30 minutes. Dilute with a little water and distil off the alcohol; filter off the precipitate of the sulphonamide of the secondary amine. Acidify the filtrate with dilute hydro-
chloric acid to precipitate the derivative of the primary amine. Recrystallise the respective derivatives from ethanol or from dilute ethanol.

Aldehydes, e.g. benzaldehyde, may be separated from liquid hydrocarbons and other neutral, water-insoluble liquid compounds by shaking with a solution of sodium metabisulphite: the aldehyde forms a solid bisulphite compound, which may be filtered off and decomposed with dilute acid or with sodium bicarbonate solution in order to recover the aldehyde.

A valuable method of separating ketones from other neutral and water-insoluble compounds utilises the Girard-T reagent. (Section 4.2.30, p. 434). It reacts with the carbonyl compound to yield another quaternary ammonium salt:

$$\text{R}^1\text{R}^2\text{CO} + [\text{Me}_3\text{N} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{NH}_2]\text{Cl}^{-} \rightarrow [\text{Me}_3\text{N} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{N} = \text{CR}^1\text{R}^2]\text{Cl}^{-} + \text{H}_2\text{O}$$

The latter is a polar compound and is therefore soluble in water. Extraction with ether removes the water-insoluble compounds, leaving the salt in the aqueous layer. The ketone is easily regenerated by hydrolysis with dilute hydrochloric acid (p. 434).

**SEPARATIONS BASED UPON DIFFERENCES IN THE VOLATILITIES OF THE COMPONENTS IN AQUEOUS SOLUTION**

This procedure is generally employed for the water-soluble compounds, and may also be applied to mixtures in which one of the components is slightly soluble in water. The water-soluble compounds include the lower members of the homologous series of alcohols, aldehydes, ketones, acids, esters, amines and nitriles; compounds containing two or more hydroxyl or amino groups, hydroxy-, amino-, di- and poly-basic acids, sulphonic acids and salts. The compounds with one functional group are usually volatile in steam and distil with the water; compounds with two or more functional groups (amino, hydroxyl or carboxyl) are not generally steam-volatile. The stable salts of steam-volatile bases and acids may be decomposed by a stronger non-volatile mineral acid (sulphuric acid or phosphoric acid) or base (sodium or potassium hydroxide), and the organic base or acid separated by steam distillation from the aqueous solution or suspension. The salts of weaker bases and acids (e.g. the amine or ammonium salts of carboxylic acids and the alkali metal salts of some phenols) are sufficiently hydrolysed by boiling water to permit the basic or acidic compound to distil with the water. It should be noted that sulphonic acids and their salts are not volatile in steam. The only disadvantage of this procedure is that certain compounds may decompose or polymerise or otherwise undergo change under the influence of aqueous alkali or acid at 100 °C, and this fact must be borne in mind when the method is employed. Thus sugars are decomposed by alkali; these may sometimes be isolated by evaporation of the solvent at pH 7, preferably under diminished pressure.

The essential basis of the scheme for the separation of water-soluble compounds is, therefore, distillation of (a) an aqueous solution of the mixture, (b) an alkaline (with sodium hydroxide) solution of the mixture and (c) an acidic (with sulphuric or phosphoric acid) solution of the mixture. The residue will contain the non-volatile components, which must be separated from inorganic salts and from each other by any suitable process.
The following are examples of the above procedure. A mixture of diethylamine and butan-1-ol may be separated by adding sufficient dilute sulphuric acid to neutralise the base: steam distillation will remove the alcohol. The amine can be recovered by adding sodium hydroxide to the residue and repeating the distillation. A mixture of diethyl ketone and acetic acid may be treated with sufficient dilute sodium hydroxide solution to transform the acid into sodium acetate and distilling the aqueous mixture. The ketone will pass over in the steam and the non-volatile, stable salt will remain in the flask. Acidification with dilute sulphuric acid liberates acetic acid, which can be isolated by steam distillation or by extraction.

SEPARATIONS BASED UPON DIFFERENCES IN THE PHYSICAL PROPERTIES OF THE COMPONENTS

When the separation procedures described in detail above are unsatisfactory for the separation of a mixture of organic compounds, purely physical methods may be employed. Thus a mixture of volatile liquids may be fractionally distilled (compare Section 2.26); or a mixture of non-volatile solids may frequently be separated by making use of the differences in solubilities in inert solvents. The progress of such separations may be monitored by application of the various chromatographic techniques detailed in Section 2.31, or indeed these techniques may be employed on the preparative scale for effecting the separation itself (e.g. flash chromatography, p. 217). The techniques of counter current distribution, fractional crystallisation or fractional sublimation (Section 2.21) may also be employed where appropriate.

9.7.2 PRELIMINARY EXAMINATION OF A MIXTURE

LIQUID MIXTURES

Physical properties. Examine the mixture with regard to odour, viscosity and colour.

Solubility in water. Transfer 1.0 ml of the mixture by means of a calibrated dropper or a small pipette into a small graduated test tube: add 1 ml of water and shake. Observe whether there is complete or partial solution and if there is any sign of chemical reaction. If solution is not complete, add more water (in 1 ml portions) and note (a) if the mixture dissolves completely, and (b) if a portion is insoluble and, if so, whether it is heavier or lighter than the aqueous layer. If an emulsion is formed, it may be assumed that at least one component of the mixture is insoluble in water and at least one component is soluble. Test the aqueous layer obtained with litmus and with phenolphthalein: if there is an acid reaction, test also with 5 per cent sodium hydrogen carbonate solution.

Presence or absence of water. Determine the absence or presence of water in the mixture by one or more of the following tests:

1. Investigate its miscibility with ether or with toluene.
2. Observe its action upon anhydrous copper(ii) sulphate.
3. Distil a small portion and note the b.p. and properties of the distillate.
4. Distil 3 ml of the mixture with 3 ml of dry toluene from a dry 10-ml distilling flask. Collect 2 ml of the distillate and dilute it with 5 ml of dry toluene; the
formation of two layers or of distinct drops suspended in the toluene indicates the presence of water.

**Behaviour upon distillation.** If the original mixture is not an aqueous solution, place 5 ml (or 10 ml) of it in a 10-ml (or 25-ml) flask set for downward distillation, immerse the latter in a small beaker of cold water and gradually heat to boiling. Observe the b.p. of any liquid which passes over and set it aside for subsequent examination. Determine the water-solubility of any residue. If it dissolves in water, examine it by Table 9.4; if insoluble in water, apply Table 9.3 (p. 1294 and p. 1296 respectively).

**Test for elements.** If the mixture is an aqueous solution, evaporate a small portion (c. 1 ml) to dryness upon platinum foil or in a small crucible. Use a portion of the residue to test for elements (Section 9.3) and another portion for the **Ignition test**, below.

If no water is present in the mixture, use it directly in the tests for elements.

**Ignition test.** Place 0.1–0.2 g of the mixture on a porcelain crucible cover: heat gently at first over a small flame and finally ignite strongly. Observe:

1. The inflammability and nature of the flame (e.g. smoky or otherwise).
2. Whether a residue is left after ignition; moisten with hydrochloric acid and test with a platinum wire.

**Spectroscopic investigation.** See Section 9.4.

**Miscellaneous tests.** Treat 1 ml of the mixture with 5 per cent sodium hydroxide solution until strongly alkaline: note whether an oil or solid separates, whether any ammonia is evolved and any colour changes which occur. Heat to boiling and cool: compare odour with that of the original mixture (a change in odour may indicate the presence of esters). Add dilute hydrochloric acid and observe the result.

Treat 1 ml of the mixture with dilute hydrochloric acid until strongly acid. Note any evolution of gas or the separation of a solid. Add dilute sodium hydroxide solution and observe the effect.

**Miscellaneous class reactions.** (Section 9.5.) Determine the effect of the following class reagents upon small portions of the original mixture: (i) bromine in dichloromethane solution; (ii) potassium permanganate solution; (iii) alcoholic silver nitrate solution; (iv) 2,4-dinitrophenylhydrazine reagent; (v) Schiff's reagent; (vi) acetyl chloride; (vii) benzoyl chloride (in the presence of aqueous sodium hydroxide); (viii) sodium (only if water is absent); (ix) iron(III) chloride solution; and (x) bromine water.

**SOLID MIXTURES**

**Physical properties.** Observe the colour, odour and crystalline form. Examine with a lens or a microscope, if available.

**Solubility in water.** Determine the solubility of 1.0 g of the sample in water. If in doubt as to whether a portion of the mixture dissolves, remove the supernatant liquid with a dropper and evaporate to dryness on a water bath. Determine the reaction of the aqueous solution or suspension to litmus and to phenolphthalein.
Test for elements, Section 9.3.

**Ignition test.** Place 0.1 g–0.2 g of the mixture upon a porcelain crucible cover or upon a piece of platinum foil; heat gently at first and finally ignite strongly. Note:

1. Whether the mixture melts and if decomposition occurs.
2. The flammability and the nature of the flame (e.g. if smoky or otherwise).
3. Whether a residue is obtained after ignition (moisten with hydrochloric acid and test with a platinum wire).

**Spectroscopic examination.** See Section 9.4.

**Miscellaneous tests.** Test the solubility behaviour of 0.5–1 g of the mixture to 5 per cent sodium hydroxide solution, 5 per cent sodium hydrogen carbonate solution and to 5 per cent hydrochloric acid (for details, see under Liquid mixtures).

**Miscellaneous class reactions.** (Section 9.5.) Determine the effect of the following class reagents upon small portions of the original mixture (for some of the tests an aqueous solution or suspension may be used): (i) bromine in dichloromethane solution; (ii) potassium permanganate solution; (iii) alcoholic silver nitrate solution; (iv) 2,4-dinitrophenylhydrazine reagent; (v) Schiff’s reagent; (vi) acetyl chloride; (vii) benzoyl chloride (in the presence of aqueous sodium hydroxide); (viii) iron(III) chloride solution; and (ix) bromine water.

A careful consideration of the results of the above tests will provide much useful information and will indicate which of the following general procedures should be applied and the modifications which are necessary. Thus if nitrogen is absent, it is doubtful whether the separation for bases would be necessary.

### 9.7.3 SEPARATION OF WATER-INSOLUBLE MIXTURES

If the water-insoluble mixture is a liquid, evaporate a small sample (say, 4 ml) in an evaporating dish on a water bath in order to determine the amount of volatile components, if any. If the solvent distils at the temperature of the boiling water bath, it is advisable to distil off this solvent on a water bath and to replace it by ether.

Place 15–20 ml of the liquid mixture in a 50-ml distilling flask arranged for distillation, and heat the flask on a boiling water bath until no more liquid passes over: redistil the distillate and if it is a single substance, identify it in the usual manner. Dissolve the residue \((R)\) in ether and employ the same proportions as given for a solid mixture.

**STEP I. EXTRACTION AND SEPARATION OF THE ACIDIC COMPONENTS**

Shake 5–10 g of the solid mixture (or of the residue \(R\) obtained after the removal of the solvent on a water bath) with 50 ml of pure ether, or other appropriate water-immiscible solvent (e.g. petroleum, dichloromethane, etc.). If there is a residue, separate it by filtration, preferably through a sintered glass funnel, wash it with a little ether and examine it appropriately. Shake the resulting ethereal solution in a small separatory funnel with 15 ml portions of 5 per cent aqueous sodium hydroxide solution until all the acidic components have been removed. Three portions of alkali are usually sufficient. Set aside the residual ethereal
solution \((E_1)\) for Step 2. Combine the sodium hydroxide extracts and wash the resulting mixture with 15–20 ml of ether; discard these washings. Render the alkaline extract acid to litmus with dilute sulphuric acid and then add excess of solid sodium hydrogen carbonate. Alternatively treat the sodium hydroxide extract with Cardice until no more is absorbed.

Separate any phenolic or enolic compounds which may be present by extracting the sodium hydrogen carbonate solution with two 20 ml portions of ether; remove the ether from the extract and examine any residue for phenols (or enols).

Strongly acidify the residual sodium hydrogen carbonate solution to Congo red with dilute sulphuric acid. If a solid acid forms, filter. Extract the filtrate or the acidified solution with two 20 ml portions of ether: keep the aqueous solution \((A)\). Distil off the ether, and add the residual acid (if a solid) to the solid separated by filtration. Identify the acid.

Now distil the filtrate \((A)\) and collect the distillate as long as it is acid to litmus. Should any solid separate out in the distilling flask during the distillation, add more water to dissolve it. Set aside the residue \((B)\) in the flask. Identify the volatile acid in the distillate. A simple method is to just neutralise it with sodium hydroxide solution, evaporate to dryness and convert the residual sodium salt into the S-benzylisothiouronium salt (Section 9.6.15, p. 1264).

The residue \((B)\) in the distilling flask may still contain a water-soluble, non-volatile acid. Cool the acid solution, neutralise it with dilute sodium hydroxide solution to Congo red and evaporate to dryness on a water bath under reduced pressure (water pump). Heat a little of the residual salt \((C)\) upon the tip of a nickel spatula in a Bunsen flame and observe whether any charring takes place. If charring occurs, thus indicating the presence of organic matter, extract the solid residue with 25 ml portions of hot absolute ethanol. Evaporate the ethanolic extract and identify the material which remains. The residue \((C)\) contains the sodium salt of a water-soluble, non-volatile acid, which may be characterised as the S-benzylisothiouronium salt.

**STEP 2. EXTRACTION OF THE BASIC COMPONENTS**

Extract the ethereal solution \((E_1)\) with 15 ml portions of 5 per cent hydrochloric acid until all the basic components have been removed: two or three portions of acid are usually sufficient. Preserve the residual ethereal solution \((E_2)\) for the separation of the neutral components. Wash the combined acid extracts with 15–20 ml of ether: discard the ether extract as in Step 1. Make the acid extract alkaline with 10–20 per cent sodium hydroxide solution: if any basic component separates, extract it with ether, evaporate the ether and characterise the residue. If a water-soluble base is also present, it may be recognised by its characteristic ammoniacal odour; it may be isolated from the solution remaining after the separation of the insoluble base by ether extraction by distilling the aqueous solution as long as the distillate is alkaline to litmus. Identify the base with the aid of phenyl isothiocyanate (compare Section 9.6.21, p. 1277) or by other means.

**STEP 3. THE NEUTRAL COMPONENTS**

The ethereal solution \((E_2)\) remaining after the acid extract of Step 2 should contain only the neutral compounds of solubility groups 5, 6 and 7 (see Table 9.1). Dry it with a little magnesium sulphate, and distil off the ether. If a residue is obtained, neutral compounds are present in the mixture. Test a portion of this

* Or other appropriate solvent.
with respect to its solubility in concentrated sulphuric acid; if it dissolves in the acid, pour the solution slowly and cautiously into ice-water and note whether any compound is recovered. Examine the main residue for homogeneity and if it is a mixture devise procedures, based for example upon differences in volatility, solubility in inert solvents, reaction with hydrolytic and other reagents, to separate the components.

The above procedure for water-insoluble mixtures is shown, in outline, in tabular form in Table 9.3. If the mixture is a liquid, the volatile solvent is assumed to have been removed.

9.7.4 SEPARATION OF WATER-SOLUBLE MIXTURES

A water-soluble mixture may be in the form of a mixture of water-soluble solids or in the form of a liquid. The liquid mixtures are frequently aqueous solutions. The preliminary examination of a liquid mixture (p. 1290) will indicate whether a volatile solvent (i.e. removable on a boiling water bath) is present. If a volatile solvent is present, distil 20 g of the mixture from a water bath until no more liquid passes over: set aside the volatile solvent for identification. Dissolve the residue (R) in water as detailed below for a mixture of solids.

STEP 1. DISTILLATION FROM ACID SOLUTION AND THE SEPARATION OF THE VOLATILE ACIDIC AND NEUTRAL COMPOUNDS

Dissolve 6–10 g of a solid mixture in 50–75 ml of water: for a liquid mixture, use 6–10 g of the residue (R) (non-volatile from a boiling water bath) and dilute with 50–75 ml of water: for an aqueous solution use sufficient of it to contain 6–10 g of the dissolved components and dilute, if necessary, to 50–75 ml. Acidify the solution with sufficient 20 per cent sulphuric acid to decompose the salts of all the acidic components and to ensure the presence of a slight excess of acid: many organic acids give an acid reaction with Congo red, hence it is necessary to add the sulphuric acid somewhat beyond the point at which the mixture is acid to this indicator. If an insoluble acidic component separates, filter it off and identify it. Distil the acid solution so long as the distillate appears turbid, or is acid to litmus, or until 100–150 ml are collected: in the last case, add more water to the contents of the distilling flask if the volume has been reduced below one-fourth of the original volume. Keep the residue (R₁) in the distilling flask for Step 2.

The distillate may contain volatile neutral compounds as well as volatile acids and phenols. Add a slight excess of 10–20 per cent sodium hydroxide solution to this distillate and distil until it is judged that all volatile organic compounds have passed over into the distillate. If necessary, the determination of the refractive index of the distillate or the application of specific chemical tests (e.g. for carbonyl compounds use the 2,4-dinitrophenylhydrazine reagent) should be used to confirm completion of distillation. Keep this distillate (S₁) for Step 4.

Cool the alkaline solution resulting from the distillation of the volatile neutral compounds, make it acid to litmus with dilute sulphuric acid and add an excess of solid sodium hydrogen carbonate. Extract this hydrogen carbonate solution with two 20 ml portions of ether; remove the ether from the combined ether extracts and identify the residual phenol (or enol). Then acidify the hydrogen carbonate solution cautiously with dilute sulphuric acid; if an acidic compound separates, remove it by two extractions with 20 ml portions of ether; if the

* The separation of a mixture of amines by means of benzenesulphonyl chloride or toluene-p-sulphonyl chloride (Hinsberg's method) is described in Section 9.7.1, p. 1288.
acidified solution remains clear, distil and collect any water-soluble, volatile acid in the distillate. Characterise the acid as described in Section 9.6.15, p. 1261.

STEP 2. DISTILLATION FROM ALKALINE SOLUTION
Treat the solution (R₁) remaining in the distilling flask after the volatile acidic and neutral compounds have been removed with 10–20 per cent sodium hydroxide solution until distinctly alkaline. If a solid separates, filter it off and identify it. Distil the alkaline solution until no more volatile bases pass over (distillate no longer turbid, or not basic to litmus: water-soluble bases also possess characteristic odours); add more water to the contents of the flask if the solution becomes too concentrated during this distillation. [Set aside the solution in the distilling flask (S₂) for Step 3.] If the volatile basic compounds are insoluble in water, remove them by extraction with two 20 ml portions of ether, and identify the bases (compare Sections 9.6.21, p. 1273 and 9.6.22, p. 1278) after evaporation of the ether. The water-soluble amines may be identified with phenyl isothiocyanate: it is best to concentrate the bases by redistilling and collecting the first half of the distillate separately.

STEP 3. THE NON-STEAM-VOLATILE COMPOUNDS
The alkaline solution (S₂) remaining in the distilling flask from Step 2 may contain water-soluble, non-volatile acidic, basic or neutral compounds. Add dilute sulphuric acid until the solution is just acid to Congo red, evaporate to dryness and extract the residual solid with boiling absolute ethanol: extraction is complete when the undissolved salt exhibits no sign of charring when heated on a metal spatula in the Bunsen flame. Evaporate the alcoholic solution to dryness and identify the residue.

STEP 4. THE STEAM-VOLATILE NEUTRAL COMPOUNDS
The solution (S₁) containing water-soluble neutral compounds obtained in Step 1 is usually very dilute. It is advisable to concentrate it by distillation until about one-third to one half of the original volume is collected as distillate; the process may be repeated if necessary. It is frequently possible to salt out the neutral components from the concentrated distillate by saturating it with solid potassium carbonate. If a layer of neutral compound makes its appearance, remove it. Treat this upper layer (which usually contains much water) with solid anhydrous potassium carbonate: if another aqueous layer forms, separate the upper organic layer and add more anhydrous potassium carbonate to it. Identify the neutral compound.

Note. Some neutral compounds (e.g. methanol) cannot be salted out with potassium carbonate: distillation of the saturated aqueous potassium carbonate solution frequently yields the organic compound in a comparatively pure state, or at least in sufficiently concentrated a form to enable certain derivatives to be prepared.

The above procedure for the separation of a water-soluble mixture is summarised in Table 9.4.
CHAPTER 10
PHYSICAL CONSTANTS OF ORGANIC COMPOUNDS

TABLES OF DERIVATIVES

The tables in this chapter contain lists of the more common members of the various classes of organic compounds arranged, as far as possible, in the order of increasing boiling points or melting points, together with the melting points of selected derivatives. Some of the tables are subdivided: thus in Table 10.6, Phenols, the additional sub-headings are Halogeno-phenols and Nitro-phenols. This subdivision renders the tables less cumbersome and facilitates their use.

In describing compounds in the literature, the range of a certain number of degrees is usually recorded for the boiling point or the melting point; the highest point of the boiling point or the melting point range is listed in the tables and the value is given to the nearest whole degree. For those compounds the author has purified or prepared, the actual observed boiling point or melting point is recorded. Densities are given for a temperature of 20 °C referred to water at 4 °C unless otherwise indicated. Refractive indices are recorded for the sodium D line at 20 °C. It must be remembered that the value obtained for a melting point depends upon the observer and upon the method which was used in the determination: this often accounts for the slightly different values found in the literature for the same compound.

Reference should be made to Section 2.3.4, p. 44, for those classes of compounds which are potentially carcinogenic; those marked C should be handled with great caution; some are subject to legal control in Great Britain or the USA or both.

Table 10.25  Aliphatic esters

It is considered that the table will be of greatest use if the esters are subdivided under the various acids rather than arranged in order of increasing b.p. or m.p. irrespective of the nature of the carboxylic acid. The latter procedure leads to an unwieldy, heterogeneous table which has relatively little pedagogic or, indeed, practical value.

Table 10.26 Aromatic esters

It is considered that the table will be of greatest use if the esters are in the main subdivided under the various acids rather than be arranged in order of increasing b.p. or m.p. irrespective of the nature of the carboxylic acid. The latter procedure leads to an unwieldy, heterogeneous table which has relatively little pedagogic or, indeed, practical value.

Table 10.40 Sulphonic acids

Note. Aromatic sulphonic acids are usually hygroscopic solids and do not generally have sharp melting points; they are frequently supplied in the form of their sodium (or other metal) salts. It is therefore not possible to classify them in order of increasing melting points. In this table

INTRODUCTION

The annual volume of published chemical papers has increased roughly five-fold over the past forty years. This volume of information imposes two sorts of tasks on the organic chemist. Firstly, to keep abreast of developments in aspects of the subject which are of particular interest by sampling the flow of published information as it appears, and secondly, to retrieve information of interest from the accumulation of published material. The information which is to be retrieved may be the physical properties of a specific compound or a reliable method for its preparation, a comprehensive list of preparative methods, a survey of recent work on a particular group of compounds, etc. Although some chemists, particularly those in large pharmaceutical companies, may have access to the services of information scientists, many still need to maintain current awareness and to carry out literature searches themselves, and all organic chemists need to be familiar with the nature of the chemical literature. Computerised methods for storage and retrieval of information are becoming increasingly common and accessible to the individual chemist and this trend is likely to continue. Given access to a good chemical library with a range of on-line facilities the experienced chemist should be able to obtain the information required without too much difficulty. The principal sources of such information are described in this appendix. The coverage is necessarily selective and readers who require a more detailed treatment are recommended to consult one of the specialised monographs on the subject.15

A.1.2 PRIMARY SOURCES — JOURNALS

Scientific journals are the principal method for communicating scientific information. The majority of papers abstracted by Chemical Abstracts is in English. These original papers are complemented by a range of other less-used primary literature such as patents, dissertations and theses, and reports of various kinds. Although a great number of journals are published which contain information of interest to the chemist, only a small proportion of them regularly contain material which is directly and immediately useful to the organic chemist. The most important journals dealing with organic chemistry are listed below. The standard abbreviation listed in the Chemical Abstracts Service Source Index (CASSI) is given in parenthesis.

APPENDIX 1
THE LITERATURE OF ORGANIC CHEMISTRY
Canadian Journal of Chemistry (Can. J. Chem.).
Chemical Communications (J. Chem. Soc., Chem. Commun.).
Chemische Berichte (Chem. Ber.).
Journal of the American Chemical Society (J. Am. Chem. Soc.).
Journal of Chemical Research, Synopses and microfiche or miniprint (J. Chem. Res. (S) and (M)).
Journal of General Chemistry of the USSR (English Translation) (Zhurnal Obschei Khimii) (J. Gen. Chem. USSR. (Engl. Transl.).).
Journal of Heterocyclic Chemistry (J. Heterocycl. Chem.).
Journal of Organometallic Chemistry (J. Organomet. Chem.).
Synthesis (Synthesis).
Synthetic Communications (Synth. Commun.).
Tetrahedron (Tetrahedron).

A.1.3 SECONDARY SOURCES — ABSTRACTS

Abstracting journals are publications giving contemporaneous, concise summaries of the various original journals and other contributions to knowledge. Each abstract usually supplies the title of the original paper, names of authors, original reference (i.e. name of journal, year of publication, volume or series number, page) and generally a brief summary of the paper. The value of the abstract in the first instance will depend on how detailed the summary is. It must be emphasised, however, that the reader should never be satisfied with the account to be found in the abstract. If at all possible the original work should be consulted. The only abstracting journal in English covering all fields of chemistry and chemical technology is Chemical Abstracts published by the American Chemical Society. All organic chemists should be familiar with the use of Chemical Abstracts. Other abstracting journals such as Biological Abstracts may contain information of interest to the organic chemist.

Chemical Abstracts was first published in 1907 and has continued ever since.
About 14,000 journals are monitored but only about 300 are abstracted completely. Chemical Abstracts Service Source Index (CASSI) provides a comprehensive list of journals currently abstracted by Chemical Abstracts. Two volumes of Chemical Abstracts are published each year, in 1988 volumes 108 and 109, and every five years a Collective Index is published covering the ten volumes published during the period. The publication of the Eleventh Collective Index, covering Volumes 96–105 (1982–86), was completed in 1988. The documents abstracted by Chemical Abstracts include journal articles, patents, reviews, technical reports, monographs, conference proceedings, symposia, dissertations and books. The abstracts are divided into eighty sections. The reader should consult Subject Coverage and Arrangement of Abstracts by Sections in Chemical Abstracts – 1982 published by Chemical Abstracts Services for a description of the subject coverage of each of the eighty sections. Chemical Abstracts appears weekly, each week containing alternately Sections 1–34 (Biochemistry and Organic Chemistry sections) and Sections 35–80 (Macromolecular Chemistry; Applied Chemistry and Chemical Engineering; and Physical, Inorganic and Analytical Chemistry sections). Each weekly issue of Chemical Abstracts contains two parts, the abstracts and the issue index (keyword, patent and author index). An Illustrative Key is included at the start of each new volume (which covers a six-month period) to assist the reader in the most effective use of the abstracts, and readers are recommended to consult this key for more detailed information than can be included in the present summary. Abstracts are numbered consecutively throughout each volume. Since 1976 (Volume 84), each abstract is immediately preceded by the volume number in lightface type, and followed by a computer-generated check-letter by which each reference is computer validated. Check letters have been in use since 1966 (Volume 66) and should not be confused with the column fractional designations (a–g) previously used to indicate the position of the abstract on the page.

The indexes of Chemical Abstracts are a key to the world's chemical and chemical engineering literature. There are six different indexes and care and practice are required to make effective use of them. In the Chemical Substance Index specified substances are identified and ordered by name; the General Subject Index lists classes of substances and general subjects; the Formula Index lists specific substances according to their molecular formula; in the Index of Ring Systems cyclic skeletons and stereoparents are identified and ordered by ring analysis; the Patent Index, which replaces the Numerical Patent Index and Patent Concordance, contains information on patent documents; and the Author Index links the names of authors to the corresponding abstract. Explanatory and illustrative matter relating to indexing is published separately as the Index Guide. Each Collective Index has its own Index Guide. The initial Index Guide for the Twelfth Collective Index (1987–91) was published in 1987 and will be revised and reissued three times during the five-year period. The Index Guides provide complete instructions on the use of Chemical Abstracts and also a comprehensive account of the policies for selecting the names of chemical substances in Chemical Abstracts. Appendix II of the Index Guide describes the organisation and use of the indexes and the relationship between them. In addition, Chemical Abstracts Service produces a workbook which provides further instruction on the use of Chemical Abstracts. The Ring Systems Handbook (1984) is a tool for searching Chemical Abstracts for specific ring systems, it provides a file of diagrams of ring systems (59,510 in the 1984 edition) together with indexes of
molecular formulae and ring names. The Ring Systems Handbook replaced the Parent Compounds Handbook which in turn replaced the Ring Index.

An additional method for the cross-referencing of chemical substances is the Chemical Abstracts Service (CAS) registry system. It is a computer-based system that assigns to each substance a unique identifying number called a registry number. The numbers have no chemical significance, but are assigned in sequential order as substances are entered into the system for the first time. Operation of the CAS registry system began in 1965. By August 1980 5 million compounds had been registered and new substances are being recorded at the rate of about 300,000 per year. The Registry Handbook includes in registry number order all substances that have been recorded since the system began, together with the molecular formula of each and one complete Chemical Abstracts index name. Registry numbers thus provide a means of structure identification without the need to resort to complex and sometimes ambiguous chemical nomenclature. A Registry Number Update is published annually. It provides a means of determining whether a registry number is still valid, and should always be consulted before using the Registry Handbook.

A useful abstracts journal specifically devoted to organic synthesis is the Journal of Synthetic Methods. This developed as an expansion and adaptation of Theilheimer's Methods of Organic Chemistry (see Section A1.4.3 below). About 6000 reactions reported in the literature are included annually. Of these, about 3000 are presented as abstracts and the remainder, mainly modifications and improvements, are given as supplementary references.

A1.4 TERTIARY SOURCES — REVIEWS, MONOGRAPHS, REFERENCE WORKS

There is a wide range of publications which gather together information from the published primary literature and organise and present it in a way which may be of value to the organic chemist. These publications range from comprehensive reference works such as Beilstein to the more recent series of specialist reports, such as those published by the Royal Society of Chemistry, which review the recent literature on one topic of specialist interest.

A1.4.1 BEILSTEIN

Beilstein's Handbook of Organic Chemistry (Beilstein's Handbuch der Organischen Chemie) is the largest compilation of information on organic compounds. Earlier volumes were published in German, but since 1984 it has been published in English; an indispensable guide to its use is available as Notes for Users of Beilstein's Handbook of Organic Chemistry, of which the following account is an extract.6

INTRODUCTION

The Beilstein Handbook of Organic Chemistry (Beilstein's Handbuch der Organischen Chemie) is a reference work containing information and data relating to the structure, preparation and properties of organic compounds reported in the primary literature. The information is condensed into short entries, each of
which records the important facts and numerical data relating to a particular compound, complete with literature citations, to achieve a very high density of information in the Handbook.

The Handbook is published in several series, each of which deals with the organic compounds reported in the literature during a given period; for each compound there is only one entry within a series. Publication of the Fourth edition (Vierte Auflage) started in 1918; it consists of the Basic Series (Hauptwerk), which covers all the compounds reported up to 1910, and Supplementary Series (Ergänzungswerke) which cover succeeding periods as indicated in Table A1.1.

* Volumes 17 to 27 of Series E III and E IV are combined in a joint issue.

Within each series of the Handbook the entries are ordered using the Beilstein System of Compound Classification; this is a set of rules which enables each organic compound to be assigned a position within the Handbook solely on the basis of its molecular structure; conversely, knowledge of the rules enables any compound from the c. 1 million compounds already described in the Handbook to be found rapidly, purely on the basis of its structure. A further advantage of the system is that many structurally related compounds are brought together within the same volume of the Handbook.

The Handbook is divided into 27 volumes (volume = Band), many of which run to several subvolumes; each compound is assigned to its particular volume, firstly on the basis of its skeletal structure, and secondly according to its functional groups. Within the individual volumes the ordering is based on structural features such as the type and number of functional groups, the degree of unsaturation, the number of carbon atoms and other similar criteria, until each compound has been assigned its position within the series. To use the Handbook effectively, however, it is not necessary to know all the rules of the Beilstein System, but merely to be able to identify in which of the 27 volumes the compound is described; this is outlined in the following sections. A more detailed description with worked examples is to be found in the booklet How to Use Beilstein (also available in German and Japanese) which, together with other informative material about the Beilstein Handbook, may be obtained free of charge by writing to

For those users of the Beilstein Handbook who are unfamiliar with the German language, a pocket-size *Beilstein Dictionary* (German/English) has been compiled by the Beilstein editorial staff and is also available free of charge. The contents of this dictionary are also to be found on the green pages in either of the subvolumes E III/IV 22/7 or E IV 6/4.

**LOCATING COMPOUNDS IN THE BEILSTEIN HANDBOOK**

The best way of finding the entry for a particular compound in the Beilstein Handbook is to identify in which volume the compound is listed, and then to consult the appropriate volume index. In order to identify the volume of interest a few basic principles of the Beilstein System need to be understood and these are described below.

For the purpose of classification in the Beilstein System, all organic compounds are divided into three basic types, viz. acyclic compounds (Volumes 1–4), isocyclic (i.e. carbocyclic) compounds (Volumes 5–16), and heterocyclic compounds (Volumes 17–27). Heterocyclic compounds are further subdivided according to the nature and number of the ring heteroatoms. All heterocycles

</tbody>
</table>

* Functional groups containing three or more nitrogen atoms, substituted by $-H$, $OH$ and $O$ only.
containing chalcogen (oxygen, sulphur, etc.) atoms as the only type of ring heteroatom are covered in Volumes 17–19; those with one chalcogen ring atom (hetero: 1 O) in Volumes 17 and 18, and those with two or more (hetero: 2 O, 3 O, ... etc.) in Volume 19. Heterocycles containing nitrogen as the only type of ring heteroatom are covered in Volumes 20–26; all other heterocyclic compounds, including those with both chalcogen and nitrogen ring heteroatoms, are dealt with in Volume 27 (further details are given in Table A1.2).

The position of the entry for any compound is determined by that fragment of its structure which is classified latest in the Beilstein System. Thus, for example, a compound containing a heterocyclic ring, a carbocyclic ring and an aliphatic chain is classified as a heterocycle, irrespective of the other structural elements, since all heterocycles are ordered after acyclic and isocyclic compounds in the Beilstein System. This feature of the systematic classification of compounds is called the Principle of Latest Systematic Entry.

Further classification of compounds within the divisions described above is based upon the type and number of the functional groups which they contain. At this level it is necessary to distinguish between

1. registry compounds, and
2. derivatives of registry compounds.

**Registry compounds** are defined as hydrocarbons or heterocycles which bear either no functional groups (i.e. parent compounds), or one or more of the functional groups listed in Table A1.2, bonded to carbon atoms; no carbon atom, however, may bear more than one functional group.* Three further restrictions apply to heterocyclic rings: the ring must contain at least one carbon atom; ring heteroatoms may neither be substituted nor bear functional groups; the ring must not contain chalcogen atoms other than oxygen as ring heteroatoms. Compounds which do not conform to these criteria are classified as derivatives (see below).

The volume of the Handbook containing the entry for any particular registry compound may be identified directly from Table A1.2 on the basis of its skeletal framework and functional groups. For compounds containing two or more different groups, the Principle of Latest Systematic Entry is again applied, and each compound is classified under the functional group which appears lowest in the list in Table A1.2. For example, 4-hydroxy-benzensulphonic acid is classified as an isocyclic sulphonic acid (Volume 11), and not as an isocyclic hydroxy-compound (Volume 6). In some cases, e.g. isocyclic amines, the second type of functional group is important to determine in which volume the compound will be dealt with; thus benzene-1,4-diamine (without a second type of functional group) is in Volume 13, whereas 4-amino-benzoic acid is in Volume 14.

---

* In carboxylic acids, the functional group consists only of the —OH and —O groups.
Further examples of registry compounds are given below:

![Registry compounds](image)

<td>3</td>
<td>14</td>
<td>24</td>
</tr>
</tbody>
</table>

All other compounds which cannot be classified as registry compounds are derivatives of registry compounds; they are not necessarily derived in the chemical sense but they are structurally related.

**Derivatives of registry compounds** are defined as compounds in which one or more of the following types of structural modification of the registry compounds occur:

(a) Modification of a functional group or the carbon atom bearing a functional group, e.g. acetyl chloride is classified as a derivative of the registry compound acetic acid.

(b) Substitution of hydrogen atoms, which are not bonded to carbon atoms bearing functional groups, by the following atoms and groups (which are classed as substituents and not as functional groups)

\[
\text{F Cl Br I NO NO}_2 \text{ N}_3 \text{ N}_5 (=\text{pentazolyl})
\]

E.g. 4-chloro-phenol is classified as a derivative of phenol.

(c) Replacement of one or more oxygen atoms in the registry compound by other bivalent chalcogen atoms, e.g. thiophene is the sulphur analogue of furan and is thus classified as a 'derivative'.

Derivatives are entered in the Handbook following the entry for the registry compound; the order is again determined by the Beilstein System. (If the registry compound was not reported in the literature covered by a particular series, its entry is omitted, but this does not affect the ordering of its derivatives in the Handbook.)

### A.1.4.2 COMPILATIONS OF DATA

Collections of spectroscopic data are listed in the references to Chapter 3, p. 393. On-line databases are described in references 4 and 7. There is, in addition, a
range of useful printed collections of data which are of great value to the organic chemist. Some of these are listed below.

*Atlas of Spectral Data and Physical Constants for Organic Compounds* (1975), 2nd edn. Eds J. G. Grassell and W. M. Ritchey. Cleveland, Ohio: CRC Press. Six volumes containing the following data on 21000 compounds: Wiswesser Line Notation, i.r., u.v., $^1$H and $^{13}$C n.m.r. and m.s. data.

### A1.4.3 SYNTHETIC METHODS AND TECHNIQUES

There are a number of valuable publications which provide accounts, of a more or less comprehensive nature, of aspects of the methodology and techniques of synthetic organic chemistry. A number of these are listed below.

*Organic Syntheses*, many editions. New York: Wiley. An annual publication of satisfactory methods for the preparation of organic compounds. The emphasis is on model procedures. 'Collective Volumes' are published after every ten annual volumes.

Reagents for Organic Synthesis, L. F. Fieser and M. Fieser. New York: Wiley-Interscience. Volumes 1–12, 1967–86. These twelve volumes provide a wealth of information drawn from the current literature, on the nature and use of hundreds of reagents used in organic synthesis. References are given to the original literature, and each succeeding volume provides references to the mention of each of the reagents in earlier volumes. This series is an essential reference manual for the practical organic chemist.

Very detailed accounts of chemistry of particular heterocyclic systems, totalling over 100 volumes.

A1.4.4 REVIEWS

With the increasing volume of primary literature, reviews and surveys of particular areas of activity are essential for the organic chemist. Some of the important review publications are Chemical Society Reviews, Chemical Reviews, Accounts of Chemical Research, Angewandte Chemie (International Edition in English), Russian Chemical Reviews, Survey of Progress in Chemistry. In addition there are a number of series of Advances in... and Progress in... various aspects of organic chemistry. The Specialist Periodical Reports, published by the Royal Society of Chemistry, London, provide systematic and comprehensive reviews of progress in major areas of research. Current titles include: General and Synthetic Methods; Carbohydrate Chemistry; Amino Acids and Peptides; Heterocyclic Chemistry; Organometallic Chemistry; Organophosphorus Chemistry.

A1.5 COMPUTERISED STORAGE AND RETRIEVAL OF INFORMATION

This is a rapidly developing subject. There is an increasing number of on-line databases readily available to the organic chemist. It is likely that all organic chemists will require skills to conduct searches of such databases in future. Any advanced course in organic chemistry should therefore provide an introduction to on-line searching techniques in order to provide the basis for development later in the student’s career. A detailed account of this field is beyond the scope of this appendix and would in any case date rapidly. The reader is referred to recent monographs for further information.4,7

1410
A general level of scientific awareness can be maintained from perusal of such periodicals as *Nature* and *Science*. In chemistry, such journals as the *Journal of the American Chemical Society* and *Chemical Communications* will keep the organic chemist in touch. At the specific level of particular aspects of organic chemistry it is necessary to scan a limited range of journals such as those listed in Section A1.2 above. The chemist is helped in this task by current awareness publications such as *Current Contents* published by ISI (Institute for Scientific Information) and *Current Titles* published by Chemical Abstracts Service. Each of these provides information on the contents of research journals in a particular field of interest. Neither gives direct access to the research journals but they provide an indicator of material of possible interest. Chemical Abstracts also publishes a range of current awareness bulletins known as *CA Selects*. Titles include Asymmetric Synthesis and Induction, Electrochemical Organic Synthesis, Natural Product Synthesis, etc. In the field of organic synthesis, *Methods of Organic Synthesis* published by the Royal Society of Chemistry provides coverage of about 200 items each month.

</table>

Notes. (a) The numbers in parentheses enable the solvent to be located in Section 4.1, where alternative names and methods of purification are to be found.
(b) Values for 25 °C unless otherwise indicated. Values <0.01 per cent described as insoluble.
(c) Recommended Limit, Control Limit and Threshold Limit Values, Section 2.3.4, p. 45.
(d) Value for p-xylene (isomer of highest m.p.).
(e) Approximate value.
(f) Value in doubt because of strong tendency to supercool and form a glass.
(g) No TLV value set.
HAZARD SYMBOLS

Legislation on packaging and labelling of dangerous substances defines hazardous chemicals under the following categories:

- **Toxic** \( T \)
- **Explosive** \( E \)
- **Corrosive** \( C \)
- **Oxidising** \( O \)
- **Highly Flammable/ Flammable** \( F \)
- **Irritant** \( Xi \)
- **Harmful** \( Xn \)

**Toxic** These products can cause death or serious illness when small amounts enter the body by ingestion, inhalation of vapour, fumes or dust, or by absorption through the skin; hygiene considerations should be rigorously observed.

**Corrosive** These products may destroy living tissue; eyes are particularly susceptible. Emergency showers should be available. If swallowed plenty of water should be given after immediate mouth rinsing.

**Explosive** These products may explode by the action of heat, sources of ignition, shock or friction. The compounds are often packaged wet to reduce the risk of explosion; they will become dangerous if allowed to dry. Some compounds form sensitive explosive salts on contact with metals.

**Oxidising** These compounds may cause fire and will always assist combustion. They produce heat on contact with organic matter and reducing agents.

**Flammable** These compounds have a low flash point, and those which react with water or damp air to give rise to flammable gases (e.g. hydrogen) from metal hydrides. Ignition sources include Bunsen burners, hot metal surfaces, electric sparks, etc. Fire fighting equipment should be readily available and frequently checked.

**Harmful** *Irritant* chemicals cause inflammation of the skin, mucous membranes, or discomfort of the respiratory system. *All* laboratory chemicals should be regarded as harmful; some are specifically harmful by skin contact, inhalation or swallowing.

APPENDIX 7
SELECTION OF MANUFACTURERS AND SUPPLIERS OF LABORATORY APPARATUS, EQUIPMENT AND CHEMICALS*

Ace Glass, 1430 Northwest Blvd, PO Box 688, Vineland, New Jersey, 08360, USA.
A.I. Scientific, London Road, Pampisford, Cambridge, CB2 4EF, UK.
Aldrich Chemical Co. Ltd, The Old Brickyard, New Road, Gillingham, Dorset, SP8 4JL, UK.
Applied Photophysics Ltd, 18/21 Corsham Street, London, N1 6DR, UK.
Baird & Tatlock Ltd, PO Box 1, Romford, Essex, RM1 1HA, UK.
Baskerville & Lindsay Ltd, 324c Barlow Moor Road, Chorlton-cum-Hardy, Manchester, M21 2AX, UK.
BDH Chemicals Ltd, Broom Road, Poole, BH12 4NN, UK.
Beckmann-RIIC Ltd, Progress Road, Sands Industrial Estate, High Wycombe, Buckinghamshire, HP12 4JL, UK.
Bellingham & Stanley Ltd, Longfield Road, North Farm Industrial Estate, Tunbridge Wells, Kent, TN2 3EY, UK.
J. Bibby Science Products Ltd, Tilling Drive, Stone, Staffordshire, ST15 0SA, UK.
BOC Ltd, The Priestley Centre, 10 Priestley Road, The Surrey Research Park, Guildford, Surrey, GU2 5XY, UK.
Cambridge Instruments Ltd, Viking Way, Bar Hill, Cambridge, CB3 8EL, UK.
Camlab Ltd, Nuffield Road, Cambridge, CB4 1TH, UK.
Ciba–Corning Diagnostics Ltd, Halstead, Essex, CO9 2DX, UK.
W. Coles & Co. Ltd, PO Box 42, Plastic Works, 47/49 Tanner Road, London, SE1, UK.
C. W. Cook & Sons Ltd, 190 Camden Street, Birmingham, B1 3DS, UK.
Corning Glass Works, Science Products, MP-21-5-8, Corning, New York 14831, USA.
Decon Laboratories Ltd, Conway Street, Hove, East Sussex, BN3 3LY, UK.
Detectawt (Gastec) Ltd, Unit 61, Garamonde Drive, Wymbush, Milton Keynes, Buckinghamshire, MK8 8DE, UK.
Draeger Ltd, The Willows, Mark Road, Hemel Hempstead, Hertfordshire, HP2 7BW, UK.
Eastman Kodak Co., 343 State Street, Rochester, New York, 14650, USA.
Edwards High Vacuum International, Manor Royal, Crawley, West Sussex, RH10 2LW, UK.
Electrothermal Engineering Ltd, 419 Sutton Road, Southend-on-Sea, Essex, SS2 5PH, UK.
Fisher Scientific Co., 711 Forbes Avenue, Pittsburgh, PA, USA.
Fluka AG, CH-9470 Buchs, Switzerland
Gallenkamp (Fisons Scientific Equipment Division), Belton Road West, Loughborough, Leicestershire, LE11 0TR, UK.

* Mostly UK addresses are given in this list. The International Directory (Buyers' Guide) is an invaluable source for addresses of companies in other countries, and is available from International Scientific Communications, Inc. 808 Kings Highway, PO Box 827, Fairfield, Connecticut, 06430-0827, USA.
Glaser Apparatus Co., 711, Hulman Street, PO Box 2128, Terre Haute, Indiana, 47802, USA.

Gow-Mac Instrument Co., PO Box G.13, Gillingham, Kent, ME7 4HA, UK.

Griffin and George Ltd, Bishop Meadow Road, Loughborough, Leicestershire, LE11 0RG, UK.

Hanovia Lamps Ltd, 145 Farnham Road, Slough, Berkshire, SL1 4XB, UK.

Interex Chemicals Ltd, PO Box 7, Warrington, Cheshire, WA4 6HB, UK.

Isopad Ltd, Isopad House, Shenley Road, Borehamwood, Hertfordshire, WD6 1TE, UK.

Jasco International Co. Ltd, through Ciba Corning Diagnostics Ltd, Halstead, Essex, CO9 2DX, UK.

Jencons (Scientific) Ltd, Cherrycourt Way Industrial Estate, Stanbridge Road, Leighton Buzzard, Bedfordshire, LU7 8UA, UK.

Jeol & Co. Ltd, Jeol House, Grove Park, Colindale, London, NW9 0JN, UK.

JJ’s (Chromatography) Ltd, Hardwick Industrial Estate, King’s Lynn, Norfolk, PE30 4JG, UK.

Jones Chromatography Ltd, New Road, Hengoed, Mid Glamorgan, CF8 8AU, UK.

Just Plastics Ltd, Cromwell House, Staffa Industrial Estate, Staffa Road, Leyton, London, E10 7PY, UK.

Koch-Light Ltd, Hollands Road, Haverhill, Suffolk, CB9 8PU, UK.

Lab-Marc, Icknield House, 1 Icknield Green, Letchworth, Hertfordshire, SG6 4DL, UK.

Macherey-Nagel AG, through Field Analytical, PO Box 113, Weybridge, Surrey, KT13 9UZ, UK.

Manostat Corporation, 519 Eight Avenue, New York, NY 10018, USA.

Mattson Instruments Ltd, Linford Forum, Rockingham Drive, Linford Wood, Milton Keynes. MK14 6LY, UK.

May & Baker Ltd, see Rhône-Poulenc

E. Merck through BDH.

Miller Howe Ltd, Watlington Industrial Park, Watlington, Oxfordshire, OX9 5LU, UK.

Millipore (UK) Ltd, see Waters Chromatography Division.

Optical Activity Ltd, Industrial Estate, Bury Road, Ramsey, Huntingdon, Cambridgeshire, PE17 1NA, UK.

Parr Instrument Co., through Scientific & Medical Products, Shirley Institute, Didsbury, Manchester, M20 8RX, UK.

PergaBase Inc., 12 Vandy Street, London, EC2A 2DE, UK.

Perkin-Elmer Ltd, Post Office Lane, Beaconsfield, Buckinghamshire, HP9 1QA, UK.

Phase Separations Ltd, Deeside Industrial Estate, Queensferry, Clwyd, CH5 2LR, UK.

Phillips Analytical, Pye Unican Ltd, York Street, Cambridge, CB1 2PX, UK.

Pierce Chemical Co, through Life Science Laboratories Ltd, Sedgwick Road, Luton, LU4 9DT, UK.

P. B. Radley & Co. Ltd, 53 London Road, Sawbridgeworth, Hertfordshire, UK.

Rhône-Poulenc, May and Baker Laboratory Products Ltd, Liverpool Road, Barton Moss, Eccles, Manchester, M30 7RT, UK.

Romil Chemicals Ltd, 63 Ashby Road Central, Shepshed, Loughborough, Leicestershire, LE12 9BS, UK.

Scientific Furnishings Ltd, Terminus Road, Chichester, Sussex, PO19 2UJ, UK.

Scientific and Medical Products Ltd, Shirley Institute, Didsbury, Manchester, M20 8RX, UK.

Shandon Southern Products Ltd, Chadwick Road, Astmoor, Runcorn, Cheshire, WA7 1PR, UK.

Sigma Chemical Co. Ltd, Fancy Road, Poole, Dorset, BH17 7NH, UK.

The Southern New England Ultraviolet Co., PO Box 4134, Hamden, Connecticut, 06514, USA.

TC Research, 9 West Parade, Norwich, Norfolk, NR2 3DN, UK.
Ultra-Violet Products Ltd, Science Park, Milton Road, Cambridge, CB4 4FH, UK.
Varian Associates Ltd, 28 Manor Road, Walton-on-Thames, Surrey, KT12 2QF, UK.
Vickers Laboratories, Greenholme Industrial Estate, Burley in Wharfedale, West Yorkshire, LS29 7DB, UK.
Vinten Instruments Ltd, Jessamy Road, Weybridge, Surrey, KT13 8LE, UK.
Waters Chromatography Division, Millipore (UK) Ltd, 11/15 Peterborough Road, Harrow, Middlesex, HA1 2YH, UK.
Whatman Ltd, Springfield Mill, Maidstone, Kent, ME14 2LE, UK.
J. Young (Scientific Glassware) Ltd, 11 Colville Road, Acton, London, W3 8BS, UK.

* These atomic weights are those adopted by the International Union of Pure and Applied Chemistry and are based on a relative atomic mass of C\textsuperscript{12} = 12.000.
INDEX

Page numbers in **bold-faced** type refer to details of preparative procedures. Page numbers in *italics* refer to mechanistic discussions.

Absorbance, 260, 283
Absorption maxima (i.r.) (*see also* Infrared absorption frequencies), 260
Absorption maxima (u.v.-visible), 388–93
  of aromatic compounds, 390
  hydrocarbons, 390
  substituted systems, 392
  of carbon–carbon multiple bonds, 388
  of carbonyl compounds, 390
  of heterocyclic compounds, 392
  rules for diene absorption, 389
  rules for enone absorption, 390
Absorptivity, molar, 385
Acetaldehyde: Doebner reaction with, 807
  reaction with Grignard reagents, 537
  reaction with triethylphosphonoacetate, 806
Acetals: characterisation by hydrolysis, 1257
  cyclic acetals (*see also* 1,3-Dioxolanes and 1,3-Dioxanes)
  hydrolysis of, 624
  of 1,2- and 1,3-diols, 553, 624, 658
  use of, in carbonyl protection, 624
  reaction with dinitrophenylhydrazine reagent, 1218
  table of, and derivatives of, 1330
Acetates: of amines, 1273
  of monosaccharides, 1247
  of phenols, 1248
Acetamide, use of, in amidomethylation, 866
*p*-Acetamidobenzenesulphonamide, and hydrolisis, 883
*p*-Acetamidobenzenesulphonyl chloride, and amide from, 883
  sulphapyridine from, 884
4-Acetamido-3-bromotoluene, and hydrolisis, 944
\(\alpha\)-Acetamidocinnamic acid, 1156
  hydrolisis of, 741
4-Acetamido-4,4-diethoxycarbonylbutanal, 756
  phenylhydrazone of, 756
  hydrolisis of, 757
2-Acetamido-5-methylbenzaldehyde, 915
2-Acetamido-5-methylbenzaldehyde trimethylene mercaptal, 916
Acetanilide: bromination of, 918
  chlorosulphonation of, 883
  nitrification (t.l.c.) of, 919
  reduction of, 774
Acetic acid: esters from, 699, 703
  physical properties of, 1442
Acetic acid equivalents, 680, 687
Acetic anhydride: acetylation of, 644, 704, 917, 1012
  i.r. spectrum of, 307
  Perkin reaction with, 1038
  physical properties of, 1442
Acetoacetic ester. *see* Ethyl acetoacetate
Acetone: acylation of, 633
  Claisen–Schmidt reaction with, 1034
  cyanohydrin from, 730
  physical properties of, 1442
  purification procedure for, 407
  reaction with Grignard reagents, 538
  reductive coupling of, 527
Acetone cyanohydrin, 730
  as *in situ* source of hydrogen cyanide, 992, 995
Acetonitrile: acylation of, 1017
  physical properties of, 1442
  purification procedure for, 410
Acetonylacetone, *see* Hexane-2,5-dione
Acetophenone: acylation of, 634
  chiral reduction of, 521, 525
  Claisen–Schmidt reaction with, 1169
  conversion to 1-phenylethylamine, 778
  glycidic esters from, 599
  i.r. spectrum of, 269
  Mannich reaction with, 1053
  mass spectrum of, 378
  oxidation of, 629
  p.m.r. spectrum of, 330
  reduction of, 831
Acetophenone phenylhydrazone and cyclisation of, 1161
Acetophenone toluene-\textit{p}-sulphonylhydrazone, and reduction of, 832
\textit{p}-Acetotoluide, and bromination of, 944
\textit{p}-Acetoxyazetidin-2-one, and reaction with 2-bromoethanol, 1143
\textit{o}-Acetoxybenzaldehyde, reaction byproduct, 1040
4-Acetoxy-3-ethylazetidin-2-one, i.r. and p.m.r. absorptions of, 1142
7-Acetoxyheptanal, 481
2-(6-Acetoxyhexyl)-1,3-dioxane, 482
1-Acetoxy-4-iodobutane, and p.m.r. absorptions of, 481
coupling reaction with, 481
Acetylacetone, see Pentane-2,4-dione
2-Acetylaminofluorene, carcinogenicity of, 49
Acetylation: of alcohols, 1223
of amines, 917, 1273
of \textit{p}-aminophenol, 984, 985
of butanal, 1141, 1142
of carbohydrates, 1247
diethyl aminomalonate, 748
d-\textit{D}-glyceraldehyde, 643, 644, 645
of \textit{a}-phenylenediamine, and cyclisation, 1162
of phenols, 976, 983, 1248
of quinones, 1261
of sulphonamides, 1285
of thiophene, 1007, 1014
of \textit{p}-toluidine, 744
of tribromoaniline, 909
Thiele, 1021, 1026, 1261
2-Acetylbutyrolactone, ring opening of, 1088, 1089
Acetyl chloride: acetylation with, 704, 1010
2-Acetylcyclohexanone, 634
Acetylcyclopentadienyl (cyclopentadienyl)iron(\textit{u}), see Acetylferrocene
Acetylene: alklylation with, 513
cylinders, precautions in use and storage of, 39
reaction with Grignard reagents, 538
reaction with sodium, 541
\textit{a},\textit{b}-Acetylenic acids, 805
Acetylenic halides, 553
Acetylferrocene, and chromatographic purification of, 1014
p.m.r. absorptions of, 1015
\textit{N}-Acetylglucose, and in heterocyclic synthesis, 1155
Acetylides, hazards of, 36
2-Acetynaphthalene, see Methyl 2-naphthyl ketone
2-Acetylthiophene, 1014
Achirality, 4
Acid anhydrides, see Carboxylic acid anhydrides
Acid esters from diesters, 697
Acid halides, see Carboxylic acid halides
Acid hydrazides, from esters, 1269
Acrolein, see Acrylaldehyde
Acrylaldehyde: conjugate addition to, 743, 756
hazards in use of, 758
RL of, 47
Acrylonitrile: addition of alcohols to, 717, 719
addition of diacylalanes to, 717, 719
addition of substituted malonic esters to, 682, 687, 718
precautions in use of, 718
Activating groups, in aromatic electrophilic substitution, 852
Acylation (see also Acetylation, Aroylation, Arylsulphonylation, Benzoylation, Carbonylbenzoylation, Formylation, Schotten-Baumann)
Friedel-Crafts, 827, 1006, 1008–16
Hoesch, 1008, 1017
of acetone, 633, 634
of alkohols, 698, 704–6
of alkylidiphosphine oxides, 497, 500
of amines, 1243
of amino acids, 746, 751, 761, 1279
of aromatic amines, 909, 916
of d-glucose, 642, 644–6
of ketones, 632, 634
of magnesium enolate of diethyl malonate, 619, 621
of malonate esters, 738, 742
of phenols, 1248
of proline, 751, 761
Acyl anion, and its equivalents, 21, 596–7, 600, 625–6, 739, 769, 788, 1089
Acyl cation, and its equivalents, 596, 626, 739, 990, 1006
Acyloins (\textit{a}-ketols), 512, 628, 1043, 1096
Acylphoroglucinols, from aliphatic nitriles, 1008, 1017, 1273
Adams' catalyst (see also Aliphatic nitriles), 459
Adapters: for ground-glass joints, expansion, 59
cone/rubber tubing, 62
multiple, 60
receiver, 61
reduction, 59
screw capped, 60
'swan-neck', 60
'take-off', 62
Addition (see also Halogenation, Hydroboration, Markownikoff, Oxymercuration, Reduction)
electrophilic: to alkenes, 509, 510, 542, 543, 545, 546, 574, 575–7, 1128, 1235
to alkynes, 1235
to dienes, 574, 575
to \textit{a},\textit{b}-unsaturated acids, 721
nucleophilic: to aldehydes and ketones, 495, 498, 520, 532, 727, 732, 681, 685, 1028–46
to \textit{a},\textit{b}-unsaturated esters, 681, 686
to \textit{a},\textit{b}-unsaturated nitriles, 682, 687
INDEX

pericyclic, see Cycloadditions
radical: to alkenes, 575, 576
1,2-Addition vs. 1,4-addition, 574, 575
Addition-elimination reaction, 900, 959, 960–
2, 1279
Adipaldehyde, see Hexanal
Adipic acid, 629, 668
esters from, 701, 703
methyl hydrogen ester from, 703
Adiponitrile, see Hexanedianitrite
Adogen, 464
reactions involving use of, 632, 989
AIBN (α,α′-azobisisobutyronitrile), 1124
Air-sensitive compounds: apparatus for handling, 121
drying of solvents and reagents, 122
separation of liquids and solids, 131
transfer of solvents and reagents, 122
gases, 125
liquids, 123
solids, 125
L-Alanine, 815
D-Alanine, 751
benzoylation of, and resolution of, 815
Alcohols
aliphatic: purification procedures for, 400
retrosynthetic strategies for, 518
structure of, 517
characteristic chemical properties of, 1223
derivatives of, 1241
polyhydric: characteristic chemical properties of, 1224
derivatives of, 1241
spectroscopic features: summaries of, 519, 1223
fragmentation (m.s.), 375
group frequencies (i.r.), 283
correlation table, 1416
table of, and derivatives of: aliphatic, 1304
aromatic, 1308
polyhydric, 1314
unsaturated analogues: retrosynthetic strategies for, 794
structure of, 794
Aldehydes of nitriles, 699, 706
Aldehydes
aliphatic: retrosynthetic strategies for, 586
structure of, 585
aromatic: retrosynthetic strategies for, 990
characteristic chemical properties of, 1218
derivatives of, 1257
spectroscopic features: summaries of, 587, 990, 1218
fragmentation (m.s.), 377
group frequencies (i.r.), 299
correlation table, 1418
table of, and derivatives of: aliphatic, 1332
aromatic, 1334
unsaturated aldehydes: strategies for, 798 et seq.
Aldol condensation, 799, 802, 1032
‘directed’ reaction, 800
intramolecular reaction, 1092, 1098
‘mixed’ reaction, 800
retro-reaction, 1093
Alicyclic hydrocarbons, see Cycloalkanes
Alizarin, 972
Alkane (saturated aliphatic hydrocarbons),
(see also Cycloalkanes)
characterisation of, 1235
purification procedures for, 397
retrosynthetic strategies for, 471
spectroscopic features: summary of, 472
fragmentation (m.s.), 374
group frequencies (i.r.), 273
correlation table, 1413
structure of, 470
table of physical constants of, 1300
Alkenes (unsaturated aliphatic hydrocarbons):
characteristic chemical properties of, 1226
derivatives of, 1235
retrosynthetic strategies for, 485
spectroscopic features: summary of, 485
fragmentation (m.s.), 374
group frequencies (i.r.), 277
correlation table, 1414, 1416
u.v.-visible absorptions, 388
structure of, 484
table of, and derivatives of, 1301
(E)- and (Z)-Alkenes, from alkynes, 494
Alkenyl halides, 553
Alkylation (see also Benzylation, Chloromethylation, Cyanomethylation, Friedel–Crafts, Hofmann exhaustive methylation, Quaternisation)
of acetamidomalic esters, 748, 755, 756
of aldehydes, 601, 602
of alkoxides, 583, 584
of alkenes, 513
of ammonia and its derivatives, 779
of anilines, 901, 902, 905
of aromatic hydrocarbons, 828, 829, 833
of (S)-cystine, 790, 791
of dialkyl sulphides, 790
of diethyl malonate, 680, 682, 1089, 1090
of enones, 1093, 1099
of hydrazones, 601
of imines, 601
of β-keto esters, 619, 620
of methylpyridines, 1167, 1171
of nitriles, 717, 719
of nitroalkanes, 768, 769
of oxazolines, 687, 689
of pentane-2,4-dione, 620, 622
of phenols, 976, 984
of phthalimide, 779, 780
of pyridines, 1167, 1171
of thiourea, 787, 788
of xanthate esters, 793
Alkylbenzenes, retrosynthetic strategies for, 826
Alkylboranes, 419, 542
Alkyl cyanides (see also Nitriles, aliphatic) amides from, 708
Alkyl (or aryl) 2,4-dinitrophenyl sulphones: from thiols, 1283 oxidation to sulphones, 1283
Alkyl- (or aryl)diphenylphosphine oxides, 497, 502
anion from, and addition to carbonyl group, 497
Alkyl fluorides, precautions in handling of, 571
Alkyl groups: group frequencies (i.r.) of, 276 correlation table, 1413
spin-spin splitting (p.m.r.) patterns of, 341, 1432
Alkyl halides, see Halogen compounds, aliphatic
Alkylidene dimethones, and anhydrides of, 1259, 1260
Alkylidenetriphenylphosphoranes, 495 reaction with carbonyl compounds, 495
S-Alkylisothiouronium picrates, from alkyl halides, 1152
Alkyllithium reagents (see also Butyllithium, Ethyllithium, etc), 442–5, 618 estimation of, 443 reaction with N,N-dimethylcarboxamides, 617, 618
Alkylmagnesium halide, structure of, 532 Alkyl mercury(II) halides, from alkyl halides, 1252
Alkyl nitriles: RL of, 47 Alkyl nitrates, see Nitrites, aliphatic analogues
Alkyl phosphonates, example in use of, 496, 798, 802, 804, 806
Alkyl sulphonates, see Sulphonates, aliphylkenes (acetylenes): derivatives of, 1237 retrosynthetic strategies for, 508 spectrophotometric features: summary of, 508 group frequencies (i.r.), 283 correlation table, 1416 u.v.-visible absorptions, 388 structure of, 507 table of, and derivatives of, 1301
Alkynyl halides, 553 Alkynyllithium, 513 Alkynylmagnesium halide, 532, 538 Alkynylsodium, 532, 541
Alkenes: chirality of, 6, 485 group frequencies (i.r.) of, 283 correlation tables, 1416 α- and β-D-Allopyranose, 642 Allyl alcohol: halides from, 558, 562, 567 RL of, 47 Allylation: of alcohols, 583, 585 of phenols, 985, 986, 988 Allyl bromide, 562 allylation with, 986 bromination of, 577 coupling reaction with, 480 nitrile from, 714
Allyl chloride, and m.s. data of, 558 allylation with, 585 RL of, 47 Allyl cyanide, 714 hydrolysis of, 673 Allyl ethers, see Ethers Allylic alcohols, 794 Allylic bromination 577, 578, 579 Allylic compounds, hazards in use of, 578 Allylic halides, 553 Allyl iodide, 567 coupling reaction with, 480 2-Allylphenol, and rearrangement of, 984 Allyl phenyl ether, 986 Claisen rearrangement of, 984 α-D-Allofuranose, methyl, 662 Alumina, chromatographic grading of, 212 Aluminium alkoxides, 414 Aluminium amalgam, 415 reactions involving use of, 843, 862 Aluminium t-butoxide, 414 Oppenauer oxidation with, 611 Aluminium chloride: as acylation/alkylation catalyst, 828, 832, 982, 994, 1006–16 hazards of, 44 other reactions involving use of, 513, 863 purification procedure for, 416 Aluminium isopropoxide, 415 reduction with, 520, 524 Amides: aliphatic, structure and synthesis, 708 aromatic, structure and synthesis, 1080 characteristic chemical properties of, 1226 from carboxylic acids (general procedure), 1261 hydrolysis of, 1227 primary: derivatives of, 1270 hydrolysis of, 1270 spectroscopic features: summaries of, 692, 1073 fragmentation (m.s.), 382 group frequencies (i.r.), 304 correlation table, 1419 substituted: fusion with soda-lime, 1271 derivatives of, 1271 table of, and derivatives of: primary aliphatic, 1361 primary aromatic, 1363 substituted aromatic, 1364 Amidomethylation reaction, 866 Amination, of α-halogenocarboxylic acids, 746, 751 Amines aliphatic: retrosynthetic strategies for, 770 aromatic: retrosynthetic strategies for, 889 classification using nitrous acid, 1215 confirmatory tests for, 1216, 1217 primary and secondary, derivatives of, 1273 spectroscopic features: summaries of, 771, 890, 1215 fragmentation (m.s.), 381
INDEX

group frequencies (i.r.), 290
correlation table, 1417
tertiary, derivatives of, 1278
table of, and derivatives of: primary and secondary aliphatic, 1370
primary aromatic, 1372
secondary aromatic, 1378
tertiary, 1380
unsaturated amines, see Enamines and Imines
Amine salts, group frequencies (i.r.) of, 293
Aminoacetaldehyde dimethyl acetal, in heterocyclic synthesis, 1189
Aminoacetic acid, see Glycine
Aminoacetonitrile, and hydrolysis of sulphate, 753
Amino acids: characteristic chemical properties of, 1230
chromatography of, 208
derivatives of, 1279
derivatives of, for protection, 750, 784-6
spectroscopic features: group frequencies (i.r.) of, 308
correlation table, 1420
structure of, 746
table of, and derivatives of, 1384
Aminoanisole, see Anisidine
p-Aminoazobenzene, 952
p-Aminoazotoluene, carcinogenicity of, 49
Aminobarbituric acid, 1177
p-Aminobenzenesulphonamide, 883
2-(p-Aminobenzenesulphonamido)pyridine, 884
2-Aminobenzenesulphonic acid, see Orthanilic acid
3-Aminobenzenesulphonic acid, see Metanilic acid
4-Aminobenzenesulphonic acid, see Sulphanilic acid
p-Aminobenzoic acid, 896
esterification of, 701, 897
iodination of, 910
L-2-Amino-3(benzyllthio)propanoic acid (S-benzyl-L-cysteine), 791
4-Aminobiphenyl, carcinogenicity of, 49
4-Amino-3-bromotoluene, and diazonium salt from, in synthesis, 945
2-Aminobutane, oxidation of, 767
4-Amino-3,5-diodobenzoic acid, 910
diazonium salt from, in synthesis, 931
p-Aminodimethylaniline, 951
2-Aminohexanoic acid, see DL-Norvaline
2-Amino-3-hydroxypropanoic acid, see DL-Serine
2-Amino-3-(3-indolyl)propanoic acid, see DL-Tryptophan
2-Amino-5-iodotoluene, 910
(S)-(—)-2-Amino-1-methoxy-3-phenylpropane, and p.m.r. absorptions of, 603
reaction with aldehydes, 603
2-Amino-5-methylbenzaldehyde trimethylene mercaptal, 915
acetylation of, 916
p.m.r. absorptions of, 916
2-Amino-3-methylbutanoic acid, see DL-Valine
2-Amino-3-methylpentanoic acid, see DL-Isoleucine
2-Amino-4-methylthiazole, 1153
1-Amino-2-naphthol, and oxidation of, 1026
1-Amino-2-naphthol hydrochloride, 949
2-Amino-5-naphthol-7-sulphonic acid, Bucherer reaction with, 901
2-Aminopentanoic acid, see DL-Phenylalanine
p-Aminophenol, and p.m.r. absorptions of, 894
in heterocyclic synthesis, 1186
p-Aminophenol, and i.r. and p.m.r. absorptions of, 955
acetylation of, 985
diazoization salt from, in synthesis, 930
DL-2-Aminophenylacetic acid, 754
2-Amino-1-phenylethanol, cyclisation of, 1129
(1S,2S)-(++)-2-Amino-1-phenylpropane-1,3-diol, oxazoline from, 689
2-Amino-3-phenylpropanoic acid, see DL-Phenylalanine
(S)-2-Amino-3-phenylpropan-1-ol, and methylation of, 602
2-Aminopropanoic acid, see DL-Alanine
2-Aminopyridine, and sulphapyridine from, 885
3-Aminopyridine, 899
4-Aminostilbene, carcinogenicity of, 49
2-Aminothiazole, 1153
3-Amino-1,2,4-triazole, carcinogenicity of, 49
Ammonia: gas, hazards of, 43
preparation of small amounts of, 417
Ammonia, liquid: apparatus assemblies for use of, 118, 1116, 1117
contamination with iron, 1115
cylinders of, siting and use of, 117
elements of reactions in, 791, 1115
Ammonolysis: of alcohols, 779
of esters, 708, 709, 1080, 1083
Ammonium 12-molybdate, test reagent, 1210
Ammonium rhodanilate, 759
(S)-(++)-Amphetamine sulphate, copper(II) complexes from, 836
Ampoules, precautions in opening, 38, 499
Amyl alcohol, see Pentan-1-ol
Anilic acids and anils, from cyclic carboxylic anhydrides, 1265
Anilides: from alkyl halides, 1251
from carboxylic acid chlorides, 1265
from carboxylic acids, 1265
from carboxylic anhydrides, 1261
from esters, 1268
Aniline, 892
alkylation of, 902
bromination of, 909
diazonium salt from, in synthesis, 928, 937, 939, 948, 952
hydrochloride from, 953
INDEX

Aniline—cont.
in heterocyclic synthesis, 1185, 1187
iodination of, 909
i.r. and p.m.r. absorptions of, and m.s. data of, 893
RL of, 48
Schiff base from, 905
substituted thioureas from, 966
substituted ureas from, 964
sulphonation of, 912
Anisaldehyde, 995
benzoin condensation with, 1045
Doebner/Knoevenagel reaction with, 1041
i.r. spectrum of, 301
Schiff base from, 906
o-Anisidine: RL of, 48
diazonium salt from, in synthesis, 935
p-Anisidine: diazonium salt from, in synthesis, 941
RL of, 48
substituted ureas from, 965
Anisole (methoxybenzene): acylation of, 1013
Birch reduction of, 1117
13C-n.m.r. spectrum of, 336
formylation of, 995
i.r. spectrum of, 292
p.m.r. spectrum of, 327
physical properties of, 1442
Anodic coupling, see Electrolytic syntheses
Antarafacial, 1118
Anthracene: chromatographic purification of, 221
formylation of, 996
oxidation of, 1023
Anthranilic acid, 898
benzene from, 834
diazonium salt from, in synthesis, 837, 931, 933
(E)-1-(9-Anthryl)-2-phenylethene, and i.r. and p.m.r. absorptions of, 500
9,10-Anthraquinone, and reduction of, 1023
sulphonation of, 876
Anthraquinone-2-sulphonic acid (sodium salt), 876
alkali fusion of, 972
Anthrone, 1023
Anti-Markownikoff addition, 542, 575
Antipyrin, see 2,3-Dimethyl-1-phenylpyrazol-5-one
Apparatus (standard assemblies), 80–6
for addition of gaseous reagent, 83
for addition of a liquid reagent, 81
for addition of solid reagent, 81
for heating under reflux, 80
for hydrogenation, 89–97
for reactions in an inert atmosphere, 85, 127–30
for reactions under pressure, 97–9
for vapour phase reactions, 99
beta-L-Arabinopyranosyl bromide, 2,3,4-tri-O-acetyl-,
1-Arabinose, acetylation/halogenation of, 648
Arc lamps, mercury, for photochemical use, 110

of hydroxaldehydes and hydroxyketones, 800, 802, 1093
of β-hydroxyesters, 727
of maleic acid, 805, 808
of nitroaldols, 768, 1032, 1035
of tartaric acid, 735, 740
Dehydrogenation: of alcohols, 587, 589
of Diels–Alder adducts, 1119, 1121
of 1,2-dihydroquinolines, 1182, 1187
of hydroaromatic compounds, 839, 841
Dehydrobromination, 509, 510, 511
Dehydrohalogenation: of alkyl halides, 488, 491
of gem- and vic-dihalides, 509, 510
INDEX

Dehydrohalogenation—cont.
of iodolactones, 729, 734
Deprotection, see entries under Protection
Derivatives: preparation of, 1234
section index, 1236
Desiccators: desiccants for use in, 150 vacuum, 69
'Dry-seal', 69
precautions in use of, 69
Desulphonation: of aromatic sulphonic acids, 1062, 1064
Diacetone alcohol, see 4-Methyl-4-hydroxypentane-2-one
Diacetoxyiodobenzene, see Iodobenzene diacetate
1,5-Diacetoxypentane, 492
Dialkylcadmiums, 617
Dialkyl disulphides, see Disulphides
O.S-Dialkyl dithiocarbonates, 792
Dialkyl sulphates, see Sulphates
Dialkyl sulphides, see Sulphides
Diaminobenzenes, see Phenylendiamines
4,4'-Diaminobiphenyl, car oncogenicity of, 49
4,4'-Diamino-3,3'-dichlorobiphenyl, carcinogenicity of, 49
4,4'-Diamino-3,3'-dichlorobiphenyl, carcinogenicity of, 49
4,4'-Diamino-3,3'-dimethoxybiphenyl, carcinogenicity of, 49
4,4'-Diamino-3,3'-dimethylbiphenyl, carcinogenicity of, 49
Diastereoisomers: definition, 4
chromatographic separation of, 402, 497
use of, in resolution of racemates, 809
Diastereoselectivity, 15
1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU): use as catalyst:
in coupling of alkynes, 515
in dehydrohalogenation reactions, 488
in esterification reactions, 706, 1079
in heterocyclic synthesis, 1143
Diazoa minobenzenes, and rearrangement of, 948, 952
Diazoketones, from acid chlorides, 676, 849
Diazomethane, 430–3, 432
carcinogenicity of, 50
chain extension with, 675
diazoketone from, 675, 849
estimation of, 432
methylation with, 433
precautions in use of, 430
ring expansion with, \(1111, 1112\)
RL of, 46
Diazonium fluoroborates, 925
coupling reactions with, 926
Diazonium hexafluorophosphates, aryl fluorides from, 925
Diazonium salts: explosive hazards with solid, 36, 922
hazardous reactions with, 927
coupling reactions of, 946, 948–53
reactions involving replacement of diazo group, 922, 927–46
reduction of, 959, 960
1-Diazo-4-phenylbutan-2-one, 849
intramolecular insertion reaction from, 848
i.r. and p.m.r. absorptions of, 849
Diazotisation, 835, 920, 927 et seq.
as a test for amines, 1215
of o-phenylenediamine, 1163
DIBAL, see Disobutylaluminium chloride
Dibenzylideneacetone, 1033
Dibenzyl ketone, 1019
in alicyclic synthesis, 1101
Dibenzyl sulphide, 790
Dibenzyl sulphoxide, 792
Diborane, see Borane
m-Dibromobenzene, 935
p-Dibromobenzene, as reaction byproduct, 1046
p.m.r. absorption and m.s. data of, 1046
\(\alpha,\beta\)-Dibromoacetophenone, see \(\beta\)-
Bromophenacyl bromide
1,4-Dibromobutane, 563, 565
1,2-Dibromoethane, carcinogenicity of, 56
RL of, 47
1,6-Dibromohexane, 565
dinitrile from, 713
Dibromomethane, carbonoids from, 1109
4,4-Dibromo-3-methylpyrazol-5-one, 808
1,5-Dibromopentane, 563, 565
dinitrile from, 713
2,3-Dibromo-3-phenylpropanoate, 510
decarboxylative/dehydrobromination of, 511
1,3-Dibromopropane, 563
dinitrile from, 713
in alicyclic synthesis, 1089, 1090, 1106
Dibutylamine, 781
N, N-Dibutylaniline, 903
Dibutylcadmium, 617
Dibutyl cyanamide, and hydrolysis of, 781
Dibutyl ether, 581
Grignard reagent solvent for, 534
i.r. spectrum of, 291
m.s. data of, 582
physical properties of, 1442
puriﬁcation procedures for, 406
2,6-Di-t-butyl ketone, i.r. absorptions of, 297
trans-1,2-Dibutylxirane, and p.m.r.
absorptions of, 1134
2,6-Di-t-butylphenol, oxidation of, 1024
Dibutylphthalate, physical properties of, 1444
Di-t-butyl pyrocarbonate, reaction involving use of, 786
Dibutyl (+)-tartrate, and periodate oxidation of, 591
Dicarboxylic compounds: in heterocyclic synthesis, 1146
retrosynthetic strategies for, 626
1,2-Dicarboxylic compounds, 627
1,3-Dicarbonyl compounds, 632
1,4-Dicarbonyl compounds, 635
Dichloramine-T, 882
Dichloroacetyl chloride, dichloroketen from, 1124
2,5-Dichloroaniline, diazonium salt from, in synthesis, 944
p-Dichlorobenzene, 944
7,7-Dichlorobicyclo[4.1.0]heptane, 1110
7,7-Dichlorobicyclo[3.2.0]hept-2-2-en-6-one, and i.r. absorptions of, 1124
reduction of, 1124
1,4-Dichlorobutane, 559
dinitrile from, 715
1,4-Dichlorobutene, carcinogenicity of, 50
Dichlorocarben: in formylation of phenols, 991
insertion reaction with, 1107
2,5-Dichloro-3,6-dihydroxy-p-benzoquinone, test reagent, 1209
1,1-Dichlorodimethyl ether, see Dichloromethyl methyl ether
1,2-Dichloroethane, RL of, 47
trans-1,2-Dichloroethylene, i.r. absorptions of, 278
(Dichloroiodo)benzene, 869
Dichloromethane: CL of, 47
physical properties of, 1442
purification procedures for, 399
Dichloromethyl methyl ether, 582
formylation with, 991, 997
hazards involving use of, 581
Dichloronitrobenzenes, hazards of, 48
2,6-Dichloronitrobenzene, 857
Dichlorophenols, hazards of, 48
2,4-Dichlorophenol, phenoxyacid from, 986
2,4-Dichlorophenoxyacetates, of amino acids, 1280
2,4-Dichlorophenoxyacetic acid, and p.m.r. absorptions, 986
2,4-Dichlorophenoxyacetyl chloride, 1280
N,N-Dichlorotoluene-p-sulphonamide, see Dichloramine-T
N,N-Dicyclohexylcarbodiimide (DCC), 433
hazards involving use of, 433, 1144
in heterocyclic synthesis, 1144
reaction involving use of, 784
Dicyclopentadiene: depolymerisation of, 1122
hydroxylation of, 549
selective hydrogenation of, 473
Dikemann reaction, 1095, 1102
Diels–Alder reaction, 833, 1117
of maleic anhydride, 1119, 1120
of 1,4-naphthoquinone, 1119, 1120
of o-nitrostyrene, 1119, 1121
of tetracyclone, 1119, 1121
Dienes: in Diels–Alder reaction, 1118
spectroscopic features: group frequencies (i.r.) of, 278
correlation table, 1414
u.v.-vis. absorption of, 388
structure of conjugated, and cumulative, 484
Dienophiles, examples of use of, 768, 805, 833, 1118
3,5-Diethoxycarbonyl-2,4-dimethylpyrrole, and p.m.r. absorptions of, 1151
4,6-Diethoxycarbonyl-3-methylhex-2-enone, 1099
Diethyl acetalidomalonate: conjugate addition with, 756
hydroxymethylation/hydrolysis of, 755
Diethyl acetonedicarboxylate, copper derivative of, 1214
Diethyl adipate, 701
in alicyclic synthesis, 1102
reduction of, 530
Diethylamine, mass spectrum of, 382
3-(Diethylamino)propionitrile, 719
hazards of, 48
Diethyl benzylmalonate, 683
in alicyclic synthesis, 1092
Diethyl butylmalonate, and hydrolysis of, 682
Diethyl s-butylmalonate, 724
α-bromination of, 844
hydrolysis of, 685
Diethyl carbitol: purification procedures for, 406
Diethyl carbonate: purification procedures for, 433
reaction with Grignard reagents, 541
Diethyl cellosolve, physical properties of, 406
Diethyl (2-cyanoethyl)malonate, 718
hydrogenation of, 758
i.r. and p.m.r. absorptions of, 718
Diethyl 2,3-diacetosuccinate, 636
Diethyl 1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate, oxidation/hydrolysis/decarboxylation of, 1168
Diethylene glycol: diethyl ether (Diethyl carbitol): physical properties of, 406
purification procedures for, 406
dimethyl ether, purification procedures for, 406
monobutyl ether, purification procedures for, 406
monoethyl ether, purification procedures for, 403
monomethyl ether, purification procedures for, 403
Diethyl ether, see Ether
Diethyl ethylphenylmalonate, in heterocyclic synthesis, 1177
Diethyl fumarate: conjugate addition to, 681
Diethyl ketone (pentan-3-one), and p.m.r. absorptions of, 613
Diethyl malonate: acylation of, 621, 742
alkylation of, 680, 682
in alicyclic synthesis, 1089, 1090, 1104
in heterocyclic synthesis, 1175, 1176
reaction with acrylonitrile, 718
reaction with formaldehyde, 685
Diethyl oxalate: in alicyclic synthesis, 1105
in heterocyclic synthesis, 1177
Diethyl phenylmalonate, and alkylation of, 1177
Diethyl phthalate, indane-1,3-dione from, 1102
Diethyl propylmalonate, and hydrolysis of, 683
conjugate addition with, 682, 687
Diethyl sebacate, 700
Diethyl succinate: condensation reaction with, 744
reduction of, 530
Diethyl sulphate: hazards involving use of, 430
RL of, 47
(2R,3R)-(+) -Diethyl tartrate, catalyst in asymmetric epoxidation, 1133
Diglyme, purification procedures for, 406
Dihexyl diglyme, 582
2,5-Dihydroanisole, 849
2,2'-Dihydro-1,1'-binaphthyl, 849
2,3-Dihydroxy-1,4-dioxane, 774
Diisobutylaluminium hydride (DIBAL), 450
use of, in partial reduction of alkynes, 494
use of, in reduction of a cyano group, 594
Diisobutyl ketone (2,6-dimethylheptan-4-one), enamine from, 784
Diisopinocamphorborane, 421
reaction involving use of, 543
Diisopropylamine: LDA from, 603, 689, 797
other uses of, 636
Diisopropyl ether, purification procedure for, 406
Diisopropyl ketone, 742
Diketen, RL of, 47
3,5-Diketocyclohexanecarboxylic acid, 1117
Diketopiperazine, see Piperazine-2,5-dione
1,3-Diketones, derivatives of, 1251
Dimedone (5,5-dimethylcyclohexane-1,3-dione), 1104
derivatives of aldehydes from, 1259
Dimerisation, of methyl acrylate, 1096
2,4-Dimethoxybenzaldehyde, Claisen–Schmidt reaction with, 1035
3,4-Dimethoxybenzaldehyde (see also Veratraldehyde), 987
2,4-dinitrophenylhydrazone of, 1004
3,4-Dimethoxybenzoyl chloride, reduction of, 1004
Dimethoxyethane (glyme), see Ethylene glycol, dimethyl ether
2,2-Dimethoxypropane, use of in esterification reaction, 703
3,3-Dimethylacrylic acid, and p.m.r. absorptions of, 670
Dimethyl adipate, 703
Dimethylaminooxybenzene, carcinogenicity of, 49
3-(Dimethylaminomethyl)-1,2-bis(trimethylsilyloxy)cyclopentene, 1103
i.r. and p.m.r. absorptions of, 1104
Dimethylaminomethylindole, 1054
Dimethylaminopropiophenone hydrochloride, 1053
phenyl vinyl ketone from, 1053
reaction with potassium cyanide, 1053
N,N-Dimethylaniline, and m.s. data of, 905
nitrosation of, 911
reaction with diazonium salts, 951
RL of, 48
2,3-Dimethylanthraquinone, 1121
N,N-Dimethylbenzamide, reduction of, 774
Dimethylbenzene, see Xylene
2,5-Dimethylbenzenesulphonic acid, and p.m.r. absorption of, 877
3,4-Dimethyl-1,2-benzoquinone, 1020
N,N-Dimethylbenzylamine, 774
3',3'-Dimethylbiphenyl, 926
2,3-Dimethylbuta-1,3-diene, 490
Diels–Alder reaction with, 1120
2,3-Dimethylbutane-2,3-diol (see also Pinacol), 527
3,3-Dimethylbutan-2-ol, alkene from, 493
3,3-Dimethylbutan-2-one, see t-Butyl methyl ketone and Pinacolone
3,3-Dimethylbut-1-ene, and g.l.c. of, 493
$^{13}$C-n.m.r. and i.r. absorptions of, 493
2,3-Dimethyl-2-benzoxathoan, thexylborane from, 419, 542
2,3-Dimethyl-2-butylopane, 419
$N,N$-Dimethylcarboxamides, reaction with alkylithiums, 617
Dimethyl cellosolve, purification procedures for, 406
1,2-Dimethylcyclohexa-1,4-diene, and g.l.c. of, 1115
5,5-Dimethylcyclohexane-1,3-dione (dimedone), 1104
Dimethyl 2-((dimethylaminomethyl)-pentanedioate, 1103
acyclon condensation with, 1103
i.r. and p.m.r. absorptions of, 1103
$meso$-Dimethyl 3,4-diphenylidipate, and cyclisation of, 843
1,1-Dimethylethylamine (t-butylamine): oxidation of, 767
reaction with 2-methylpropanal, 783
$N-(1,1$-Dimethylethyl)-2-methylpropylindine, and i.r. and p.m.r. absorptions of, 783
$N,N$-Dimethylformamide (DMF), 409
as reaction solvent, 556, 559, 712, 765, 837, 944
formylation with, 996
physical properties of, 1444
purification procedures for, 409
2,5-Dimethylfuran, and g.l.c. of, 1148
Dimethylglyoxime, see Butane-2,3-dione
2,6-Dimethyletha-1,5-diene, and p.m.r. absorptions, 504
2,6-Dimethylethanal-4-one, see Diisobutyl ketone
4-(2,6-Dimethyl-3-hepten-4-yl)morpholine, 783
1,1-Dimethylnitroprine, carcinogenicity of, 49
Dimethyl 2-methylenepentanedioate, and addition of dimethyramine to, 1103
Dimethyl ketone, see Acetone
1,2-Dimethylphenalene, i.r. absorptions of, 280
$N,N$-Dimethyl-$p$-nitroanilone, conformation of, 9
(E)-3,7-Dimethylocta-2,6-dien-1-ol, see Geraniol
2,7-Dimethylocta-3,5-diyne-2,7-diol, 515
2,6-Dimethyloctan, mass spectrum of, 374
Dimethylxosulphonium methylide, in situ generation of, 1110
2,4-Dimethylpentan-3-one, see Diisopropyl ketone
2,6-Dimethylphenol, oxidation of, 1025
3,4-Dimethylphenol, oxidation of, 1020
2,2-Dimethylopropanoic acid, 669
2,2-Dimethylopropan-1-ol (neopentyl alcohol), alkyl halide from, 559
2,3-Dimethyl-1-phenylpyrazol-5-one, 1150
3,5-Dimethylpyrazole, 1149
2,6-Dimethylpyridine, 1168
2,5-Dimethylpyrrole, and p.m.r. absorptions of, 1148
2,2-Dimethyl-2-silapentane-5-sulphonic acid, in n.m.r. spectroscopy, 322
Dimethyl succinate, amide from, 709
2,2-Dimethylsuccinic acid, and p.m.r. absorptions of, 686
Dimethyl sulphone: carcinogenicity of, 50, 430
methyl with, 584, 663, 987, 1150
precautions in use, 430
purification procedures for, 430
RL of, 47
Dimethyl sulphide, decomposition of ozonides with, 104, 592
Dimethyl sulphoxide, 412
explosive mixtures with, 412
purification procedures for, 412
synthetic uses of, 496, 608, 792
use as reaction solvent, 714, 765
Dimethyl terephthalate, and p.m.r. absorption of, 1079
2,5-Dimethylthiophene, 1149
2,4-Dinitroaniline, p.m.r. absorption of, 961
3,5-Dinitroaniline, and i.r. and p.m.r. absorptions of, 899
$m$-Dinitrobenzene, 855
i.r. absorptions and m.s. data of, 855
partial reduction of, 895
p.m.r. spectrum of, 349
reduction of, 893
RL of, 48
$o$-Dinitrobenzene, and p.m.r. absorptions of, 941
RL of, 48
$p$-Dinitrobenzene, and p.m.r. absorptions of, 941
RL of, 48
2,4-Dinitrobenzenesulphonyl chloride, adds with alkenes and alkynes, 1237
3,5-Dinitrobenzoates: of alcohols, 1241
of amino acids, 1279
of phenols, 1249
from esters, 1268
from ethers, 1255
3,5-Dinitrobenzoic acid, 1072
acid chloride from, 1074
Schmidt rearrangement with, 899
3,5-Dinitrobenzoyl chloride, 1074
(R)-$N-(3,5$-Dinitrobenzoyl)phenylglycine, use of in h.p.l.c., 811
2,2'-Dinitrobiphenyl, 837
Dinitro cresols, RL of, 48
Dinitrophenols, RL of, 48
2,4-Dinitrophenol, and p.m.r. absorptions of, 973
reduction of, 896
2,4-Dinitrophenylacetic acid, 1072
2,4-Dinitrophenyl: derivatives: of amines, 1276
of amino acids, 1279
Di-o-nitrophenyl disulphide, and sulphonyl chloride from, 913
2,4-Dinitrophenyl ethers, from phenols, 1250
2,4-Dinitrophenylhydrazine, 960
    preparation of 2,4-DNPh-reagent from, 1218
2,4-Dinitrophenylhydrazones: of aldehydes and ketones, 1257
    from ozonides, 106
t.l.c. separation of, 208
3,5-Dinitrothiobenzoates, from thiols, 1283
2,4-Dinitrotoluene, and i.r. and p.m.r. absorptions of, 856, 1239
    R.L of, 48
1,2-Diols, i.r. absorptions of, 286
1,4-Dioxane, physical properties of, 1442
    purification procedures for, 407
1,3-Dioxanes, see under Acetals, cyclic acetals
    trans-2,11-Dioxo-1,2,9,10,11,18-hexahydrochrysene, and reduction of, 843

purification procedures for, 398
cis-2-Methylcyclohexanol, 8
trans-2-Methylcyclohexanol, 8, 9, 543
2-Methylcyclohexanol, dehydration of, 491
2-Methylcyclohexanone, and g.l.c. of, 610
1-Methylcyclohexene, and g.l.c. of, 491
hydroboration/oxidation of, 610
reaction with borane, 543
3-Methylcyclohexene, in admixture with
1-methylcyclohexene, 491
3-Methylcyclohex-2-ene, and reaction with
Grignard reagents, 1098
2-Methylcyclooctanone: reaction with organic peracids, 734
INDEX

2-Methylcyclooctanone—cont.
strategy for synthesis of, 734
2-Methylcyclopentane-1,3-dione, Robinson annelation with, 1100
3-Methylcyclopentane-1,2,4-trione, 1105
3-Methylcyclopent-2-ene, 1098
Methyl (R)-cysteinate, 1130
in heterocyclic synthesis, 1128
N-Methyleaaminoacetanitrite, 753
Methylene chloride, see Dichloromethane
Methylenecyclohexane, and g.l.c. of 498
reaction with chlorosulphonyl isocyanate, 1143
3,4-Methylenedioxybenzaldehyde: Claisen–Schmidt reaction with, 1035
Doebner reaction with, 1040
oxidation of, 502
Wittig–Horner reaction with, 500
3,4-Methylenedioxybenzoic acid, 502
methyl ester from, 502
3,4-Methylenedioxycinnamic acid, and p.m.r. absorptions of, 1040
3,4-Methylenedioxynitrostyrene, 1035
Methylenephosphorane, 499
3-Methylethane: 13C-n.m.r. spectrum of, 320
p.m.r. spectrum of, 320
6-Methylheptan-2-one: chiral reduction of, 520
6-Methylhept-5-en-2-one, reaction with trimethylsilylmethylmagnesium chloride, 504
1-Methylethyl acetate, and p.m.r. absorptions of, 706
1-Methylethylamine, 776
(S)+(-)-2-Methylhexanoic acid, 689
2-Methylhexan-2-ol, and 13C-n.m.r. absorptions of, 538
5-Methylhex-5-en-2-one, and g.l.c. of, 623
Methylhydrazine, carcinogenicity of, 49
Methyl hydrogen adipate, 703
anodic coupling with, 679
Methyl hydrogen sebacate, 703
anodic coupling with 678, 680
5-Methyl-2-hydroxybenzaldehyde, 993
4-Methyl-7-hydroxycoumarin, 1193
4-Methyl-4-hydroxypentan-2-one (diacetoxy alcohol), 802
Methyl iodide (iodomethane): carcinogenicity of, 50
Grignard reagent from, 540
methylation with, 689
RL of, 47
Methyl 11-iodoundecanoate, and g.l.c. of, 576
Methyl isocyanate, see Isocyanatomethane
6-Methylisoquinoline, 1189
Methyllithium, and estimation of, 443
Methyl 3,4-methylenedioxybenzoate, 503
i.r. and p.m.r. absorptions of, 503
reaction with ethyl diphenylphosphino oxide, 503
6-Methyl-2-(4-methylphenyl)hepta-1,5-diene, and p.m.r. absorptions, 797
Methyl methylthiomethyl sulphotide, reaction involving use of, 1091
1-Methylnaphthalene, 841
Methyl 2-naphthyl ether, 987
Methyl 2-naphthyl ketone, 1010
Willgerodt reaction with, 1054
4-Methyl-2-nitroaniline, diazonium salt from, in synthesis, 944
Methyl m-nitrobenzoate, and hydrolysis of, 1071
N-(2-Methyl-5-nitrobenzyl)acetamide, 866
i.r. and p.m.r. absorptions and m.s. data of, 867
reaction with phosphorus oxychloride, 867
N-Methyl-N-nitrosouannine, carcinogenicity of, 49
N-Methyl-N-nitrosotoluene-p-sulphonamide, 431
diazomethane from, 432, 1112
N-Methyl-N-nitrosourea, carcinogenicity of, 49
N-Methyl-N-nitrosouannine, 50
(R)- and (S)-2-Methylcyclohexane, 602
Methyl Orange, and reduction of, 951
3-Methyl-2-(3-oxobutyl)cyclopentane-1,3-dione, and i.r. and p.m.r. absorptions of, 1100
3-Methylpenta-1,2-diene, and g.l.c. of, 505
i.r. absorption of, 506
2-Methylpent-2-enal, 802
2-Methylpentan-2-ol, 538, 540
4-Methylpentan-2-one: i.r. spectrum of, 298
mass spectrum of, 379
p.m.r. spectrum of, with shift reagent, 356

**Octadecanedioic acid, 680**

cis-Octadec-9-enio acid, see Oleic acid

Octanal, 596, 600
  aldimine from, 603
  alkylation of, 603
  reaction with diethyl 2-oxopropanephosphonate, 802

Octane, 477, 479
  purification procedures for, 398

Octanedinitrile, 713
  hydrolysis of, 672

Octanedioic acid, see Suberic acid

Octanenitrile, 715

Octane-1-thiol, 789

Octanoic acid, conversion to octanal, 596

Octan-1-ol, and g.l.c. of, 544
  alkyl halides from, 564, 569
  (±)-Octan-2-ol, oxidation of, 609
  resolution of, 813

Octan-2-one: and g.l.c. of, 609
  oxime of, 776
  reduction of, 477

Oct-1-ene: methylene insertion reaction on, 1109
  hydroboration/oxidation of, 544
  hydroxylation of, 549
  i.r. spectrum of, 279

Octylamine, 772

Octyl azide, reduction of, 772

Oct-2-yn-1-ol, oxidation of, 590

Oleic acid: esterification of, 702
  ozonolysis of, 593

Oleum, see Sulphuric acid

Oligosaccharides, structural characteristics of, 637

Oppenauer oxidation, 608, 611

Optically active compounds, see Asymmetric synthesis, Resolution

Optical activity definition, 4

Optical purity, see Enantiomeric excess (ee)

Optical rotation: molecular, 248
  specific, 248

Optical rotatory dispersion, 248

Optical rotatory power, determination of, 244

Orange II, 950
  reduction of, 1026

Organocopper reagents, 616, 618

Organolithium reagents, see Butyllithium, Methylithium, etc

Organosodium reagents, see Arylsodium

Organosulphur compounds, see Sulphur compounds

Organzinc reagents, 727

Orthoesters, 699
  oxazolines from, and alkylolation of, 687

Orthoformates, 699

Osmium tetroxide, and precautions in use of, 452, 548

RL of, 46
  with hydrogen peroxide, in hydroxylations, 548

4-Oxa-1-azabicyclo[3.2.0]heptan-7-one, and i.r. and p.m.r. absorptions of, 1143

Oxalic acid: RL of, 46
  Oxalic acid equivalent, 735

Oxalyl chloride: reaction with carboxylic acids, 618
  hazards of, 47
  use of, in oxidations, 608

2-Oxa-5-thiaspiro[4.6]undecane, 625

1,4-Oxathiiaspiro[4.4]nonane, reaction with Chloramine-T, 625

1,3-Oxathiolanes, formation of, 625
  reaction with Chloramine-T, 625

Oxidation: of alcohols, 587, 588, 607, 609–11, 667, 668, 869, 1241
  of aliphatic amines, 765, 766, 767
  of alkenes, 592, 593
  of alkylboranes, 542
of alkenes, 629, 631
of aminophenols, 1021, 1026
of aromatic side-chains, 999, 1057, 1239, 1254, 1282
of aromatic amines, 857, 858
of boronic acids, 971, 973
of carbohydrates, 653
of cholesterol, 608, 611
of cinnamyl alcohol, 445
of dihydric phenols, 1021, 1025
of dihydropryridines, 1166, 1168
of 1,2-diketones, dihydrazones of, 512
of 1,2-diols, 1224
of N,N-diphenylpicrylhydrazine, 959, 962
of α-hydroxyacids, 454
of α-hydroxyketones, 454, 1043, 1045, 1224
of α-ketols, 454
of ketones, 728, 733
of α-methylene groups, 627, 629
of methyl ketones, 627, 629
of nitriles, 1080
of nitroaldehydes, 739, 743
of nitronate salts, 600
of oximes, 765, 766
of phenols, 836, 838, 1021, 1024
of N-phenylhydroxylamine, 953
of polycyclic aromatic hydrocarbons, 1020, 1022
of sulphides, 791, 792, 1231, 1283
of thiols, 790
of trialkylboranes, 542, 588
of toluene-α-sulphonamide, 879, 880
of α,β-unsaturated alcohols, 799
of α,β-unsaturated carbonyl compounds, 587
safety precautions, 36
Oxidative cleavage: of alkenes, 668
of alkenes, 668, 670
of carbohydrates, 653, 657
of cyclic ketones, 667, 668
of 1,2-diols, 590, 591
Oxidative coupling, 836, 838, 1020, 1024
Oxidative hydrolysis, of nitronate salts, 599, 600
Oximes, of aldehydes and ketones, 1259
characterisation by hydrolysis, 1228
group frequencies (i.r.), 314
correlation table, 1421
Oxine, see 8-Hydroxyquinoline
Oxirane, and its derivatives, 1127, 1131, 1132
4-Oxodecanoic acid, and i.r. absorptions of, 744
6-Oxodecanoic acid, reaction with oxalyl chloride, 618
6-Oxodecanoyl chloride, reaction with lithium dialkylecuprates, 618
4-Oxopentanoic acid, 743
10-Oxoundecanoic acid, 612
2-Oxoundec-3-ene, 802
Oxygen: cylinders leaking, hazards, 41
liquid, hazards, 38
Oxymercuration-demercuration, 545, 546
Ozone: determination of, 105
examples of use of, 593, 600
hazards and toxicity of, 105
preparation of, 104
RL of, 46
Ozonides, 104
decomposition of, 104, 106, 592
Ozoniser, laboratory, 104
Ozonolysis, 593, 600

Palladium: on barium carbonate, 453
on barium sulphate, 453
deactivated for Rosenmund reduction, 453, 1004
use in partial hydrogenation, 495
on calcium carbonate, 453
use in partial hydrogenation, 495
on charcoal, 452
catalyst in borohydride reduction, 894
dehydrogenation with, 839, 841
Palladium black, 453
Palladium catalysts, 452–4
Palladium hydroxide on calcium carbonate, 453
reduction of ozonides with, 593
Paracyclogenes, chirality of, 6
Paraformaldehyde: amidomethylation with, 866
formylation with, 993
in alicyclic synthesis, 1098
Mannich reaction with, 1053
Paraldehyde, in heterocyclic synthesis, 1187
Partition coefficient, 158
PCC, see Pyridinium chlorochromate
PDC, see Pyridinium dichromate
Pechmann reaction, 1191, 1192
Pelargonic acid, see Nonanoic acid
Pentachloroethane, hazards of, 47
Penta-1,4-diene, 492
13C-n.m.r. absorptions of, 493
i.r. absorptions of, 493
Pentanal (see also Valeraldehyde), 590
Pentanenitrile, 712
hydrolysis of, 672
Pentanedioc acid, see Glutaric acid
Pentane-1,5-diol, dihalide from, 563, 567
Pentane-2,4-dione (acetylacetone), 633
alkylation of, 622
in hetertcyclic synthesis, 1149, 1188
Pentanitrile (butyl cyanide), 714
Pentane, physical properties of, 1442
purification procedures for, 398
Pentane-1-thiol, 789
Pentanoic acid (valeric acid), 671, 683
Pentan-1-ol, 529
alkyl halides from, 557, 562, 569
oxidation of, 590
Penan-1-ol—cont.
   physical properties of, and purification
   procedures for, 402
Penan-3-ol, alkyl halides from, 559
Penan-2-one, 614
   \(^{13}\)C-n.m.r. absorptions, 614
Penan-3-one (diethyl ketone), 613
Pentanoyl chloride (valeryl chloride), 693
TCPentyl alcohol, see 2-Methylbutan-2-ol
Pentylamine, 773
Pentylbenzene, and m.s. data of, 830
Pentyl bromide, see 1-Bromopentane
Pentyl cyanide, see Hexanenitrile
Pentyl nitrite, 413
   nitration with, 922
2-Pentylpyridine, 1171
3-Pentylpyridine, 1172
4-Pentylpyridine, 1172
6-Pentylundecan-6-ol, 541
Peptides: dipeptide synthesis, 761
   structural features, 750
   strategy of synthesis, 750
Peracetic acid, 455
Peracids, precautions in use of, 766
Perbenzoic acid, and estimation of 456
   epoxidation with, 1135
   hazards in use of, 455
Perchloric acid, hazards in use, 37, 43
   reactions involving use of, 644, 647
Performic acid, 455
   hazards in use of, 455, 549
   hydroxylation with, 549
Pericyclic reactions, 11
   stereochemistry of, 1117
Periodic acid, 454
   reactions involving use of, 1024
Periodic acid test, 1224
Periodinane (see also 1,1,1-Triacetoxy-2,1-
   benzoxiodol-3(3H)-one), 588, 869, 871
   anti-Periplanar conformation, 488, 1088
Perkin reaction, 1037, 1038, 1041, 1155, 1157, 1160
Permaleic acid, 733
   oxidation of ketones with, 733
Peroxides: in solvents, hazards, 36, 37
   removal of, 397, 402, 404, 406
   test for, 402
Peroxyxmonosulphuric acid, 857
Pertrifluoroacetic acid (peroxytrifluoroacetic
   acid), 455, 766, 858
   hazards in use of, 766
   oxidation of amines with, 858
   oxidation of ketones with, 734
   oxidation of oximes with, 766
Peterson reaction, 498
Phenacetin, and p.m.r. absorptions of, 985
   9,10-Phenanthraquinone, 1023
Phenanthenrene, oxidation of, 1061, 1023
   purification of, 1061
9-Phenanthrol, oxidative coupling of, 836
1,10-Phenanthroline, in butyllithium
   estimations, 443
p-Phenetidine (p-ethoxyaniline), substituted
   ureas from, 966
Phenobarbitone, see 5-Ethyl-5-
   phenylbarbituric acid
Phenol: O-alkylation of, 985
   by PTC procedure, 988
   bromination of, 980
   esters from, 705
   formylation of, 997
   hazards involving use of, 48
   in heterocyclic synthesis, 1192
   nitrosation/oxidation of, 975, 978
   RL of, 48
   sulphonation/bromination of, 981

Pinacol (and hydrate) (2,3-dimethylbutane-2,3-diol), 527
  dehydration of, 490
  rearrangement of, 623
Pinacol-pinacolone rearrangement, 623, 1152
Pinacolone (t-butyl methyl ketone), 623
  haloform reaction with, 669
  (−) or (+)-α-Pine, carbene insertion of, 1108
  reaction with borane, 421, 543, 545
β-Pine, carbene insertion of, 1109
Piperazine-2,5-dione, and ring opening/
  esterification of, 1176
Piperonal (see also 3,4-
  Methylene dioxy benzaldehyde), Doebner/
  Knoevenagel reaction with, 1040
Piran/Penning gauge, 195
Pivalic acid, see 2,2-Dimethylpropanoic acid
Platinium: as dehydrogenation catalyst, 839
  re-using from residues, 460
Platinium dioxide (Adams’ catalyst), 459
  catalytic hydrogenations with, 91, 472, 897,
  1034, 1038
Polarimeter, 245
Polycyclic aromatic compounds: group
  frequencies (i.r.) of, 280
  u.v.-vis. absorptions of, 391
Polyphosphoric acid, 458
  reactions involving use of, 1015, 1161, 1193
Polystyrene, use in i.r. calibration, 260
Pomeranz–Fritsch reaction, 1183, 1189
Potassium: disposal of residues, 37
  precautions in use of, 37, 460
  reactions involving use of, 744
Potassium borohydride, chemoselectivity of,
  in reduction, 519
Potassium bromate, reaction involving use of, 871
Potassium bromide discs: preparation of, 261
  faults in, 262
Potassium t-butoxide, 744
  use in deprotection of allyl ethers, 551
Potassium cyanide, reactions involving use of, 686, 715, 1045
Potassium fluoride, 460, 571
  halogen exchange reaction with, 571
Potassium hydride, and hazards in use of, 449
Potassium iodide-starch paper, use of, 912
Potassium metaperiodate, 455
Potassium nitrosodisulphonate, 1020
Potassium permanganate: finely powdered
  grade, 631
  reactions involving use of, 600, 668, 670,
  767, 792, 880, 1058
Potassium persulphate, reactions involving use of, 871
Potassium thiocyanate-on-silica gel, 1137
DL- or (+)-Proline, 758
  i.r. absorptions of, 308
(S)- or L-Proline, and t.l.c. of, 759
  acylation of, 730
  use as chiral auxiliary agent, 726
  use as chiral inducing agent, 534, 1094
L-Prolylglycine, and t.l.c. of, 761
Propanal, 589
  aldime from, 602
  alkylation of, 602
  aldol condensation with, 802

1498
Propane-1,3-diol, dihalides from, 563, 569
use of, in carbonyl protection, 625
Propane-1,3-dithiol, reaction with aldehydes
and ketones, 625, 788
1,3-Propanesultone, carcinogenicity of, 50
Propane-1-thiol, 789
Propane-2-thiol, 789
Propane-1,2,3-triol, see Glycerol
Propanoic acid: acid chloride of, 706
α-bromination of, 722
eristerification of, 705
pyrolysis of, 613, 615
Propan-1-ol: alkyl halides from, 569
esterification of, 701
mass spectrum of, 376
oxidation of, 589
physical properties of, 1442
purification procedures for, 402
Propan-2-ol: alkyl halides from, 561, 566, 569
esterification of, 702
physical properties of, 1442
removal of peroxides from, 402
Propan-2-one, see Acetone
Propanoyl chloride, 706
acylation with, 742, 1009
bromination of, 706
reaction with dialkylcadmium, 1018
Prop-2-en-1-ol, see Allyl alcohol
2-(Prop-1-enyl)phenol, 984
β-Propiolactone, carcinogenicity of, 50
Propionic aldehyde (see also Propanal), 589
Propiophenone, 1009, 1018
Willgerodt reaction with, 1055
Propylamine, oxidation of, 767
N-Propylaniline, 903
Propyl benzoate, 1078
Propyl bromide, and p.m.r. absorptions of,
701
alkylation with, 620, 683, 829
coupling reactions with, 480
Grignard reagent from, 538
sulphide from, 790
Propyl formate, and p.m.r. absorptions of,
701
2-Proplyglutaric acid, 687
4-Proplyheptan-4-ol, 541
Propyl iodide, 569
Propyllithium, and estimation of, 443
Propylmalonic acid, 684
Pro-(R), 16
Pro-(S), 16
Protection (and deprotection): examples of use
of, in multistage synthesis, 478, 751, 1138
general principles, 13
of amino acids, 751, 784
of amino group, 784, 906, 918
of carbonyl groups, 478, 623, 1056
of carboxyl groups, 690, 1072
of hydroxyl groups, 550, 644, 652, 659, 988
of imino groups, 784, 906
of phenolic hydroxyl groups, 988
Prototropic shift, 978, 984
Pseudosaccharin chloride, 881
Pseudosaccharin ethers: from alcohols, 1244
from phenols, 1250
PTC (phase transfer catalysis): for
α-alkylation of nitriles, 718
for alkylation of a hydroxyl group, 652, 985
for biphenyl synthesis, 926, 943
for coupling reactions, 943
for dehydrohalogenation reactions, 488, 509
for dichlorocarbene additions, 1107
for ether formation, 583, 988
for glycidic ester formation, 598
for halogen displacement reactions, 474,
571, 572, 712, 772
for hydroxylation of alkenes and alkynes,
547, 629, 668
for methylene insertion reactions, 1107,
1131
for oxidation reactions, 588
for reductions, 520, 772
in Horner–Emmons reaction, 804
inhibition of, by iodide ion, 988
trans-Pulegolic acid, and ester from, 1113
(+)-Pulegone, as chiral auxiliary, 534
bromination and Favorinskii rearrangement
with, 1112, 1113
Pumps: oil, 192
water, 191
vapour diffusion, 192

Sodium anthraquinone-2-sulphonate, 867
conversion to alizarin, 972
Sodium azide, reactions involving use of, 772, 899
Sodium benzophenone ketyl, 407, 741
Sodium borohydride, 447
borane from, 543
chemoselectivity of, in reductions, 519, 697
estimation of, 448
other reactions involving use of, 474, 477, 494, 497, 523, 546, 602, 772, 774, 777
stabilised solution of, 92
Sodium bromate, oxidation with, 1046
Sodium p-bromobenzencesulphonate, 875
Sodium N-chlorotoluene-p-sulphonamide (see also Chloramine-T), 883
Sodium cyanamide, alkylolation with, 780
Sodium cyanate, reaction involving use of, 964
Sodium cyanide: hazards in use of, 464
reactions involving use of, 712, 729, 1044, 1054
Sodium cyanoborohydride, 448
reaction involving use of, 795
Sodium dichromate, 425
reactions involving use of, 588, 609, 1057
Sodium dihydro-bis-(2-methoxyethoxy)aluminate [sodium bis(2-methoxyethoxy)alumium hydride, ‘Red Al’]: deprotection of allyl aryl ethers with, 989
reduction with, 775
Sodium disulphide, in situ preparation of, 913
Sodium dithionite, reductions with, 949, 952, 1026
Sodium ethoxide, 464
dry reagent, 634
ethanol solution of, 620
precautions in use of, 621
reactions involving use of, 620, 634, 636, 1102, 1104, 1105, 1113
Sodium fluoroborate, reaction involving use of, 939
Sodium hydride: dispersion in oil, 449
precautions in use of, 449
reactions involving use of, 494, 497, 600, 769, 797, 806, 1110
Sodium hypobromite, reactions involving use of, 516, 669, 898
Sodium hypochlorite, 670
Sodium iodide, solution in acetone, 571, 1233
Sodium metaperiodate, 454
on silica gel, 455
example of use of, 592
reactions involving use of, 657, 792
Sodium naphthalene-2-sulphonate, 876
fusion with potassium hydroxide, 971
Sodium nitrite: diazotisation with, 921, 927 et seq., 1129, 1163
other reactions involving use of, 765, 978, 1151
Sodium paraperiodate, 454
Sodium perborate, reaction involving use of, 792
Sodium polysulphide, 895
Sodium sulphide, 790, 913, 1142
Sodium sulphite, reductions with, 960, 1143
Sodium toluene-p-sulphonate, 887
Sodium toluene-p-sulphonate, 874
Sodium trifluoroacetoxyborohydride, reduction of amides and nitriles, 774
Solubility of organic compounds, 1198

  preparations involving use of, 492, 613, 614,
  694, 1122
Veratraldehyde, 987
Veratraldoxime, and dehydration, 1084
Veratronitrile, 1084
Vibro-mixer, 77
Vilsmeier reaction, 991, 992, 996
Vinylacetic acid, 673
  esters from, 705
Vinylacetyl chloride, 705
Vinylbenzene, see Styrene
Vinyl bromide, Grignard reagent from, 539
Vinyl chloride, carcinogenicity of, 50
1-Vinylcyclobutanol, and i.r. and p.m.r. absorptions of, 539
Vinyl halides, structural features, 553
Vinylic alcohols, structural features, 517

Wadsworth–Emmons reaction, see Horner–Emmons reaction
Water, physical properties of, 1442
Wheaton–Hickman flask, 189
Willgerodt reaction, 1052, 1054
Williamson ether synthesis, 583, 584, 789, 984
  PTC conditions for, 584, 988
  Willstatter 'filtration nail', 146
  Wittig reaction, 495–8, 796
  Wittig–Horner reaction, 497
  Wohl–Ziegler reaction, 577
  Wohler's synthesis of urea, 963
  Wolff rearrangement, 676, 676
  Wolff–Kischner reduction, 476, 827, 831
  Woodward–Hoffman Rules, 1118
  Wurtz reaction, 478, 479
  Wurtz–Fittig reaction, 826, 829
Xanthate esters, 792
Xanthhydril, 1270
Xanthone, reduction of, 1270
Xanthylamides, of primary amides, 1270
N-Xanthy1 sulphonamides, from primary sulphonamides, 1289
α-Xylene: Birch reduction of, 1115
  i.r. spectrum of, 281
  mass spectrum of, 364
p-Xylene: oxidation of, 1058
  sulphonation of, 877
Xylenes (o,p,m):
  physical properties of, 1442
  purification procedures for, 399
  spectroscopic comparison of isomers, 825
p-Xylene-2-sulphonic acid (2,4-
  dimethylbenzenesulphonic acid), 877
Xylidines, RL of, 48
α-D-Xylofuranose, 642
  1,2-O-cyclohexyli dine-, 657
β-D-Xylofuranose, 642

Yields, calculation of: g.l.c., 34
  optical, 34
  percentage, 33
  theoretical, 33
Ylides: of phosphorus, 495, 498
  of sulphur, 496, 499, 790, 1089, 1131
Zeolites (molecular sieves), 396
Zemplen's method of decacylation, 644
Zinc: amalgamated, 467
  reactions involving the use of, 476, 830,
  843
  powder or turnings, 467
  activation of, 467, 727
  reactions involving use of, 732, 893, 955–8
Zinc chloride, reactions involving the use of,
  Zinc-copper couple, 467
  activation of, by sonication, 1108
  reactions involving the use of, 505, 1017,
  1108
Zinc cyanide, 467
  use in formylation reactions, 994
Zirconium-alizarin red S test paper, 1210
Zwitterionic structures: of amino acids, 746
  i.r. absorptions of, 308
  of benzenediazonium-2-carboxylate, 833
  of sulphanilic acid, 908

ABBREVIATIONS

NOMENCLATURE

R  alkyl  n straight-chain
Me or CH$_3$— methyl  s secondary
Et or C$_2$H$_5$  ethyl  t tertiary
Pr or C$_3$H$_7$—  n-propyl  i iso
Pr$^t$ or (CH$_3$)$_2$CH— isopropyl (1-methylethyl)
Bu or C$_4$H$_9$—  n-butyl
Bu$^t$ or (CH$_3$)$_2$CH:CH$_2$— isobutyl
Bu$^i$ or (CH$_3$)$_3$C— t-butyl (1,1-dimethylethyl)
Bu$^s$ or CH$_3$:CH$_2$:CH(CH$_3$)— s-butyl (1-methylpropyl)
Sia or (CH$_3$)$_2$:CH:CH(CH$_3$)— s-isoamyl (1,2-dimethylpropyl)
Thex or (CH$_3$)$_2$:CH:C(CH$_3$)$_2$— t-hexyl (1,1,2-trimethylpropyl)
Ph or C$_6$H$_5$  phenyl

Ac or Me:CO— acetyl
Bz or Ph:CO— benzoyl
Bn or Ph:CH$_2$— benzyl
Boc or Me$_3$:CO:CO— t-butoxycarbonyl
Cbz or Ph:CH$_2$:O:CO— benzyloxycarbonyl
MEM or Me:O:CH$_2$:CH$_2$:O:CH$_2$— 2-methoxyethoxymethyl
Ms or Me:SO$_2$— methanesulphonyl (mesyl)
Ts or p-Me:CH$_2$:CH$_2$:O:SO$_2$— toluene-p-sulphonyl (tosyl)

THP or

$	ext{O}$

tetrahydropyranyl

REAGENTS AND SOLVENTS

AIBN  $\alpha,\alpha'$-azobisisobutyronitrile
9-BBN  9-borabicyclo[3.3.1]nonane
BDSC  t-butyldimethylchlorosilane
BTMSA  N,O-bis(trimethylsilyl)acetamide
DBU  1,8-diazabicyclo[5.4.0]undec-7-ene
DCC  dicyclohexylcarbodiimide
DDQ  2,3-dichloro-5,6-dicyano-1,4-benzoquinone
DEG  diethylene glycol
DET  diethyl tartrate
DIBAL  diisobutylaluminium hydride
DME  1,2-dimethoxyethane (glyme)
DMF  dimethylformamide
DMSO  dimethyl sulfoxide
DNFB  2,4-dinitrofluorobenzene
DSS  sodium 3-(trimethylsilyl)-1-propanesulphonate
EAA  ethyl acetoacetate
HMDS  hexamethyldisilazane [bis(trimethylsilyl)amine]
HMPA  N,N,N',N',N'',N''-hexamethylphosphotriamide
LAH  lithium aluminium hydride
LDA  lithium isopropylamide
MCPBA  m-chloroperbenzoic acid
MEK  ethyl methyl ketone
MVK  methyl vinyl ketone
NBS  N-bromosuccinimide
NCS  N-chlorosuccinimide
PCC  pyridinium chlorochromate
PDC  pyridinium dichromate
PEG  polyethylene glycol
PPA  polyphosphoric acid
PPTSA  pyridinium toluene-p-sulphonate
Py  pyridine
SBH  sodium borohydride
TEG  triethylene glycol
TFA  trifluoroacetic acid
THF  tetrahydrofuran
TMEDA  N,N,N',N'-tetramethylethylenediamine
TMCS  chlorotrimethylsilane
TMS  tetramethyldisilane
This fifth edition of the most widely used and respected reference manual for the organic chemistry laboratory incorporates important new reactions and techniques now available to the organic chemist, and retains many of the standard procedures of previous editions. These are all set within a theoretical framework based on developments in the strategy and methodology of organic synthesis, reflecting the fundamental changes in approach to the subject made during the last decade.

**New to this edition:**

- An introductory chapter on the structural and theoretical principles required when designing a synthesis.
- The disconnection or synthon approach now integrated into the text, and the principles of retrosynthetic analysis applied to relevant aliphatic, aromatic, alicyclic and heterocyclic compounds.
- Synthesis methodology is expanded to cover a range of new reagents, including oxidants and reductants; reagents for asymmetric synthesis, and those derived from lithium, boron, silicon, phosphorus and sulphur.
- Recent developments in reaction techniques which include: handling of airsensitive and moisture-sensitive compounds; new chromatographic procedures; phase transfer catalysis; and solid support reagents.
- Over 100 new experiments selected from the literature to illustrate new reagents and techniques, and the operation of protection, selectivity and control in synthesis.
- A more detailed treatment of carbon-13 n.m.r. spectroscopy, and the interpretation of spectroscopic data for many of the synthesised compounds.

This completely updated edition of *Vogel*, as with previous revisions over the past forty years, will continue to be an indispensable text for organic chemists throughout their undergraduate, postgraduate and subsequent careers.

The late Arthur I. Vogel was formerly Head of the Chemistry Department at Woolwich (now Thames Polytechnic, London.

Brian S. Furniss, Antony J. Hannaford, Peter W. G. Smith and Austin R. Tatchell are former and current members of The School of Chemistry, Thames Polytechnic, London.

*From reviews of the fourth edition:*

"... this best-selling standard reference work contains everything that students, teachers and research workers need to know about practical organic chemistry ..."

**NEW SCIENTIST**

"The book may be recommended without hesitation ..."  **EDUCATION IN CHEMISTRY**

"Copies purchased for libraries or for shared use in a laboratory may well have to be chained down."

**TIME'S HIGHER EDUCATION SUPPLEMENT**
